- Explain the steps required to prepare a domestic refrigerator or freezer for internal service.
- Summarize the steps required to return a domestic refrigerator or freezer to service after a motor burnout.
- Apply the proper procedure to remove and replace a compressor in a domestic refrigerator or freezer.
- Use the proper procedures to repair leaks in condensers and evaporators.
- Apply the proper procedures to clean or replace a capillary tube.
- Summarize the procedure for selecting, removing, and installing filter-driers.
- Compare the different methods of charging a small hermetic refrigeration system.
- Summarize different methods of calibrating, testing, and adjusting thermostatic controls in refrigerator-freezers.
- Explain considerations to take when removing system components from a cabinet.
- Summarize the steps required to properly discard or store a domestic refrigerator or freezer.

Chapter Outline

26.1 External Service Operations
- 26.1.1 Cleaning the Condenser and Compressor
- 26.1.2 Using Pressurized Air for Cleaning

26.2 Internal Service Operations
- 26.2.1 Replacing a Hermetic Compressor
- 26.2.2 Installing a Hermetic Compressor
- 26.2.3 Repairing Condenser Leaks
- 26.2.4 Repairing Evaporators
- 26.2.5 Servicing Capillary Tubes
- 26.2.6 Servicing Filter-Driers
- 26.2.7 Evacuating and Charging a Hermetic System
- 26.2.8 Installing and Servicing Thermostats
- 26.2.9 Removing System Components from the Cabinet

solid desiccant

Review of Key Concepts

Reviewing these concepts from earlier chapters will help you understand new concepts presented in this chapter:

- Refrigerant recovery is the removal of refrigerant from a refrigeration system in whatever condition that refrigerant may be. Sequential steps must be followed during a recovery process. (Chapter 11)
- Low head pressure, low suction pressure, and a lack of cooling are all possible indicators that a system has a refrigerant leak. Methods for locating leaks vary with the refrigerant used. However, all methods require the application of pressure to the system. (Chapter 11)
- Epoxy resin is a thermosetting polymer that forms a strong adhesive. It may be used to repair cracks and leaks in evaporators and joints. (Chapter 11)
- Moisture and other substances often enter a refrigeration system during service work. This happens after refrigerant has been recovered and the system is opened to atmosphere. To remove this unwanted moisture, a technician must evacuate the system. (Chapter 11)
- The amount of refrigerant that should be charged into a system is specified by weight. In order to charge a system by weight, an HVACR technician must first determine the proper charge for the system. Often this information can be found on a label or tag. (Chapter 11)

Introduction

Before servicing refrigeration units, a technician should check all service information and system specifications. System specifications are usually located on an identification plate mounted on the compressor. This information will help you determine the type of refrigerant, refrigerant charge, compressor hp, compressor speed, running amperes, voltage, phase, and other data for the unit. **Figure 26-1** shows the system specifications of a typical domestic refrigerator-freezer.

The servicing of refrigerators with hermetic systems can be divided into three areas:

- External servicing.
- Internal servicing.
- Overhaul.

Figure 26-1. Chart showing operating data for a side-by-side, automatic defrost refrigerator using R-134a. The data represents no-load operation, with no door openings and with thermostatic controls set at their midpoint.

26.1 External Service Operations

Some of the more common external service operations include replacing cabinet hardware, cleaning the unit, finding and eliminating noises, and repairing ice makers. The fixes for many of these problems were covered in Chapter 25, *Installation and Troubleshooting of Domestic Refrigerators and Freezers*.

In addition, there are many electrical components and circuits that can be checked and repaired. These include the power-in circuit, thermostat, interior light circuit, fan motors and circuit, damper controls, compressor motor circuit, and defrost circuit.

26.1.1 Cleaning the Condenser and Compressor

A compression refrigeration system is basically a heat-transfer system. Air must circulate around the compressor and through the condenser to carry away the heat. Dirt and lint buildup on the condenser and compressor act as insulation, decreasing the amount of heat transferred. Therefore, the condenser and compressor must be kept as clean as possible. To make the refrigerator or freezer operate efficiently and to extend the life of the compressor, the condenser and compressor should be completely cleaned about every three months.

The compressor and condenser should be cleaned using a small vacuum cleaner. A special vacuum cleaner nozzle with a brush attachment is ideal for cleaning the condenser and compressor. The vacuum cleaner keeps lint from circulating and settling on the floor. It is also quicker and more thorough than hand brushes or cleaning cloths. If a brush or cleaning cloth is used, place a paper or cloth underneath the unit to catch loosened dirt and lint.

Units that use condenser fans should be disconnected from electrical power before the compressor or condenser are cleaned. Sometimes it is necessary to remove panels from the cabinet in order to access the compressor or condenser.

26.1.2 Using Pressurized Air for Cleaning

In the shop, pressurized air, nitrogen, or carbon dioxide is often used to blow lint and other dirt from between the fins or coils. Areas that otherwise would be difficult to reach can be cleaned with this method. This is also good for components that could be easily damaged with physical cleaning or during transport, such as natural convection condensers.

Copyright Goodheart-Willcox Co., Inc. 2017

Safety Note

Cleaning with Compressed Air or Gas

Always wear goggles and a dust mask when using compressed air to remove dust and dirt. The goggles can prevent eye injuries ranging from an annoying speck of dust in the eye to a scratched cornea. The dust mask will keep irritating and damaging materials from entering your nose, mouth, throat, and lungs.

26.2 Internal Service Operations

Internal service operations include removing any part of the hermetic system, determining whether there is air in the system, checking for a lack of refrigerant, and checking for a clogged filter-drier or capillary tube. These operations require gauges and servicing devices, including refrigerant recovery machines, vacuum pumps, and refrigerant cylinders. A sealed system should not be opened unless absolutely necessary.

Before attempting any field service operations that require opening the system, begin by thoroughly cleaning all connections, valve fittings, and accessible surfaces. Next, install a valve adapter or piercing valve as needed. Attach a gauge manifold and connect the refrigerant recovery equipment. Recover the unit's refrigerant charge using the proper procedure prior to opening the system.

The service operations most commonly performed are locating and repairing a refrigerant leak, adding oil to the system, evacuating a system, charging and recovering refrigerant, cleaning or replacing a capillary tube, replacing a compressor, replacing an evaporator or condenser, replacing a filter-drier on the high side, and installing a filter-drier on the low side.

Usually, you will be required to perform these tasks in the field. However, they can also be performed in the shop. Shops have better facilities to do the job. Study this chapter carefully before performing any service operation.

Preparing a Domestic Refrigerator or Freezer for Internal Service

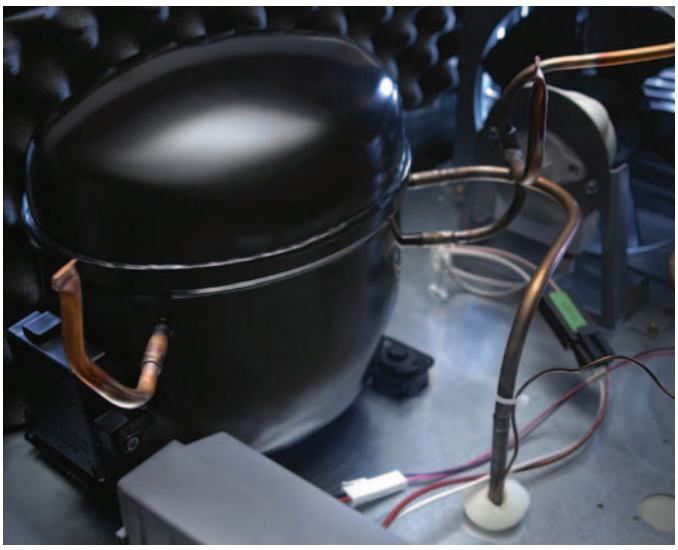
It is sometimes necessary to replace parts of a system. The internal parts most commonly in need of replacement are the compressor, condenser, capillary tube, evaporator, accumulator, and filter-drier. The system should be prepared as follows:

1. Unplug the refrigerator or freezer from the electrical outlet.
2. Carefully clean all surfaces. It is good to clean every component in the system. This will reduce the chance of dirt and other contamination entering the system.
3. Install a service valve and gauge manifold.
4. Use a recovery/recycling machine to remove and recover the refrigerant. The system must be purged in accordance with Environmental Protection Agency (EPA) regulations.
5. Cut the tubing and remove the part to be replaced. If the part will not be immediately replaced, plug the ends of the tubing until ready to replace the part. Remember to use a low-pressure flowing nitrogen purge while brazing to prevent harmful oxidation from forming within the tubing.

26.2.1 Replacing a Hermetic Compressor

Domestic refrigerators use hermetically sealed rotary or reciprocating compressors in fractional horsepower sizes ranging from 1/10 hp to 1/3 hp. The compressor in a domestic refrigerator is located at the bottom of the cabinet. The lines that connect the compressor to the refrigerant piping may be copper or steel.

Compressors can have a suction line, discharge line, process tube, and two oil cooler lines. Therefore, it may be difficult to determine which lines connect to which tube when replacing a compressor. Try following the lines back to see where else they connect into the system. A line running straight to the condenser is most likely the discharge line. A manufacturer's diagram will illustrate the correct connections, **Figure 26-2**.



Maytag Corporation

Figure 26-2. A hermetic compressor in a refrigerator-freezer.

Copyright Goodheart-Willcox Co., Inc. 2017

Removing a Hermetic Compressor

Follow this procedure to remove a hermetic compressor from a refrigerator-freezer.

1. Unplug the refrigerator or freezer from the electrical outlet.
2. Install piercing valves to the suction line and discharge lines if necessary.
3. Install a gauge manifold.
4. Recover the refrigerant charge.
5. Disconnect all electrical connections to the compressor.
6. Disconnect the suction and discharge lines using one of following techniques. Wear goggles when performing this step.

   A—Clean both the suction and discharge tubing on straight sections near the compressor. Use a tube cutter to cut the lines. *Plug the lines immediately.*

   B—Clean the tubing or fittings at the compressor. Put brazing flux on the connection. Heat the joint and pull the tubing out of the fittings. *Plug the openings immediately.*
7. If the compressor has oil-cooler lines, they must be pinched, then cut with a tubing cutter. The compressor tubing openings should be sealed.
8. Remove the compressor.

The unit is now ready to have a replacement compressor installed.

Hermetic Compressor Burnout

When internal problems occur, such as shorted windings, locked rotor, or bearing seizure, a compressor seizes up. These failures can result in the melting or burning of internal components, referred to as a ***burnout***. If a compressor suffers an internal failure, the burnt electrical wiring mixes with the refrigerant and oil to create a highly acidic, tar-like substance. A strong pungent refrigerant odor may be present when a piercing valve is opened slightly. This is a certain indication of a burnout.

The causes of compressor burnout have been widely studied. Moisture, dirt, and air in the system are possible causes. Another cause may be too much current flowing through the compressor motor, as a result of inaccurate or malfunctioning safety devices in the electrical circuit. Additional reasons may be a stuck compressor, low voltage, or a lack of refrigerant (poor motor cooling).

Preventing Motor Burnout

High head pressure, or excessive pressure at the compressor's outlet, is one of the most common reasons for motor burnout. The most frequent cause of high head pressure is a clogged condenser. High pressure creates very high temperatures as the vapor passes the compressor discharge valves. These high temperatures increase chemical action, leading to increased corrosion in the system. If the temperature at the discharge line to the condenser reaches 350°F (177°C), the oil in the system breaks down and forms carbon and sludge.

It is very important that the condenser be large enough for the system. It must be clean and the air must flow over it efficiently and effectively. To ensure good airflow, fans, fan motors, ducts, and air-in and air-out passages must all be free of dust buildup and in good condition.

If the unit is cycling too much or getting hot, the head pressure of the unit should be checked. If the head pressure is found to be excessively high, take all necessary steps to bring this pressure down. Blow off the condenser coil with compressed air. Use a long bristle brush and a vacuum cleaner to remove any stuck-on dirt from the coil. Be careful not to damage the condenser tubing. Check the air-in and air-out passages. They must be in good condition. Recover and recharge the system with the proper amount of refrigerant and oil, and then recheck the head pressure to ensure the system is operating properly.

Safety Note

Cleaning the Condenser

Wear safety goggles and a dust mask when cleaning the condenser coil.

Cleanup after Motor Burnout

When a motor begins to burn out, it overheats. This overheating causes the refrigerant to break down. If moisture is present, overheating can cause the formation of hydrochloric and hydrofluoric acids. The acid causes the insulation on the motor windings to deteriorate, which can increase the motor temperature. Eventually, the motor windings will short-circuit and the motor will burn out.

If a system's compressor burns out, it must be replaced. The refrigerant controls, including metering devices and solenoid valves, may also need to be replaced. Always install a new filter-drier in any system that has suffered a burnout. After replacing the components, flush the system with nitrogen or use a

Copyright Goodheart-Willcox Co., Inc. 2017

refrigerant recovery machine equipped with a flush mode to flush refrigerant through the system.

Safety Note

Acidic Oil

Do not touch the oil from a burned-out compressor. It will cause a severe acid burn! Wear goggles and rubber gloves when working with acidic oil.

It is important to check the oil in a system even if it is assumed that the burnout is mild. Any acid in the refrigerant system can destroy components. An ***acid test kit***, like the one shown in **Figure 26-3**, is used to test for acidic oil.

To test the oil, a small sample of the refrigerant oil is taken out of the system and mixed with a predetermined amount of each test chemical. The acidity of the oil is then measured against a color-coded chart included in the kit. If the oil is too acidic, the compressor should be removed and the system flushed prior to installation of a new compressor.

Pro Tip

Cutting Oil Cooler Lines

If oil cooler lines must be cut, do not allow the oil to run onto the floor. Trap it in glass containers.

The burnout can be mild or severe. If the burnout is severe, the oil will be black and acidic with a pungent, very unpleasant odor. If the burnout was mild, the oil will be clear but pungent and mildly acidic. Many acid test kits are available for determining the amount of contamination. If oil is clean and odor-free, there is no burnout. The trouble is mechanical.

Courtesy of Sporlan Division—Parker Hannifin Corporation

Figure 26-3. Refrigerant oil test kit. The kit is used to test the acidity of refrigerant oil.

26.2.2 Installing a Hermetic Compressor

A bad compressor should be replaced with a compressor having the same specifications. The replacement compressor must have the same pumping capacity as the compressor being replaced. It must also produce the same low-side pressure (low-, medium-, or high-temperature rated).

Installing a Replacement Compressor

The following is the recommended procedure for installing a replacement compressor.

1. Recover the refrigerant and disconnect and remove the bad compressor.
2. Carefully clean about 2″ (50 mm) at the ends of the suction, discharge, and oil lines of the system. Be sure to remove all oxidation.
3. Use emery cloth or 200-grit sandpaper to remove paint and oxidation from the ends of the suction, discharge, and oil stub tubes on the replacement compressor. The last 2″ (50 mm) of each of the stub tubes should be cleaned down to shiny copper tubing.
4. Attach a piercing valve on the discharge line if necessary. Braze an extension tube and access port to the process tube on the replacement compressor. Connect the gauge manifold.

Caution

Isolate the Brazing Area

When brazing, keep the heat away from other brazed joints. Protect the other joints in the line by draping wet cloths over them or by covering them in special heat-absorbing compounds. Position metal sheets around the work area to shield the cabinet, wires, and plastic parts from the flame.

5. Connect the suction, discharge, and oil lines to the corresponding stub tubes on the replacement compressor. Braze the connections. See **Figure 26-4**.

Caution

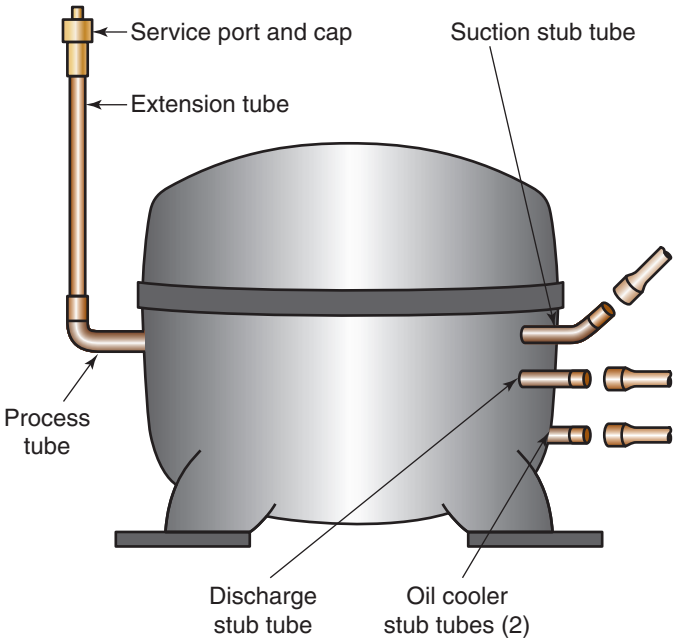
Tubing Size Mismatch

If the compressor stub tubes are smaller in diameter than the suction and discharge lines before they are swaged, the replacement compressor may be too small. Ensure that the replacement compressor has the correct capacity before proceeding. If you are absolutely certain the compressor capacity is sufficient, use reduction fittings to connect the compressor to the lines.

8

Copyright Goodheart-Willcox Co., Inc. 2017

6. If the system is equipped with a filter-drier, remove and replace it. If the system is not equipped with a filter-drier, install a new filter-drier of the proper capacity. If the refrigeration system is equipped with a capillary tube, the filter-drier should be installed at the capillary tube inlet.
7. In some instances, replacement compressors burn out soon after they are installed. Most repeat burnouts are due to the system containing moisture or not being clean enough. For this reason, it is good practice to install a second filter-drier in the suction line between the evaporator and compressor to reduce the risk of a repeat burnout.
8. Pressurize the system with nitrogen and a trace amount of refrigerant to (about 25 psig [175 kPa]). Check for leaks. Vent the charge to atmosphere and prepare to apply a vacuum to the system.
9. Using a gauge manifold or a T-fitting in the hoses, connect a vacuum gauge between the vacuum pump and the system. Draw as high a vacuum as possible. Turn off vacuum pump and close the vacuum pump's inlet valve to isolate it from the system. Hold this high vacuum for at least an hour, watching the vacuum gauge. If the vacuum measurement does not hold constant, there is a leak in the system.
10. Charge the system with a small amount of the proper refrigerant. Add just enough refrigerant to bring the pressure to atmospheric pressure or very slightly above.
11. Replace the unit's relays and capacitors and reinstall all electrical connections to the compressor. Plug the unit in and allow it to run for a few seconds to pressurize the system.
12. Charge the system with the correct amount of refrigerant and leak check again.
13. Close all gauge manifold valves and operate the system through several cycles.
14. Check the system's superheat and adjust the refrigerant charge if necessary.
15. Remove the gauge manifold and recovery unit. Carefully seal all openings into the system, depending on the gauge manifold connections used.
16. It is good practice to place a data logger in the refrigerator cabinet. This enables the operation to be checked continuously for at least 24 hours.



Goodheart-Willcox Publisher

Figure 26-4. If necessary, an expander or swaging tool can be used to increase the diameter of the suction line and discharge lines, allowing the stub tubes from the compressor to telescope into them. Apply a thin coating of flux to the outside of the compressor stub tubes before inserting them into the system lines. Wipe excess flux from the joints and then braze the connections.

26.2.3 Repairing Condenser Leaks

Condenser troubles are usually caused by leaks or by lint and dirt accumulation on the outside. It may be possible to repair leaks without bringing the unit into the shop. Most condensers are copper and leaks in them can be plugged using a high-pressure and high-temperature brazing alloy. The technician must install piercing valves, recover refrigerant using the proper equipment, repair the leak, test the repair, evacuate the system, and then recharge the system. If the leak is not repairable, the condenser must be replaced.

26.2.4 Repairing Evaporators

Evaporators are made of either stainless steel or aluminum. For stainless steel, repairs are made by brazing the evaporator tubing using an oxyfuel torch or by welding the tubing using the gas tungsten arc welding (GTAW) process. For aluminum evaporators, repairs can be made by soldering, brazing, or welding, but the use of epoxy is the most common method of evaporator repair.

Copyright Goodheart-Willcox Co., Inc. 2017

Pro Tip

Welding Terminology

In the field, the gas tungsten arc welding (GTAW) process is often referred to as the tungsten inert gas (TIG) process. Be aware that both terms describe the same welding process.

Repairing a Stainless Steel Evaporator

The following is the recommended procedure for repairing a stainless steel evaporator:

1. Locate the leak.
2. Remove the refrigerant using a recovery/recycling machine.
3. Clean the metal around the leak by sanding with emery cloth or sandpaper of 200 grit or higher.
4. Braze or weld the leak while purging the evaporator with nitrogen at a very low pressure.
5. Polish the weld or clean the brazed joint.
6. Test for leaks.

Repairing an Aluminum Evaporator

The following is the recommended procedure for repairing an aluminum evaporator:

1. Locate the leak.
2. Acquire an epoxy repair kit. An ***epoxy repair kit*** contains all the materials needed to prepare and patch a small hole in an aluminum evaporator, **Figure 26-5**.
3. Remove the refrigerant using a recovery/recycling machine.
4. Clean around the leak. The surface oxide is hard and must be removed. Sand the area around the leak, file down any sharp edges, and then clean the area with epoxy cleaner. Begin the repair immediately after cleaning because the oxide surface will reform quickly. If the leak is a large hole, use a metal plug to fill most of the opening.
5. Mix the specified ratio of epoxy resin and hardener.
6. Apply the epoxy with a mixing spatula. (Be sure there is no positive pressure in the system. The system must be open to atmosphere at some other opening.)
7. Allow the epoxy to harden for at least an hour.
8. Sand the patch to a smooth finish.
9. Test for leaks using a soap solution or electronic leak detector.

If the system still leaks at the repaired joint, remove the epoxy by filing and/or grinding. Then, install a new patch. Aluminum foil can be used with the epoxy to strengthen the joint. It can also improve the appearance of the repair. Another method of repair is to heat the tubing and apply a paste mix (or stick) of special epoxies and resins.

Avoid brazing aluminum tubing, as it overheats too easily. Too much of the tubing will be annealed (softened), weakening the tubing walls. Aluminum tubing is usually 3003 alloy. However, 5005 and 1100 alloys are also used. If a brazed repair is unavoidable, aluminum solder, containing 92% to 100% zinc, is used. The melting temperatures are 700°F to 800°F (370°C to 430°C). Do not use a flux. Aluminum can also be welded using the gas tungsten arc welding (GTAW) process.

Ritchie Engineering Co., Inc. – YELLOW JACKET Products Division

Figure 26-6. Capillary tube cutter.

26.2.5 Servicing Capillary Tubes

To prepare for replacing a capillary tube in a domestic refrigerator or freezer, follow the procedure entitled *Preparing a Domestic Refrigerator or Freezer for Internal Service* presented earlier in this chapter. However, instead of cutting the tubing as directed in step 5, heat the brazed joint at the filter-drier to loosen the bond, and then pull and twist the capillary tube to separate it from the filter-drier. Repeat the process at the other end of the capillary tube to separate it from the evaporator. Clean the separated joints with emery cloth and a file.

It is sometimes possible to repair a capillary tube by cleaning and flushing it with a hydraulic capillary tube cleaner. However, in most cases, capillary tubes that are suspected of being clogged are simply replaced. The new capillary tube must have the same inside diameter (ID) and the same length as the one removed. These traits determine the pressure drop that occurs through the capillary tube and are critical to the proper operation of the system.

There are universal replacement capillary tubes on the market that can be used if necessary. Calibrated wires of different sizes can be inserted into these capillary tubes to adjust the amount of restriction provided by the tube.

If wax caused the tube to become clogged, remove the oil from the system. Replace it with fresh, clean, wax-free oil. When servicing frozen foods equipment, use only the best low-wax oil.

Pro Tip

Cutting Capillary Tubing

Capillary tubing should be cut by filing a notch around it and then breaking the tubing using small back-and-forth motions. Cutting the tubing with a PVC or copper tubing cutter would change the inside diameter of the tubing too much. Specially made capillary tube cutters are also available, **Figure 26-6**.

Caution

Liquid Drying Agents

Never use a liquid drying agent (such as methanol) to stop moisture from freezing at the refrigerant control. These "antifreeze" substances do not remove the moisture. They merely keep it in circulation. In many cases, they can damage the motor insulation. Never use a liquid drying agent in a unit equipped with a ***solid desiccant*** (drying chemical in solid form). The liquid drying agent will release any moisture already trapped in the drier by the solid desiccant.

26.2.6 Servicing Filter-Driers

A filter-drier should be replaced any time the refrigeration system is opened. A new filter-drier may also be installed to remove moisture from the system. Filter-driers trap debris and moisture to keep the rest of the refrigeration system clean and dry inside. A typical combination filter-drier is shown in **Figure 26-7**.

A solid moisture adsorption material will usually do a satisfactory job. Silica gel, alumina gel, and synthetic silicates are excellent at adsorbing moisture. Silica gel in bead form also provides good results.

As noted earlier, liquid drying agents should never be used in a system equipped with a solid desiccant, and a solid-desiccant drier should not be put in a system that is already using a liquid drying agent. To avoid this danger, all systems should be labeled to indicate which type of drying agent is used. The moisture adsorbing capabilities of several solid desiccants are shown in **Figure 26-8**.

Figure 26-9 lists the recommended volume of drying agents according to horsepower of the system's compressor. All driers are sealed by the manufacturer. The sealing caps should not be removed from the filter-drier until just before installation.

Driers adsorb water faster at lower temperatures. If at all possible, the drier should be installed just ahead of the refrigerant control. If the filter-drier accidentally becomes heated, the moisture it has adsorbed may be driven out. The moisture will recirculate with the refrigerant. Locating the filter-drier just before the refrigerant control has the following advantages:

- It is likely that both the filter-drier and refrigerant control will become heated at the same time. This reduces the chance that ice will form in the refrigerant control.
- The filter-drier is kept far away from the heated tubing of the condenser.

The body of a filter-drier will have an arrow stamped or cast into it. This arrow indicates the direction in which the refrigerant should flow. Be sure the

Filter-Drier Sizes—Domestic Refrigerator-Freezers

Filter-Drier Size in Cubic Inches	Compressor Size in Horsepower
2	1/8
3	1/6 to 1/4
6	1/4 to 1/2
9	1/2 to 3/4

Goodheart-Willcox Publisher

Figure 26-9. The drier capacities (in cubic inches) recommended for systems with various horsepower ratings.

filter-drier is installed properly so that the refrigerant flow matches the direction of the arrow. Filter-driers may be installed with flared or brazed connections.

Whenever a system is opened, a new filter-drier must always be installed in the liquid line. Many service technicians install two filter-driers on a system after repairing it. One is placed on the high side just before the refrigerant control. Another is placed on the low side, between the evaporator and compressor. Two filter-driers improve the chance of removing all moisture or contaminants that may have entered the system during servicing.

Replacing a Filter-Drier

The following are the basic steps in replacing a filter-drier:

1. Connect a gauge manifold.
2. Recover the refrigerant.
3. Dry and clean the new filter-drier connections.
4. Disconnect the old filter-drier from the system. If done using brazing, use low-pressure flowing nitrogen through the inside of the joints.
5. Install the new filter-drier. The new filter-drier may be connected by brazing the joints or by tightening flare connectors. When brazing, use low-pressure flowing nitrogen through the inside of the joints.
6. Test for leaks.
7. Evacuate the system.
8. Charge the system.
9. Operate the system while warming the refrigerant control enough to melt any ice that may form in it. The filter-drier will adsorb this moisture as it circulates.

26.2.7 Evacuating and Charging a Hermetic System

After any internal refrigeration system component in a domestic refrigerator or freezer has been replaced, the system must be evacuated and recharged before being returned to service. A small hermetic system is evacuated and charged in the same way as other refrigeration systems. Basic evacuation and charging techniques were presented in Chapter 11, *Working with Refrigerants*.

The biggest difference in working with small hermetic systems is that the refrigerant and oil charge is much smaller than it is in larger systems. Most small

Copyright Goodheart-Willcox Co., Inc. 2017

hermetic systems use a capillary tube as a metering device. This allows system pressures to equalize quickly during the Off cycle, which makes evacuating and charging much faster than on larger TXV systems.

Small hermetic capillary tube systems are very sensitive to refrigerant charge amount, so proper charging is critical to system operation. Always check the manufacturer's nameplate for correct amount of refrigerant charge. Also, be sure to record the amount of oil removed from a system to ensure that the same amount of oil is added during recharging.

If testing indicates a lack of refrigerant, there is a system leak. The leak must be repaired before refrigerant is added. The following are signs that a hermetic system is low on refrigerant:

- A partially frosted evaporator.
- Low head pressure.
- Low suction pressure.
- A visible or audible leak.
- Frequent cycling.

Charging with a Digital Scale

Figure 26-10 shows a digital charging scale. A digital charging scale allows a precise amount of refrigerant to be charged into a system. After evacuating the system, hook up a refrigerant cylinder using quick-connect fittings to prevent or minimize refrigerant escaping to the atmosphere. Open the cylinder valve, gauge manifold valve, and piercing valve to begin vapor charging the system, **Figure 26-11**.

When a digital scale indicates the proper charge has been added, close the cylinder valve, gauge manifold valve, and piercing valve. Pinch off the process tube between the compressor and piercing valve. Remove the piercing valve, trim and crimp the process tube, and braze the end. See Chapter 11, *Working with Refrigerants*, for additional information on the use of a digital charging scale for system charging and recovery.

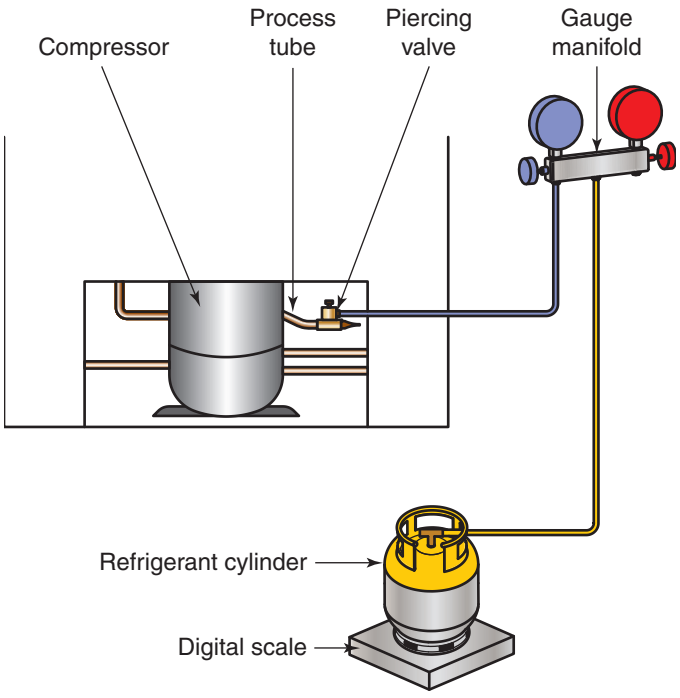
Charging by Observing Frost Back

It is always best to recover the refrigerant from a system, evacuate the system, and then recharge the system with the exact amount of refrigerant specified by the manufacturer. However, in cases where the recommended refrigerant amount is unknown, it may be necessary to charge the unit by observing frost back on the evaporator.

The refrigerant cylinder and gauge manifold should be connected as shown in **Figure 26-12**. Start the unit. Open the piercing valve, gauge manifold valve, and refrigerant cylinder valve and watch the low-side pressure gauge. The pressure must stay within a range

Mastercool Inc.

Figure 26-10. Digital charging scale. A precise quantity of charge is entered into the scale controller. When the proper charge is reached, the charging solenoid module shuts off the flow of refrigerant from the cylinder.



Goodheart-Willcox Publisher

Goodheart-Willcox Publisher

Figure 26-12. Setup for charging a system while observing frost back.

of 5 psig to 25 psig (35 kPa to 175 kPa). This pressure is controlled by adjusting the refrigerant cylinder valve. Allow the refrigerant charge to enter the system for 3 to 5 minutes.

After the allotted time elapses, close the gauge manifold valve. Allow the unit to operate and check the frost line on the evaporator. If the frost line is inadequate, repeat the charging for short intervals, checking for frost after each interval. The frost line must not go beyond the accumulator in the suction line. If the frost line extends beyond the accumulator, recover a small amount of the refrigerant and then recheck the frost line.

When the proper amount of frost has been observed, close the refrigerant cylinder valve, valve adapter or piercing valve, and gauge manifold valve. After closing all valves, follow these steps:

1. If a piercing valve was installed on the suction line, leave it mounted for future service operations.
2. Check for leaks using a leak detector.

For a system that uses a separate process tube, follow these steps:

1. Pinch the process tube between the compressor and the valve with a pinch-off tool. See **Figure 26-13**.
2. Remove the valve. Crimp the tube end to flatten it. Remove the pinch-off tool. Braze the end of the tube closed and then check for leaks.

Adding Oil to the System

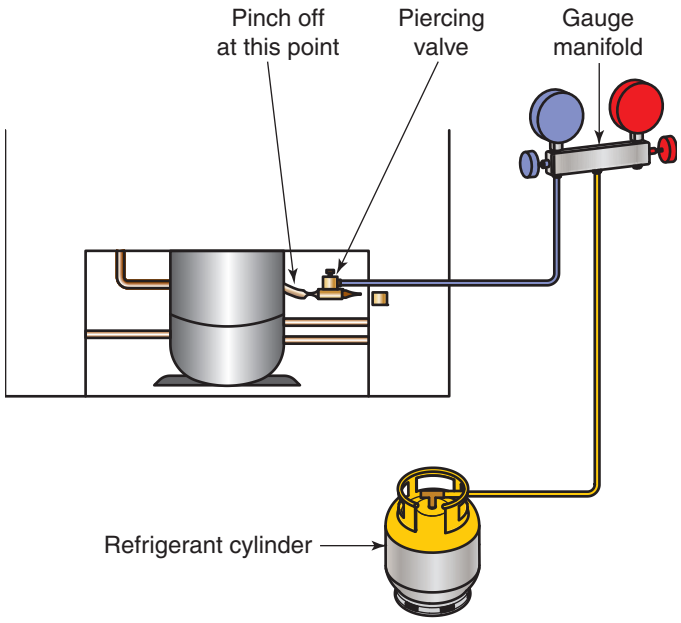
The correct amount of oil in a system is very important. Lack of oil will increase friction, cause noise, and shorten the life of the compressor. An overcharge will cause the compressor to pump excessive amounts of oil. This will reduce the compressor's refrigerant-pumping capacity. It will also subject the compressor valves to severe strain.

Refrigerant oils are available in several viscosities. *Viscosity* is a rating of a fluid's ability to flow at different temperatures. Be sure to follow the manufacturer's viscosity recommendations. On a service call, add oil only if there is a sign of oil leakage.

It is rarely necessary to add oil to a hermetic system. However, leaking refrigerant always carries some oil with it. This lost oil should be replaced. If the hermetic unit is completely equipped with service valves, oil may be added using a conventional method. That is, oil can be siphoned or poured in.

If the system has had a low-side leak, moisture and air may have entered. In this case, it is best to replace the refrigerant oil. Measure the amount of oil removed and replace it with the same amount of clean, dry oil. See Chapter 11, *Working with Refrigerants*. The unit should be charged in much the same way as when adding refrigerant to the system.

A hand pump can be used to put oil into a system. The charging lines must be purged to remove air, moisture, and dirt. A hand oil pump can build up pressures as high as 300 psig (2100 kPa). Oil can be forced into the system even when the system is under pressure.



Goodheart-Willcox Publisher

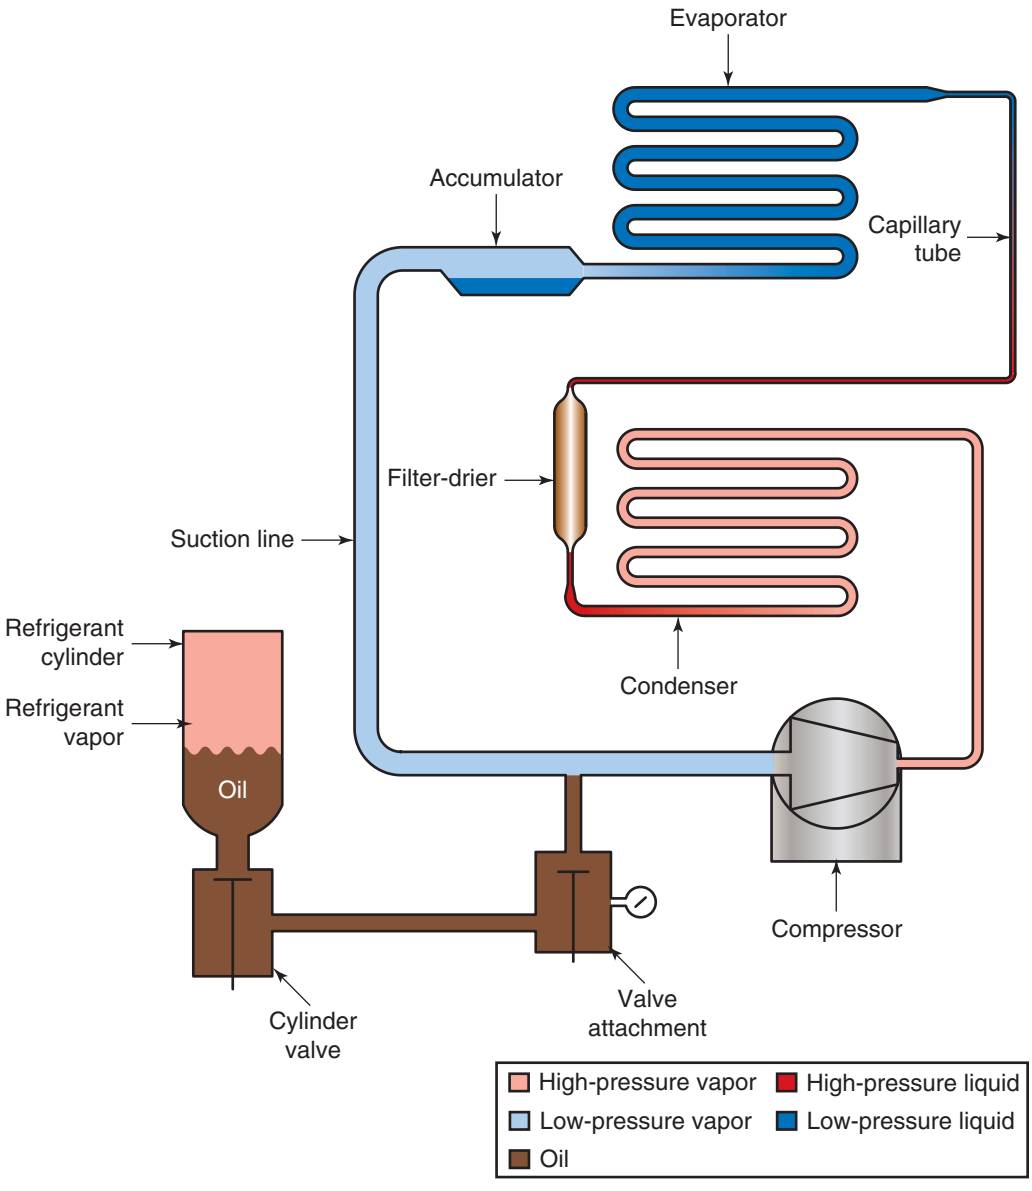
Figure 26-13. After the piercing valve, refrigerant cylinder valve, and gauge manifold valve are closed, the process tube is pinched off. Note the pinch-off point.

Copyright Goodheart-Willcox Co., Inc. 2017

The single-service-line technique shown in **Figure 26-14** can also be used to add oil. The correct amount of oil is put into the service cylinder. A small amount of refrigerant (the same type used in the system) is also put into the cylinder. This creates a pressure. The cylinder is inverted. Its cylinder valve is connected to the valve attachment by clean lines. Be sure the cylinder pressure is higher than the system pressure. Then, open the cylinder valve and valve attachment. The pressure in the cylinder will force oil into the refrigeration system.

26.2.8 Installing and Servicing Thermostats

When installing an electromechanical thermostat, be careful not to bend the sensing bulb's capillary tube back and forth. This small copper tube will work-harden and may break. Also, be sure that once the capillary tube is installed, it does not contact any part of the evaporator. If the tubing rubs against any part, it may wear through or work-harden at that spot



Goodheart-Willcox Publisher

Figure 26-14. Single-service-line technique for adding oil to a small hermetic system. First, place the correct amount of oil in a service cylinder, along with small amount of refrigerant to create pressure. Then turn the service cylinder upside down. Its pressure must be higher than low-side pressure, so that oil will enter the system.

Copyright Goodheart-Willcox Co., Inc. 2017

and crack. If any of the capillary tube is coiled, tape the coil to prevent vibration.

Calibrating a Thermostat

A mixture of crushed ice and water can be used to calibrate a refrigerator's thermostat. With these materials, it is easy to determine the operation of the thermostat at 32°F (0°C), the temperature of melting ice. To check the operation of a thermostat, use a temperature data logger or temperature-recording thermometer like the one shown in **Figure 26-15**. Chart the temperature and time for the unit over a 24-hour period to determine how much it is cycling and at what temperatures it is cutting in and cutting out.

Testing a Thermostat

The following test uses solutions at specific temperatures to test the operation of the thermostat:

1. Connect an ohmmeter or continuity tester across the control contact terminals of the thermostat. Check the manufacturer's wiring diagram to ensure correct connections.
2. Check the temperature of the ice and water solution with a thermometer to ensure that it has stabilized at 32°F (0°C).
3. Place the thermostat control bulb in the ice and water mixture.
4. With the control bulb in the ice and water mixture, set the thermostat control to 32°F (0°C). The thermostat's contact points should open, in which case the ohmmeter will read either ∞ Ω or OL (infinite resistance).
5. After a few minutes, lift the control bulb from the mixture. As the control bulb warms, the points should again close, in which case the ohmmeter will read 0 Ω.
6. To check further, place the control bulb in a container of water that is at 45°F (7°C). Set the thermostat control to 45°F. At this setting, the points should be open, reading ∞ Ω or OL (infinite resistance) on an ohmmeter. The contact should begin to open at temperatures below 45.5°F or 46°F.
7. Lift the control bulb out of the water and let it warm up for a few minutes. The points should close, reading 0 Ω on an ohmmeter. If the points do not open and close properly, the thermostat should be replaced.

Sealed Unit Parts Co., Inc.

Figure 26-15. To check the operation of a freezer thermostat with a data logger, place the device inside the freezer cabinet and record the temperature over a 24-hour period. Then connect it to a mobile device to download the recorded values.

Freezer cabinet temperatures are usually in the 0°F to –20°F (–18°C to –29°C) range. Ice and water mixtures maintain a temperature of 32°F (0°C) and, therefore, cannot be used in setting these thermostats. Dry ice must be used to test a thermostat below freezing.

Adjusting Thermostat Controls

The four variables that affect thermostat operation are cut-in temperature, cut-out temperature, temperature range, and temperature differential. Cut-in temperature is the temperature at which the refrigeration system is activated. Cut-out temperature is the temperature at which the refrigeration system deactivates. The temperature range refers to the group of temperatures that fall between the cut-in and cut-out temperature. The temperature differential refers to the size of the temperature range.

For example, if a refrigerator turns on when the evaporator temperature rises to 45°F (7°C), the thermostat has a cut-in temperature of 45°F (7°C). If the same refrigerator turns off when the evaporator temperature reaches 32°F (0°C), it has a cut-out temperature of 32°F (0°C). The range of the refrigerator is 32°F to 45°F (0°C to 7°C), and the differential is 13°F (7°C).

As you can see, a change to either the cut-in temperature or cut-out temperature will also affect the range and differential. Manufacturers use different types of controls to adjust these four variables, so you must always refer to the manufacturer's instructions before adjusting the thermostat settings.

Copyright Goodheart-Willcox Co., Inc. 2017

Some thermostats have simple cut-in and cut-out temperature adjusting screws. The cut-in and cut-out temperatures are set independently. This determines the range and differential. Then, to change the range without changing the differential, the cut-in adjusting screw and the cut-out adjusting screw must be turned the same number of times and in the same direction.

Other thermostats have one adjusting screw that adjusts just the cut-out temperature and another adjusting screw that adjusts both the cut-in and cut-out temperature settings at the same time. On these thermostats, the desired temperature differential can be set by turning the cut-out adjusting screw, and then the desired temperature range can be set without changing the differential by simply turning the cut-in adjusting screw. On this type of thermostat, the cut-out adjustment is referred to as a cut-out differential adjustment, and the cut-in adjustment is referred to as a cut-in range adjustment.

A variation of this design has an adjusting screw that sets the cut-in independently and a second adjusting screw that adjusts both the cut-out and cut-in temperature settings simultaneously. On this design, the cut-in adjustment is referred to as a cut-in differential adjustment and the cut-out adjustment is referred to as a cut-out range adjustment.

Still other thermostats have a single adjustment screw that is referred to as a dual differential adjustment. Turning the screw one direction will bring both the cut-in and cut-out settings closer together. Turning the screw the other direction will move both the cut-in and cut-out settings farther apart.

The adjustment provided for the owner is usually a limited range adjustment screw. However, some models allow the owner to adjust only the cut-out setting. This design ensures a safe cut-in temperature at all times.

Contact points may chatter as they open or close. Operate the thermostat to check for this condition. A likely cause of chatter is pitting or burning of contact points. If there are any visible indications of this, replace the entire thermostat.

26.2.9 Removing System Components from the Cabinet

Sometimes, mechanical or electrical trouble cannot be fixed easily during a service call. System components may need to be removed from the cabinet and sent to a shop for repair. When a complete overhaul of a hermetic system is necessary, it is usually done in a specialty repair shop. The condensing unit is disconnected from the refrigeration system and all electrical connections are either disconnected or cut. Any cut electrical connections will need to be spliced when the condensing unit is hooked back up to the system.

It is important to protect the refrigeration system while it is being moved. If shipped disassembled, cradles or crates should be used to hold the components. Wooden frames and C-clamps will hold the parts down. This will help keep them from being damaged in transit.

If an entire refrigerator-freezer is being transported in a truck back to a shop for service, it should be wrapped in a padded blanket for protection. Once the unit is in the shop, the procedure for removing the system components from the cabinet varies. Some evaporators are removed from the rear of the cabinet. Others are removed from the front (by way of the cabinet door). Refrigerator-freezers that have the evaporator removed from the rear are not difficult to dismantle. Skill and patience are required to remove an evaporator from the front of the cabinet.

The compressor and condenser are sometimes fastened to the rear of the cabinet by several mounting screws and bolts. Care should be taken not to damage the compressor or condenser as these fasteners are removed. Care should also be taken not to kink or buckle the refrigerant lines as they are removed from the compressor and condenser.

Refrigerant lines are mounted in the back of the refrigerator cabinet. They may also be hidden behind the breaker strip at the refrigerator doorjamb (frame). ***Breaker strips*** are plastic strips that connect the cabinet's outer shell to the liner. These breaker strips must be removed in order to remove the lines. Do this carefully, since the strips are brittle. If the strips are allowed to come up to room temperature, they will be more flexible. There are several methods used to fasten the breaker strips to the cabinet shell and the liner. Always follow the manufacturer's instructions for dismantling the system.

It is important to avoid pinching or buckling the refrigerant lines. Support the lines when handling them to prevent wear or breakage. Many liquid lines are soldered or brazed to fittings.

26.3 Storing or Discarding a Refrigerator-Freezer

When a refrigerator-freezer is going to be out of service for an extended period of time, certain precautions should be taken to prevent rusting and to remove odor. Begin by unplugging the unit's electrical power. Next, allow several hours for the unit to completely defrost.

Copyright Goodheart-Willcox Co., Inc. 2017

If the unit is being discarded, its doors must be removed. It is also necessary to reclaim the refrigerant inside the system, following all certification procedures. After the refrigerant has been reclaimed, the unit should be labeled to indicate that the refrigerant has been removed by a certified technician. Chapter 11, *Working with Refrigerants*, describes recovery of refrigerant.

Code Alert

Preparing to Discard Refrigerator-Freezers

Federal law states that the door must be removed from an out-of-service refrigerator or freezer. This law resulted because children were accidentally suffocated while hiding or playing in an unused or carelessly discarded unit. When taking a refrigerator or freezer out of service, always remove the cabinet door.

Chapter Review

Summary

- The condenser and compressor of a domestic refrigerator must be kept clean in order for the unit to function properly. The condenser and compressor should be cleaned regularly using a brush, a small vacuum cleaner, or compressed air. Refrigerators or freezers that have condenser fans should be unplugged before the condenser and compressor are cleaned.
- The most common internal service procedures on a domestic refrigerator or freezer are replacement of a compressor, leak repair, replacement of a condenser or evaporator, replacement of a filter-drier, and replacement of a capillary tube. To prepare for any of these procedures, the tubing and joints around the component being serviced must be cleaned. Refrigerant must be recovered from the unit in accordance with EPA regulations, and the unit must be unplugged. The component can then be removed and replaced using the proper techniques.
- If a compressor needs to be replaced because of burnout, the cause of the original burnout must be identified and corrected before the system can be put back into service. Burnouts are usually caused by excessively high head pressure. High head pressure can result from a restriction in the system or by dust buildup on the condenser. After a burnout, all refrigerant controls should be thoroughly cleaned or replaced. The system should be flushed, and the refrigerant oil should be replaced if it is found to be acidic.
- After any internal component is replaced, the refrigeration system must be evacuated and recharged. A digital charging scale is used to charge the system with a specific amount of refrigerant. If the exact amount of the proper charge cannot be determined, the system can be vapor charged until the proper amount of evaporator frosting appears.
- Thermostat operation can be tested using a mixture of ice and water. Modern thermostats usually have two adjusting screws; however, these two screws have four possible functions: cut-in, cut-out, dual differential, and range. Refer to manufacturer literature before attempting any adjustments.
- Occasionally a problem is encountered that cannot be repaired in the field. In such cases, the entire refrigerator-freezer is sent to a shop for service. Care must be taken not to damage any of the components during removal and transport.
- To prepare a refrigerator or freezer for storage or disposal, the unit must be completely defrosted and dried out. The cabinet door must be removed to prevent children or animals from becoming accidentally trapped inside. The refrigerant inside the unit must be recovered in accordance with EPA regulations.

Review Questions

Answer the following questions using the information in this chapter.

1. A condenser and compressor should be completely cleaned _____.
   A. daily
   B. every three months
   C. once a year
   D. every four years
2. Which of the following can be used to clean a condenser coil?
   A. A vacuum cleaner with a brush attachment.
   B. A hand brush and cleaning cloth.
   C. Compressed air.
   D. All of the above.
3. Before a valve adapter or piercing valve is installed, _____.
   A. evacuate the system
   B. flush the system with the appropriate solvent
   C. thoroughly clean all connections, valve fittings, and accessible surfaces
   D. All of the above.
4. In a compressor burnout, _____ mixes with refrigerant and oil to form a pungent, acidic, tar-like substance.
   A. atmospheric pollutants
   B. burnt electrical wiring
   C. scorched desiccant
   D. All of the above.
5. If the refrigerant oil is found to be clear and odorless, the compressor _____.
   A. burnout was mild
   B. burnout was severe
   C. did not burn out
   D. was not exposed to moisture during the burnout

Copyright Goodheart-Willcox Co., Inc. 2017

6. A filter-drier on the high side of a capillary tube system should be installed at the _____.
   A. capillary tube inlet
   B. capillary tube outlet
   C. condenser inlet
   D. condenser outlet
7. Which of the following is most likely to help prevent a repeat compressor burnout?
   A. Add a second accumulator just before the compressor inlet.
   B. Add a second filter-drier on the high side of the system.
   C. Add a second filter-drier on the low side of the system.
   D. Adjust the thermostat to increase the differential.
8. Using _____ to plug a leak is the most common method of repairing an aluminum evaporator.
   A. epoxy
   B. gas tungsten arc welding
   C. high-strength aluminum foil tape
   D. oxyacetylene brazing
9. The best method of cutting capillary tubing is by _____.
   A. burning through with an oxyacetylene torch
   B. making a notch around the tubing with a file and bending the tubing back and forth until it breaks
   C. using a copper tubing cutter
   D. using a hacksaw
10. Which of the following can be an indication that a system is low on refrigerant?
    A. A frosted suction line.
    B. High head pressure.
    C. Low suction pressure.
    D. All of the above.
11. The preferred method of charging a small domestic refrigeration system involves evacuating the system and then _____.
    A. pouring liquid refrigerant into the low side until the bottom half of the compressor crankcase is frosted
    B. using a digital scale to vapor charge a precise amount of refrigerant
    C. vapor charging the system while watching the frost back
    D. vapor charging according to the subcooling
12. Refrigerant oil should be removed and replaced _____.
    A. any time the system is accessed
    B. in the event of a low-side leak
    C. once a year
    D. All of the above.
13. Which of the following statements regarding a thermostat's temperature differential setting is true?
    A. If the thermostat has just cut-in and cut-out adjustment screws, the differential can be changed by turning a single screw.
    B. The temperature differential is determined by the cut-in and cut-out temperatures.
    C. On a thermostat with a dual differential adjustment, turning the adjustment screw one direction increases the differential and turning the screw the other direction decreases the differential.
    D. All of the above.
14. When removing a refrigeration system from its cabinet, breaker strips must be removed in order to remove the _____.
    A. compressor's electrical controls
    B. defrost controls
    C. refrigerant lines
    D. thermostat
15. On any refrigerator-freezer that is to be discarded, which two things must be properly removed and handled?
    A. Accumulator and filter-drier.
    B. Cabinet door and refrigerant.
    C. Compressor and breaker strips.
    D. Evaporator and condenser.

CHAPTER 27 Air Movement and Measurement

Chapter Outline

27.1 Climate
- 27.1.1 Equivalent Temperature
- 27.1.2 Definition of Air Conditioning

27.2 Atmosphere and Air
- 27.2.1 Physical Properties of Air
- 27.2.2 Humidity
- 27.2.3 Air Temperature
- 27.2.4 Psychrometric Properties of Air

27.3 Comfort Conditions
- 27.3.1 Effective Temperature
- 27.3.2 Temperature-Related Illnesses
- 27.3.3 Comfort-Health Index (CHI)

27.4 Air Movement
- 27.4.1 Wind
- 27.4.2 Air Velocity Measurement
- 27.4.3 Ventilation
- 27.4.4 Stratification

27.5 Factors Affecting Indoor Air Conditions
- 27.5.1 Sun Heat Loads
- 27.5.2 Heat Sinks
- 27.5.3 Vapor Barriers
- 27.5.4 Heat Insulation

Learning Objectives

Information in this chapter will enable you to:

- Understand the concepts of climate and weather.
- Summarize the purpose of air-conditioning systems.
- Identify the layers of the atmosphere and the primary components of air.
- Understand the relationships between humidity, relative humidity, and dew point.
- Use a hygrometer to measure moisture in the air.
- Differentiate between wet-bulb and dry-bulb temperatures.
- Explain the principles of psychrometry and the use of psychrometric charts.
- Summarize the range of air conditions that fall within the human comfort range.
- Understand how air movement affects human comfort.
- Use anemometers, pitot tubes, and manometers to measure air velocity.
- Identify external factors that affect indoor air conditions.

windchill index

Review of Key Concepts

Reviewing these concepts from earlier chapters will help you understand new concepts presented in this chapter:

- Enthalpy is the total amount of heat in a substance, calculated from an accepted reference temperature. Specific enthalpy is enthalpy per unit of mass. (Chapter 4)
- Heat that brings about a change of state with no change in temperature is called latent heat. Heat that causes a change in the temperature of a substance is called sensible heat. (Chapter 4)
- A manometer is a type of pressure gauge that measures values around atmospheric pressure. When measuring differential pressure with a manometer, air velocity can be determined. (Chapter 7)
- A manometer with a pitot tube is used for measuring air velocity in ductwork. The common procedure is to connect a pitot tube to a manometer and insert the pitot tube into the duct. This will give the technician both the total pressure and static pressure reading on the manometer. (Chapter 7)
- Charles' law states that at a constant pressure, the volume of a gas varies in direct proportion to temperature. With pressure held constant, the volume of a gas will increase as the gas heats up or will decrease as the gas cools down. (Chapter 5)
- Radiation is the transfer of heat by heat rays. The earth receives heat from the sun by radiation. Light rays from the sun turn into heat when they strike materials. (Chapter 4)

Introduction

Temperature, humidity, air movement, and air cleanliness are all conditions that affect how comfortable an environment is. A specific range of values for each of these conditions provides the most comfort. However, if one of these conditions falls outside of the comfort range, the other conditions can often be adjusted to compensate. For instance, high relative humidity tends to be uncomfortable. However, a relatively low temperature and rapid air movement may counteract it. In many homes during the wintertime, an increased room temperature and little air movement compensate for low relative humidity. This chapter addresses the temperature and humidity conditions that an HVAC system must maintain in order to provide for human comfort.

As the seasons change, accommodations must be made to ensure comfort. Winter heating conditions require automatic control of the heating source to maintain desired room temperatures. The lower the humidity, the higher the temperature required. Humidity control for winter conditions may require the addition of moisture by a humidifier. In the summertime, air-conditioning systems are used to maintain the desired room temperature. As warm, moist air is blown over the evaporator coil, the air is cooled and dehumidified.

9

Copyright Goodheart-Willcox Co., Inc. 2017

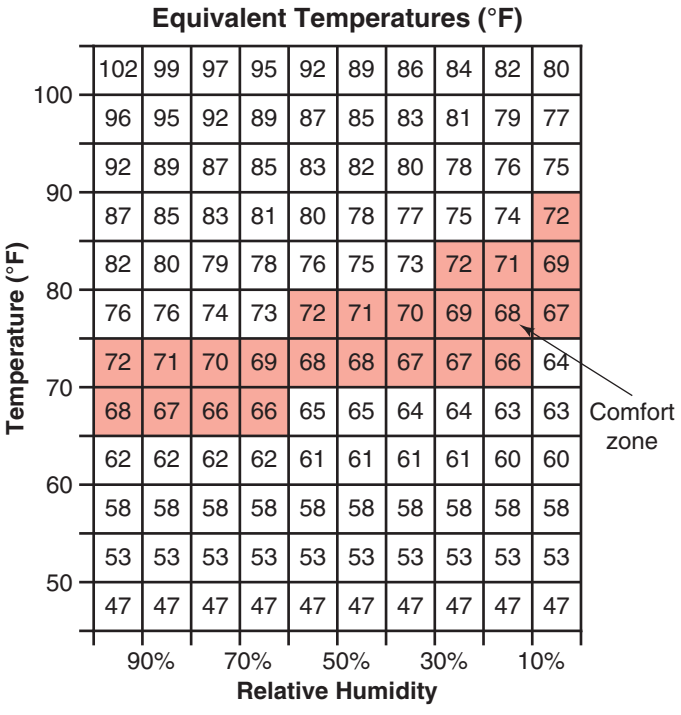
27.1 Climate

Weather refers to conditions in the atmosphere. These include temperature, wind velocity and direction, clouds, moisture, and atmospheric pressure. Weather affects the need for and requirements of air conditioning. The term ***climate***, when applied to outdoor conditions, describes the long-term weather trends for a region. When the term *climate* is used in reference to indoor environments, it refers to the conditions that are normally maintained in the conditioned space. Outdoor climates, of course, cannot be affected by air conditioning (heating, cooling, and humidity control). However, in an enclosed space, the factors that determine comfort can be completely controlled. Many homes and workplaces use air conditioning, furnaces, and humidity control to maintain a comfortable environment.

27.1.1 Equivalent Temperature

An ***equivalent temperature*** represents how warm the combination of humidity and temperature feels to the occupant of a space. The chart in **Figure 27-1** shows the equivalent temperatures for given combinations of temperature and relative humidity.

If the ambient air temperature is cooler than 98.6°F (36°C), air movement cools the human body. If the heating system provides over 15 to 20 feet per minute (fpm) of air movement, a temperature increase may be necessary to help maintain a comfortable indoor environment.



Goodheart-Willcox Publisher

Figure 27-1. Chart listing the equivalent temperatures for various combinations of temperature and humidity. Comfortable combinations of temperature and humidity are highlighted. Note that with high relative humidity, the comfort zone has lower temperatures.

27.1.2 Definition of Air Conditioning

The American Society of Heating, Refrigerating and Air-Conditioning Engineers (ASHRAE) define ***air conditioning (a/c)*** as "the process of treating air so as to control simultaneously its temperature, humidity, cleanliness, and distribution to meet the requirements of the conditioned space."

In order to meet these demands, various parts of an air-conditioning system must work together. The systems are usually equipped with automatic controls in order to maintain the desired temperature inside a room under changing outdoor conditions. The system controls humidity by passing air over the cold evaporator surfaces, which causes excess humidity to condense out of the conditioned air. When humidity is high, increased air movement is beneficial. By contrast, in the winter heating season when the air is typically dry, a humidifier can be used to add moisture to the air.

In general, air filtering is accomplished the same way in summer and in winter. Air filtering equipment usually consists of very fine, porous substances through which air is drawn to remove dust and other particles. Activated carbon filters and electrostatic precipitators can be added to the usual filtering mechanisms to improve air cleaning. Air pollutants and methods for removing them from the air will be covered in more detail in Chapter 28, *Air Quality*.

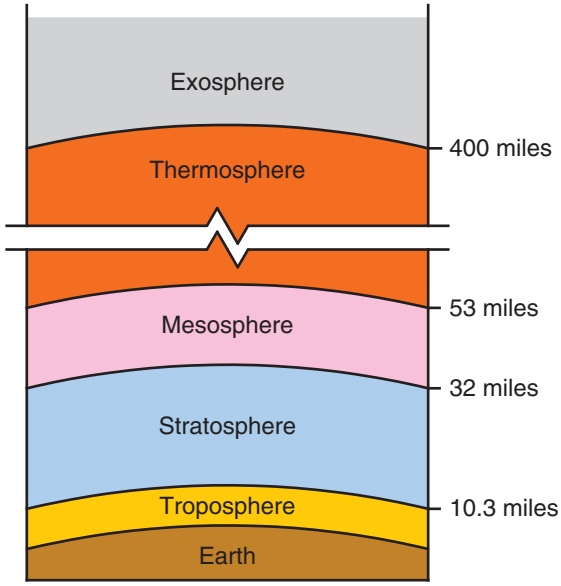
Many industries air-condition their plants for two reasons: to provide comfort for their workers and to achieve more complete control of manufacturing processes and materials. Better control of temperatures and relative humidity during a manufacturing process improves the quality of the finished product.

27.2 Atmosphere and Air

Air is an invisible, odorless, and tasteless mixture of gases. The air surrounding the earth is called the *atmosphere*. It extends above the earth about 6,200 miles and is divided into several layers. See **Figure 27-2**.

The layer closest to the earth, the ***troposphere***, extends from sea level to 56,000′ (10.6 mi) at the equator.

Copyright Goodheart-Willcox Co., Inc. 2017



Goodheart-Willcox Publisher

Figure 27-2. The earth's atmosphere comprises several layers. The exosphere extends into outer space.

This layer contains 75% of the earth's air. The layer extending from 56,000′ (10.6 mi) up to 170,000′ (32 mi) is called the ***stratosphere***. The stratosphere contains the ozone layer.

The ***mesosphere*** extends from 170,000′ (32 mi) to 280,000′ (53 mi). The ***thermosphere*** extends from 280,000′ (53 mi) to 2,100,000′ (400 mi). This layer contains the ionosphere, a layer of charged particles, and is marked by temperatures that increase with altitude, reaching 2730°F (1500°C).

The ***exosphere*** is the outermost layer of earth's atmosphere. It extends outward from the edge of the thermosphere to a distance of 6,200 miles, as it gradually blends with space. Most satellites orbit in this layer of the atmosphere.

Air as we know it in our atmosphere is a mixture of oxygen, nitrogen, argon, carbon dioxide, hydrogen, sulfur dioxide, and water vapor (moisture). It also contains a very small percentage of rare gases. The exact composition of air changes with altitude and other factors. **Figure 27-3** lists the average percentages of these gases, both by volume and by weight, for air at sea level.

- Nitrogen. About three-fourths of the earth's atmosphere consists of nitrogen. Nitrogen is a gaseous element that does not readily combine with other substances. When combined with other elements, nitrogen is usually unstable. Nitrogen is combined commercially with hydrogen to form ammonia, which is the basis of most fertilizers and an important refrigerant, NH_3 (R-717). Liquid nitrogen is also a special purpose expendable refrigerant.
- Oxygen. The atmosphere is approximately 23% oxygen by weight. Oxygen readily combines with many substances. When fuels such as wood, coal, or oil are burned, their carbon and hydrogen combine with the oxygen in the atmosphere, forming carbon dioxide and water, respectively. The oxygen in the atmosphere is replenished by plants, which absorb carbon dioxide and release oxygen.
- Argon. Argon is a noble gas that composes approximately 0.93% of the atmosphere by volume. It is the most common and most widely used of the noble gases. Noble gases, also called inert gases, are very stable gases with extremely low reactivity.
- Carbon dioxide. Carbon dioxide makes up 0.03% to 0.04% of the atmosphere. Carbon dioxide is a combination of carbon and oxygen. Absorbed by growing plants, it becomes one of the building blocks in the development of plant cells.
- Hydrogen. Hydrogen (H_2), a very light gas, does not show in weight percentage. Hydrogen is present in most fuels. When burned, it combines with oxygen to form water (H_2O) in steam and vapor form.
- Sulfur dioxide. Sulfur dioxide is the most common gaseous contaminant. It is formed by combustion of fuels that contain sulfur. Many large power plants now have facilities for removing sulfur from these fuel sources and sulfur dioxide from the stack gases.

Components of Dry Air at Sea Level

Name	Chemical Symbol	Amount by Weight (%)	Amount by Volume (%)
Nitrogen	N_2	75.47	78.03
Oxygen	O_2	23.19	20.99
Argon	Ar	1.29	0.93
Carbon dioxide	CO_2	0.04	0.03
Hydrogen	H_2	0.00	0.01
Water	H_2O	0.00	0.00
Dust	—	0.00	0.00

- Water vapor (moisture). The amount of water vapor in the atmosphere varies with the temperature. For any given time, the percentage of moisture in the air relative to the maximum amount the air can hold is indicated by the term *relative humidity*.
- Rare gases. Rare gases make up a very small percentage of the atmosphere. These gases include neon, helium, krypton, and xenon.

Atmospheric air is a combination of gases, water vapor, and pollutants. These pollutants vary considerably among different regions and time periods, and may include industrial pollution, smog, and pollen. Air contaminants also exist indoors. Indoor air pollution is among the top five environmental health risks. Air conditioning plays an important role in the reduction of indoor air contaminants. This role will be discussed further in Chapter 28, *Air Quality*.

27.2.1 Physical Properties of Air

People often do not think of air as matter because it is invisible and all around us. However, air has weight, volume, temperature, specific heat, and heat conductivity. In motion, air has momentum and inertia. It holds substances in suspension and in solution.

Air pressure at the earth's surface is due to the weight of air above the earth. Air pressure decreases as altitude increases. The higher the altitude, the less the volume of air is above. Less air being above results in a reduction of the weight of the air above. Air presses against the earth at sea level with a pressure of 14.7 psi (101 kPa).

Since air has mass, energy is required to move it. Once in motion, air has kinetic energy. For example, the weight of moving air turns wind turbines. The wind turbines convert the kinetic energy to mechanical or electrical energy.

According to Bernoulli's principle, increasing the velocity of air decreases the pressure. For example, in a tornado, the velocity is very high, reducing the pressure. Tiny dust particles may be picked up and held in suspension in moving air. These particles may remain in suspension for long periods of time.

The density of air varies with atmospheric pressure and humidity. The volume of space that air occupies under a given set of conditions is known as its *specific volume*. The less dense the air is, the greater its specific volume will be. One pound of air at standard conditions (14.7 psia [101 kPa], 69.8°F [21°C]) occupies 13.341 ft^3. One kilogram of air at standard conditions occupies 0.83285 m^3. By dividing the weight of air by volume it occupies, you can calculate its density. Air under standard conditions has a density of 0.07496 lb/ft^3 (1.2007 kg/m^3).

Air temperatures can be measured with either the Fahrenheit scale or the Celsius scale. Under ordinary conditions, glass-stemmed thermometers or digital thermometers can satisfactorily measure air temperature. Expanding metals, such as bimetal strips or rods, are also used. When measuring very low temperatures, thermocouple thermometers or resistance temperature detectors (RTDs) are used. Thermocouple thermometers, pyrometers, and thermistor thermometers are used for measuring high temperatures.

The specific heat of air is the amount of heat required to raise the temperature of one pound of air one degree Fahrenheit, or one kilogram of air one degree Celsius. The specific heat of air at sea level is 0.24 Btu/lb (0.557 kJ/kg).

Air has low heat conductivity, meaning that it does not transfer heat efficiently. For this reason, air spaces are often used for insulating purposes.

27.2.2 Humidity

Humidity is the presence of moisture or water vapor in the air. Since humidity is moisture in vapor form, it is invisible. The amount of moisture that air will hold depends on the air temperature. Warm air holds more moisture than cold air.

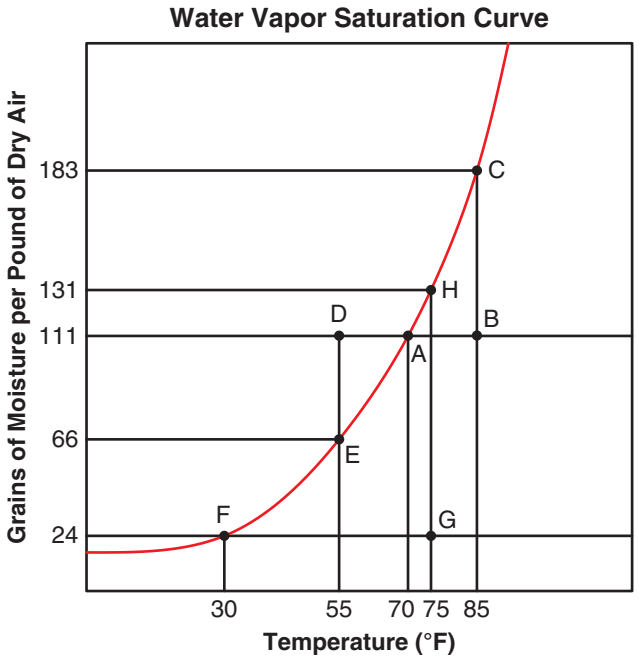
The amount of humidity in the air affects the rate of evaporation of moisture from a surface. Dry air causes rapid evaporation, cooling the surface quickly. Moist (humid) air prevents rapid evaporation of moisture from a surface. Since less moisture evaporates in humid conditions, the surface does not cool as rapidly. This principle explains why people are more prone to heat exhaustion in hot, humid climates than in hot, dry climates.

Relative Humidity

Relative humidity (rh) is a term used to express the amount of moisture in an air sample compared to the total amount of moisture the same sample would hold if it were completely saturated at the same temperature. Relative humidity is stated as a percentage. For example, air with a relative humidity of 25% contains only one-fourth of the moisture it is capable of holding.

A water vapor saturation curve, **Figure 27-4**, is a graph showing the amount of water that air can hold at different temperatures. The line from Point A to Point B represents what happens when saturated air is warmed. Point B contains 111 grains of moisture per pound of air at 85°F (29.4°C). The saturated condition for air at the same temperature (at Point C) is 183 grains of moisture per pound of air. The line between Point B and Point C represents how much additional moisture

Copyright Goodheart-Willcox Co., Inc. 2017



Goodheart-Willcox Publisher

Figure 27-4. A typical water vapor saturation curve for air. As the temperature of the air increases, the amount of moisture it can hold also increases.

the air could hold. In this case, the air could hold an additional 72 grains of moisture per pound.

Therefore, the relative humidity at Point B is:

$$\text{rh} = \frac{111 \text{ grains/lb}}{183 \text{ grains/lb}} \times 100\%$$
$$= 0.606 \times 100\%$$
$$= 61\%$$

The lines from Point A to Point D and Point D to Point E represent what happens when saturated air at 70°F (21.1°C) is cooled to 55°F (12.8°C). Air at 70°F (21.1°C) will hold 111 grains of moisture per pound (Point A), but the same air at 55°F (12.8°C) will hold only 66 grains of moisture per pound (Point E). The line between Point A and Point D represents how much the air is cooled. The line between Point D and Point E represents the moisture condensed out of the air as it cools. To calculate the amount of moisture condensed, subtract the moisture content of the air at 55°F (12.8°C) from the moisture content of the air at 70°F (21.1°C):

111 grains/lb – 66 grains/lb = 45 grains/lb

A typical outdoor condition in winter is represented at Point F. This outdoor air is 30°F (–1°C) and has 100% relative humidity. At that temperature, the air holds 24 grains of moisture per pound. If the same air is brought indoors and heated to 75°F (24°C) with no moisture added, its new condition is shown at Point G. The saturated condition at 75°F (24°C) would be 131 grains per pound (Point H). The original air had only 24 grains of moisture per pound. Therefore, the relative humidity of the air at Point G is calculated as follows:

$$\text{rh} = \frac{24 \text{ grains/lb}}{131 \text{ grains/lb}} \times 100\%$$
$$= 0.18 \times 100\%$$
$$= 18\%$$

Indicators of Low Humidity

Low atmospheric humidity is indicated by an increase in the amount of noticeable electrostatic energy. As a person moves about and touches grounded metal objects, a spark jumps from the hand or fingers to the object. Also, human hair tends to become more unmanageable. The surface of the skin and membranes in the nose become dry. Furniture joints shrink and become loose. Woodwork, such as wood in doors and floors, can crack. If these symptoms are present, more moisture must be added to the air to create comfortable conditions.

Dew Point

Dew point is the temperature below which water vapor in the air will start to condense. In other words, it is the temperature at which air will have 100% relative humidity.

A window during the winter heating season offers a good example of dew point. **Figure 27-5** shows the

9

Dew Point at Various Humidity Levels		
Relative Humidity of Air (%)	Dry-Bulb Temperature of Surface When Condensation Starts (°F)	
	70°F (21°C) Air Temp.	80°F (27°C) Air Temp.
100	70	80
90	67	77
80	64	73
70	60	69
60	56	65
50	51	60
40	45	54
30	37	46
20	28	35

Goodheart-Willcox Publisher

surface temperature that will cause condensation (dew point) for various humidity levels. Cold air cannot hold as much water vapor as warm air, so when the outdoor air temperature falls and the interior of the home is heated, water vapor (condensation) forms on the inside (warm surface) of the window.

Several methods can be used to find the dew point. Dew point is professionally and accurately measured using a chilled mirror hygrometer, which is an expensive and highly sensitive thermometer. Dew point can be determined inexpensively and with fair accuracy using the following method. Cut a shiny aluminum soda can in half. Fill the can approximately 2/3 full of water. Add ice cubes to the water. This will lower the can's surface temperature. Stir the mixture. Continue adding ice until condensation forms on the exterior of the can. When condensation forms on the exterior of the can, this indicates the dew point temperature.

Humidity Measurement

Factors such as quality controls, product testing, energy efficiency, and the comfort of the work environment have created an increased need for humidity measurement. A wide variety of instruments can be used to measure humidity. These range from simple mechanical indicators to highly complex and expensive analytical instruments.

A ***hygrometer*** is an instrument that measures moisture in the air. Originally, the operation of these instruments depended on the use of some moisture-absorbing material. Human hair, wood, and fibers were often used. These materials change their shape or size, depending on the relative humidity of the air. The moisture absorbing materials were linked to a gauge needle. As the materials changed size or shape, they moved the gauge needle, **Figure 27-6**.

Today, relative humidity is most often measured electronically. The most frequently used electronic instruments base their measurements on electronic impedance or input from capacitive sensors that respond to varying levels of water vapor pressure.

Typically, humidity is displayed in the form of percentage relative humidity (% rh), which can be easily converted into other measurement variables, such as dew point or wet-bulb temperature. Modern instruments provide measurements over wide humidity and temperature ranges. Such instruments are available in a number of configurations, such as handheld models, analog or digital transmitters, and data loggers. See **Figure 27-7**.

Palm-held electronic hygrometers are equipped with quick and accurate sensors. These hygrometers can use the power of mobile PCs to display, record, document, annotate, and report measurements. Such units are typically capable of measuring relative

humidity, temperature, dew point, wet-bulb temperature, and more. They have internal data memory and are typically capable of storing enhanced survey information, data and text, and graphic notes under specific file names. In addition, they have an infrared port that can be used to transfer data to a PC for detailed analysis and reporting. The data that is collected can be reviewed at a later time.

It is sometimes helpful to have an extended reading of temperature and humidity in a controlled space. A seven-day recorder that indicates the moisture and temperature can fulfill this purpose, **Figure 27-8**. When using this instrument, refer to a psychrometric chart to find the relative humidity. Psychrometric charts are explained later in this chapter.

Desiccants

Desiccants are substances that absorb moisture from the air. Common desiccants include activated alumina, silica gel, calcium sulfate, and zeolites. Many desiccants can be reactivated (dried out) by heating.

Often, instruments are packaged in containers with a packet of desiccant. The desiccant absorbs the moisture in the container, keeping the instrument dry to reduce corrosion.

Humidity Controls

Health studies indicate that humidity control is an important factor in air conditioning. Humidity controls operate during the winter heating season to add moisture to the air. They keep the humidity inside the conditioned space at a satisfactory level even though the air outside is dry.

Humidity controls operate in the summer to remove moisture from the air. To remove moisture in a home, a central air-conditioning system may use the cold evaporator to condense moisture out of the air. A drip pan and drain line or condensate pump carry the moisture to a drain. Some air-conditioning systems use a central dehumidifier to dehumidify all the air in a building. An alternative is to use a portable dehumidifier in damp rooms, such as in the basement for local dehumidification.

To remove moisture in large commercial air-conditioning installations, the humidity controls usually operate solenoid valves or dampers that vary the airflow over the air-conditioning system's evaporators. The control element may be a synthetic fiber or human hair. These elements are sensitive to the amount of moisture in the air. Construction principles of a humidity control mechanism are shown in **Figure 27-9**.

Thermo-humidigraphs (temperature and humidity recorders) may be equipped with alarms. These will alert attendants if the temperature or humidity fails to remain at the proper level. This is helpful in computer rooms and other installations that require close humidity control. **Figure 27-10** shows a temperature and humidity recorder.

27.2.3 Air Temperature

The behavior of air varies with its temperature. As previously stated, the higher the temperature, the greater the air's ability to hold moisture. Air temperature is measured with a thermometer. Several different scales are commonly used, including Fahrenheit, Celsius, and Kelvin.

Dry-Bulb Temperature

Human comfort and health depend a great deal on air temperature. In reference to air conditioning, the air temperature measurement most frequently used is ***dry-bulb temperature***. It is taken with the sensitive element of the thermometer in a dry condition. The dry-bulb temperature does not take into account the effect of humidity in the air.

Wet-Bulb Temperature

If a moist wick is placed over a thermometer bulb, the evaporation of moisture from the wick will lower the thermometer reading. The resulting temperature

Goodheart-Willcox Publisher

Figure 27-9. Diagram showing a simple humidity control mechanism. When the element absorbs moisture, it expands. This expansion causes the contact arm to rotate clockwise around the pivot, closing the dehumidify circuit. When the element becomes dry, it shrinks, causing the contact arm to rotate counterclockwise around the pivot. This closes the humidify circuit. The adjusting screw sets the preload on the element.

Sealed Unit Parts Co., Inc.

Figure 27-10. Digital temperature and humidity data logger.

measurement is known as ***wet-bulb temperature***. Wet-bulb temperature is a function of the amount of moisture in the air. The rate of evaporation from the wet wick on the bulb, and the temperature difference between the dry bulb and wet bulb, depends on the humidity of the air. Wet-bulb temperature is always lower than dry-bulb temperature, but will be exactly the same at 100% relative humidity. If the air surrounding a wet-bulb thermometer is dry, evaporation from the moist wick will be rapid, increasing the drop in temperature. If the air is very moist, evaporation will be slower, reducing the drop in temperature. **Figure 27-11** compares dry-bulb temperature and wet-bulb temperature.

When the air is saturated with moisture, no water can evaporate from the cloth wick, and the wet and dry-bulb temperatures remain identical. However, if the air is not saturated, water can evaporate from the wick, and the wick's temperature is lowered. Then, heat from the mercury flows to the wet wick and lowers the thermometer's temperature.

The wet-bulb reading depends on how fast the air passes over the bulb. Also, the wet bulb should be protected from heat-radiating surfaces, including radiators and electric heaters. Errors as high as 15% are possible if too much radiant heat is present.

Perception of Temperature

Air temperatures in the United States vary from a low of about –55°F (–48°C) to a high of around 120°F (49°C). The desirable temperature is 72°F (22°C). **Figure 27-12** shows how different combinations of relative humidity and temperature affect comfort.

The normal temperature of the human body is 98.6°F (37°C). Skin temperature is lower, about 91°F (33°C). In

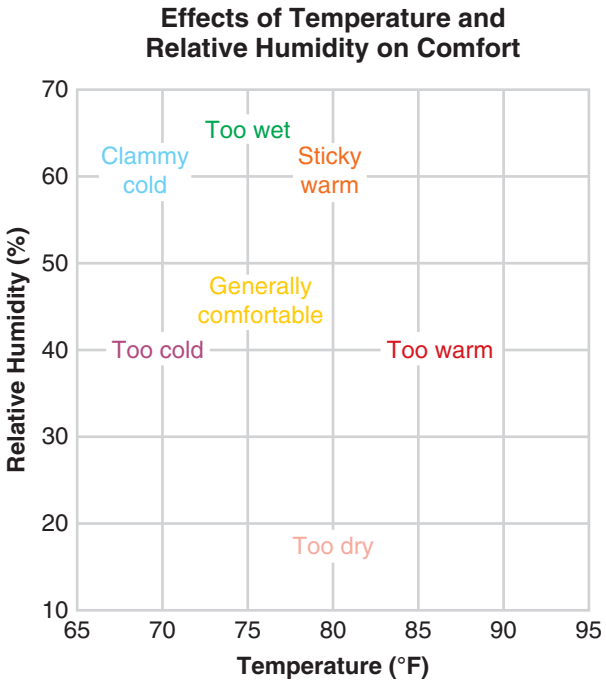
Goodheart-Willcox Publisher

Figure 27-11. A wet-bulb thermometer is essentially a dry-bulb thermometer with a moist wick over the bulb. Note that temperature shown on wet-bulb thermometer is considerably lower than dry-bulb thermometer. This indicates that the air is fairly dry.



Lennox Industries Inc.

Figure 27-12. Graph demonstrating the effects of temperature and relative humidity on comfort. Most people will feel comfortable at the temperature and relative humidity combinations near the center of the graph.

Temperature/Humidity Ranges for Comfort

Conditions	Relative Humidity	Acceptable Operating Temperatures	
		°F	°C
Summer	30%	76–82	24.5–28
	60%	74–78	23–25.5
Winter	30%	69–78	20.5–25.5
	60%	68–75	20–24

Adapted from ASHRAE 55-2010—Thermal Environmental Conditions for Human Occupancy

Figure 27-13. Table showing comfortable temperature ranges for the humidity conditions indicated.

temperate zones, the average outdoor temperature in winter is well below the body temperature. Clothing is required to help conserve body heat. Also, heat needs to be added to occupied spaces for the comfort of its occupants. According to ASHRAE 55-10, certain temperature/humidity ranges are most comfortable for the majority of people, **Figure 27-13**.

The human body loses heat easily when the air temperature falls below 98.6°F (37°C). The body also loses some heat at air temperatures above 98.6°F (37°C) through evaporation of perspiration and by respiration. Moisture is fed to the skin from the sweat glands. Evaporation of this moisture lowers the skin temperature. The evaporation of moisture constitutes a considerable heat exchange from the human body. Evaporative heat exchange can be considered a form of convection. The evaporated moisture is carried away along with its heat content.

In order to maintain comfortable temperatures, energy is required to heat or cool the air to the desired temperature. The specific heat of dry air is 0.24 Btu/lb.

Degree Days

Degree days are a measure used to indicate the heating or cooling needed for a given region. Calculations are based on a temperature of 65°F (18°C). If the average temperature for a day is below this temperature, it is referred to as ***heating degree day***. If the average temperature for the day is above 65°F (18°C), it is referred to as a ***cooling degree day***. The numeric

Copyright Goodheart-Willcox Co., Inc. 2017

value of the heating or cooling degree days equals the difference between the average temperature that day and 65°F (18°C).

Formula for calculating degree days:

$$\text{degree days (F)} = 65°\text{F} - \frac{\text{high temp} + \text{low temp}}{2}$$

Example:
The low temperature for a certain day was 28°F (–2°C). The high temperature for the same day was 36°F (2°C). What was the number of heating degree days in Fahrenheit?

Solution for Fahrenheit degrees:

$$\text{degree days (F)} = 65°\text{F} - \frac{28°\text{F} + 36°\text{F}}{2}$$
$$= 65°\text{F} - 32°\text{F}$$
$$= 33 \text{ heating degree days}$$

If the temperature conditions continued for two days, the result would be 66 heating degree days. If Monday has 30 cooling degree days and Tuesday has 20 cooling degree days, the result is 50 cooling degree days for the two days.

Celsius degree days are calculated the same way as Fahrenheit degree days. For the equations below, use the Celsius numbers from earlier.

Solution for Celsius degrees:

$$\text{degree days (C)} = 18°\text{C} - \frac{\text{high temp} + \text{low temp}}{2}$$
$$= 18°\text{C} - \frac{2°\text{C} + (-2°\text{C})}{2}$$
$$= 18°\text{C} - 0°\text{C}$$
$$= 18 \text{ degree days (C)}$$

Degree days can be added by weeks, months, or for a season. To do this, add all of the heating degree days together for the period and record the total. Then, add all of the cooling degree days together for the period and record the total. The two totals provide an estimate of the heating and cooling demands for the period. You can then divide the totals by the numbers of days in the period to determine the average daily heating and cooling demands for the period.

27.2.4 Psychrometric Properties of Air

Psychrometry is the science studying the thermodynamic properties of air and water vapor. Knowledge of psychrometry allows the technician to better control temperature and humidity of the air in an air-conditioning system. The comfort of occupants is due not only to the temperature of the surrounding air, but also to the level to which this air is saturated with water vapor.

The use of psychrometric principles allows technicians to design air-conditioning systems that control environmental conditions. **Figure 27-14** shows a computer system that interfaces with the air-conditioning and filtration systems in a large industrial facility. Such systems monitor and maintain temperature and humidity within preset levels.

Tables and graphs have been developed to show the pressure, temperature, heat content, volume of air, and steam content of air. A pressure of 29.92 in. Hg (76 cm Hg) is used as standard atmospheric pressure. These psychrometric charts display a representation of air properties in a visual format. Psychrometric charts are important in the designing and sizing of air-conditioning systems. Their use ensures efficiencies based on the specifics of a site. Psychrometric charts will be further described in a later section.

Psychrometer

Airflow over a wet-bulb thermometer should be quite rapid to ensure accuracy. In the past, a sling psychrometer was often used to whirl a pair of thermometers, one dry-bulb and one wet-bulb. The benefit of a sling psychrometer was that it offered a simple, rapid measurement of relative humidity without using tables, charts, or formulas, **Figure 27-15**.

To use a sling psychrometer, the wick on the wet bulb was saturated and then the sling psychrometer was whirled. When the mercury stopped dropping,

Johnson Controls, Inc.

Abbeon Cal, Inc.

Figure 27-15. A sling psychrometer uses a dry-bulb and a wet-bulb thermometer to determine relative humidity.

the wet bulb would be read immediately, followed by reading the dry bulb. The wet-bulb temperature was placed over the dry-bulb temperature scale on a psychrometer slide rule. An arrow on the scale indicated the relative humidity.

Electronic psychrometers can measure dew points even in extremely cold conditions. They can also display relative humidity, temperature, and dew point simultaneously. Some digital psychrometers provide a port so the data they collect can be downloaded to a PC, **Figure 27-16**.

Psychrometric Charts

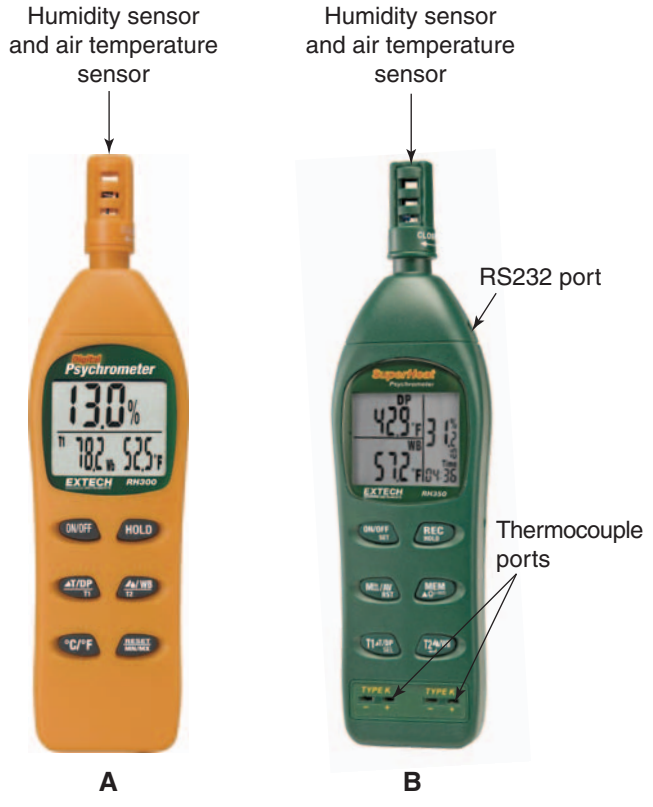
A ***psychrometric chart*** is a graph of the properties (dry-bulb and wet-bulb temperatures, relative humidity, specific volume, and specific humidity) of air. It is used to determine how changes in one property affect the other properties of the air. At first glance, a psychrometric chart may seem complicated and difficult to read. However, once you familiarize yourself with the lines on the graph and what they represent, you will find a psychrometric chart to be a relatively simple and useful tool.

Figure 27-17 shows the lines on the psychrometric chart that represent constant conditions. In **Figure 27-17A**, the red lines represent constant dry-bulb temperature. These lines represent the temperature of the air without accounting for the effect of humidity. They are always vertical lines.

In **Figure 27-17B**, the red lines depict constant wet-bulb temperatures. These lines represent the temperature of the air adjusted for the effect of humidity.

In **Figure 27-17C**, the red lines represent constant specific humidity. The specific humidity is simply a measure of the quantity of moisture in the air. These lines are always horizontal. You will notice that on the left side of the graph, the red lines all end at different points, leaving the left edge of the graph as a curve. This occurs because there is a maximum amount of moisture that air at any given temperature is capable of holding.

For example, air with a temperature above 35°F (1.7°C) is capable of holding 30 grains of moisture per pound, but air must be over 80°F (26.7°C) in order to



Extech Instruments Corp.

Figure 27-17. A psychrometric chart is a graph of temperature and humidity conditions. Because of the interdependent relationships among different air properties, the graph is useful for determining unknown air properties based on known properties. Lines representing various properties are shown in red on the charts. A—These lines represent constant dry-bulb temperatures. B—These lines represent constant wet-bulb temperatures. C—These lines represent constant specific humidity levels. D—These lines represent constant relative humidity levels. E—These lines represent constant specific volumes. F—These scales are used to determine the total heat energy in the air sample and the ratio of sensible heat to latent heat.

Copyright Goodheart-Willcox Co., Inc. 2017

hold 160 grains of moisture per pound. The quantity of moisture air can hold increases as the temperature of the air increases.

In **Figure 27-17D**, the red lines represent constant relative humidity (%). The relative humidity is the ratio between the amount of moisture the air is capable of holding (which is dependent on its temperature) and the amount of moisture the air is actually holding. The 100% relative humidity line, the upper curve along the graph, is also known as the dew point or saturation temperature line. The line for air with 0% relative humidity would be completely horizontal and positioned right on top of the dry-bulb temperature scale. Note that the curvature of the lines increases as the relative humidity increases.

In **Figure 27-17E**, the red lines represent constant specific volume. Keep in mind that specific volume is inversely proportional to the air's density. As specific volume increases, air density decreases. Also, note that the specific volume increases with temperature and humidity. This is Charles' law in action. With pressure maintained at a constant value, specific volume and temperature will both increase or decrease together. With more volume, more moisture (humidity) can be absorbed into the air.

In **Figure 27-17F**, the scales representing enthalpy and sensible heat ratio are shown in red. You will notice that the lines on these scales do not extend across the graph. In order to plot these values on the graph, a technician would position a straightedge so it crosses the graph and aligns with the hash mark for the desired value on the scale.

Enthalpy is the total heat content in the air sample. Remember that there are two different types of heat. Sensible heat changes the temperature of the air, and latent heat changes the level of humidity in the air. The hash marks on the scale at the left side of the chart represent the sum of latent heat and sensible heat in the sampled air in Btu/lb. Note that if these hash marks are extended so they cross the graph, they would be parallel to the wet-bulb temperature lines.

The ***sensible heat ratio (SHR)*** is the amount of heat that affects the air temperature compared to the total heat added to or released from the air. It is shown on the scale at the right side of the chart. A horizontal line on the graph represents a change in dry-bulb temperature only (pure sensible heat). A vertical line on the graph represents a change in the air's moisture content only (pure latent heat). The lines on the sensible heat ratio scale are horizontal at the bottom of the scale and more angled at the top of the scale. This occurs because the values at the top of the scale represent an increased percentage of latent heat and a decreased percentage of sensible heat. This scale is useful for determining heat requirements when heating or cooling processes are plotted on the graph.

Reading a Psychrometric Chart

Each point on a psychrometric chart represents air at a specific set of conditions. The primary conditions displayed on the graph are dry-bulb temperature, wet-bulb temperature, specific humidity, relative humidity, and specific volume. If any two values are known, the chart can be used to determine the other values.

To plot a point on the chart, simply find the value of your first measured property on the appropriate scale. Then, find the value of the second measured property on the appropriate scale. Follow the lines extending from those values until they intersect inside the graph.

For example, imagine a sling psychrometer is used to measure dry-bulb and wet-bulb temperatures. The dry-bulb temperature is 80°F (26.7°C) and the wet-bulb temperature is 60°F (15.6°C). Refer to **Figure 27-18**.

Locate 80°F on the dry-bulb temperature scale at the bottom of the graph and 60°F on the wet-bulb scale on the left side of the graph. Trace the lines extending from those points (orange line for dry-bulb temperature and green line for wet-bulb temperature) until they intersect on the graph at Point A. This is the point that represents the properties of the air.

Place a straightedge through Point A and parallel to the specific humidity lines. Follow the straightedge to the specific humidity scale on the right side of the graph (see the dotted blue line). Note that the specific humidity of the air is roughly 45 grains per pound. Point A is sitting on the curve that represents a relative humidity of 30% (red curved line).

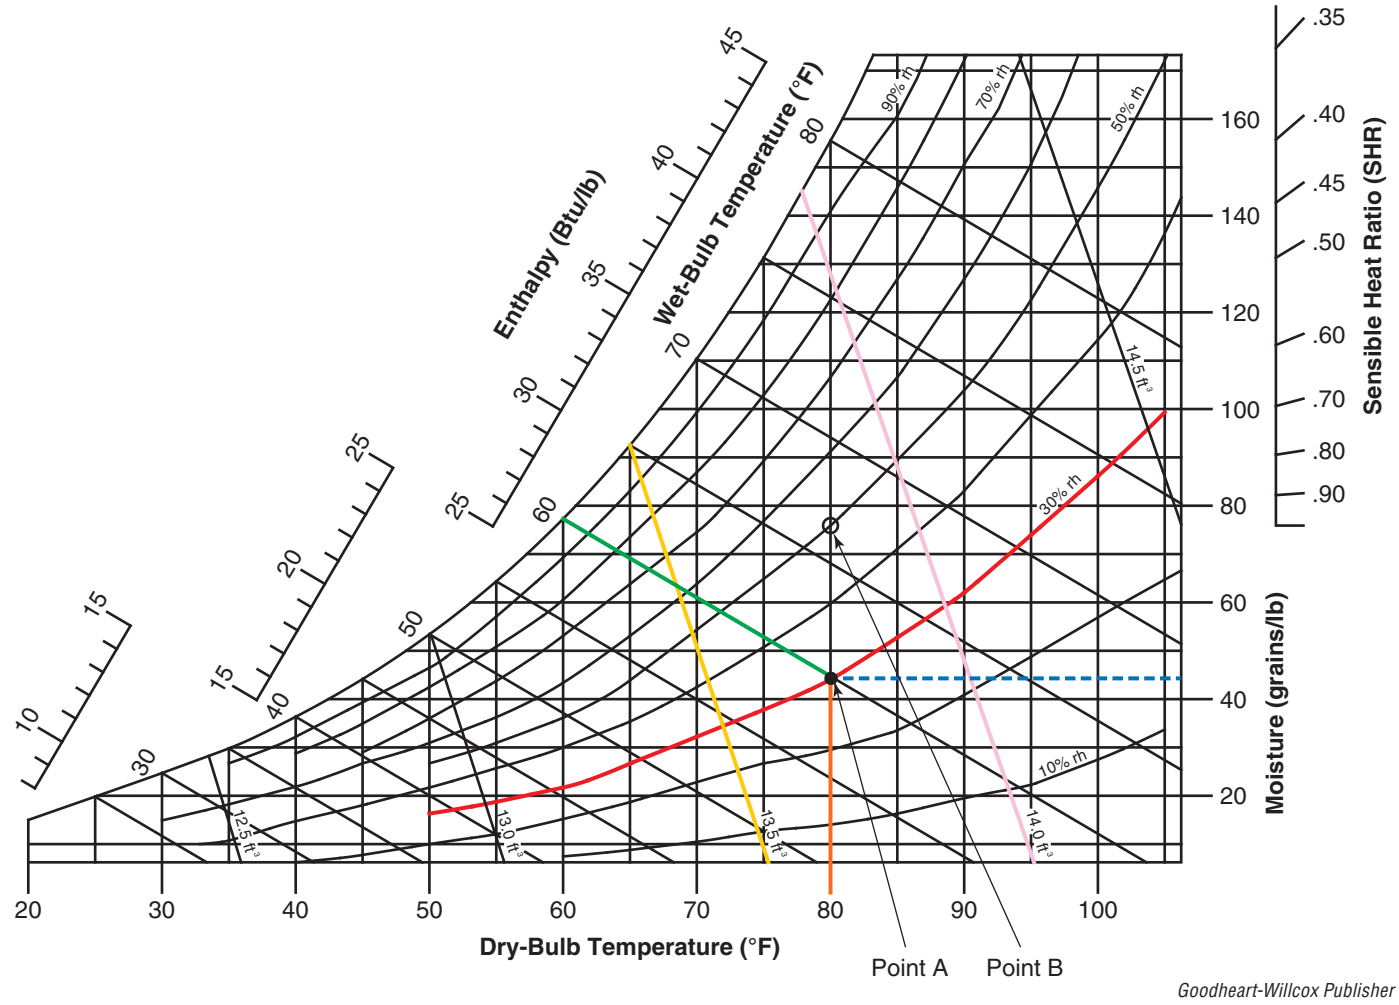
To the left of Point A is the specific volume line that represents 13.5 cubic feet (yellow line). If you look to the right of Point A, you see the specific volume line that represents 14.0 cubic feet (pink line). Since Point A sits between these two lines, the air's specific volume is 13.75 cubic feet per pound.

Next, place a straightedge along the wet-bulb temperature line and extend the line so it intersects with the enthalpy scale. Note that the air contains approximately 26 Btus of heat energy per pound.

Point B on the graph represents standard comfort conditions. Point B has the same dry-bulb temperature as Point A. However, the specific humidity scale to the right of Point B indicates that the air at Point B contains approximately 75 grains per pound of moisture, compared to 45 grains per pound at Point A. As a result, the relative humidity at Point B is 50% rather than 30%.

To the upper left of Point B, you will see that the wet-bulb temperature is about 67°F, and its enthalpy is 31 Btu/lb. In order to change the air from the condition

Copyright Goodheart-Willcox Co., Inc. 2017



Goodheart-Willcox Publisher

Figure 27-18. A typical psychrometric chart. All of the graph lines relating to conditions at Point A are shown in color. Point B represents standard comfort conditions. Notice that Point B is directly above Point A, indicating that the air at Point B is the same dry-bulb temperature as the air at Point A, but with more humidity.

shown at Point A to the condition at Point B, 5 Btus of latent heat and 30 grains of moisture would need to be added to each pound of air.

In the following example, use dry-bulb and wet-bulb temperatures to determine the relative humidity. Refer to **Figure 27-19**.

Example:
Dry-bulb temperature is 75°F (24°C). If the wet-bulb temperature is 60°F (16°C), what is the relative humidity?

Solution:
Follow the vertical line corresponding to the 75°F (24°C) dry-bulb temperature. Then follow the 60°F (16°C) wet-bulb temperature line. These lines cross each other at Point A. This point is just above the 40% relative humidity line. Therefore, the correct answer would be about 41% relative humidity.

In the following example, use dry-bulb temperature and relative humidity to find the dew point. Refer to **Figure 27-19**.

Example:
A sample of air has a dry-bulb temperature of 80°F (27°C) and a relative humidity of 60%. Determine the dew point.

Solution:
Find where the 80°F (27°C) dry-bulb line crosses the 60% relative humidity line. This point is labeled B. If the air represented by this point were cooled without a change in moisture content (represented on the psychrometric chart by the dotted horizontal line), the dew point line would be intersected at about 65°F (18°C). This is labeled as Point C.

Therefore, 65°F (18°C) is the dew point for the sample of air. The 80°F (27°C) temperature and the

Copyright Goodheart-Willcox Co., Inc. 2017

60% relative humidity could represent a typical summer evening. Dew would appear on surfaces when the 65°F (18°C) temperature was reached.

In the following example, use dry-bulb temperature and specific humidity to find relative humidity. Refer to **Figure 27-19**.

Example:
Find the relative humidity when the dry-bulb temperature is 75°F (24°C) and the specific humidity is 100 grains per pound of dry air.

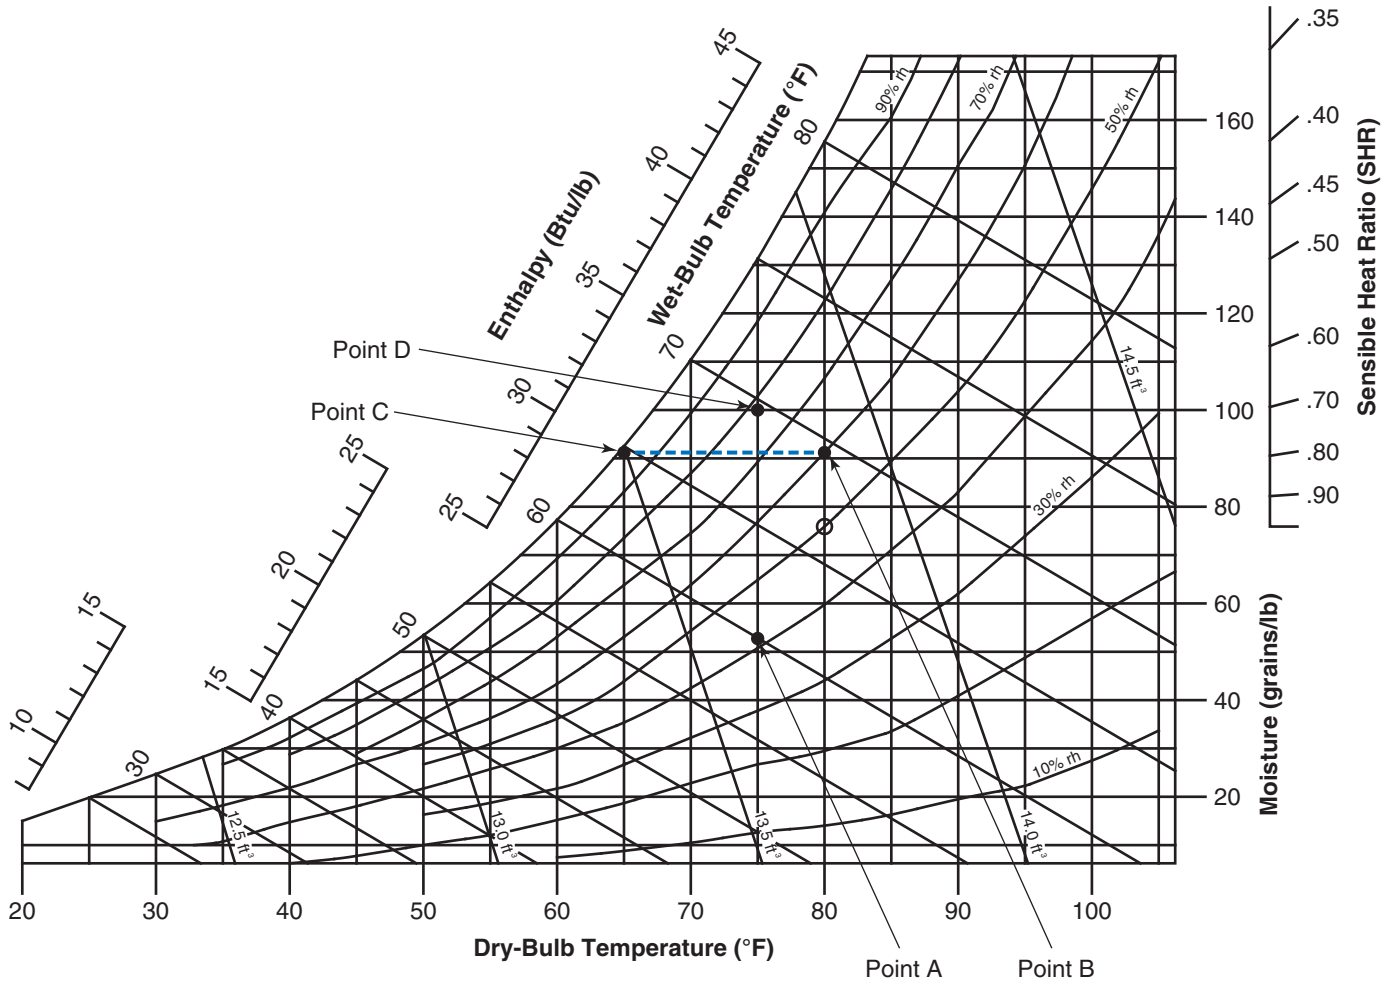
Solution:
First, find the vertical line representing a constant dry-bulb temperature of 75°F (24°C). Follow that line until it crosses the horizontal line representing 100 grains of moisture per pound of dry air. The intersection point is labeled Point D. This point falls between the 70% and 80% relative humidity lines. The answer would be a relative humidity of about 77%.

Study the psychrometric chart carefully. It provides a simple way for determining the various conditions of air. Remember, the warmer the air, the more moisture it will hold.

Using Psychrometric Charts

Many air conditioning problems in this text will require the use of a psychrometric chart. When air conditions are plotted for the various stages in a heating, ventilation, or air-conditioning process, a psychrometric chart can reveal exactly what is happening during each stage of the process.

People can be comfortable under a variety of temperature and humidity combinations. Most people are comfortable in an atmosphere with the relative humidity between 30% and 70% and the temperature between 70°F and 85°F (21°C to 29°C). These temperature and humidity conditions are plotted on a psychrometric chart in **Figure 27-20**. Every point inside the red lines represents a comfortable set of air conditions.



Goodheart-Willcox Publisher

Figure 27-19. With practice, you should be able to quickly and easily read psychrometric charts.

Copyright Goodheart-Willcox Co., Inc. 2017

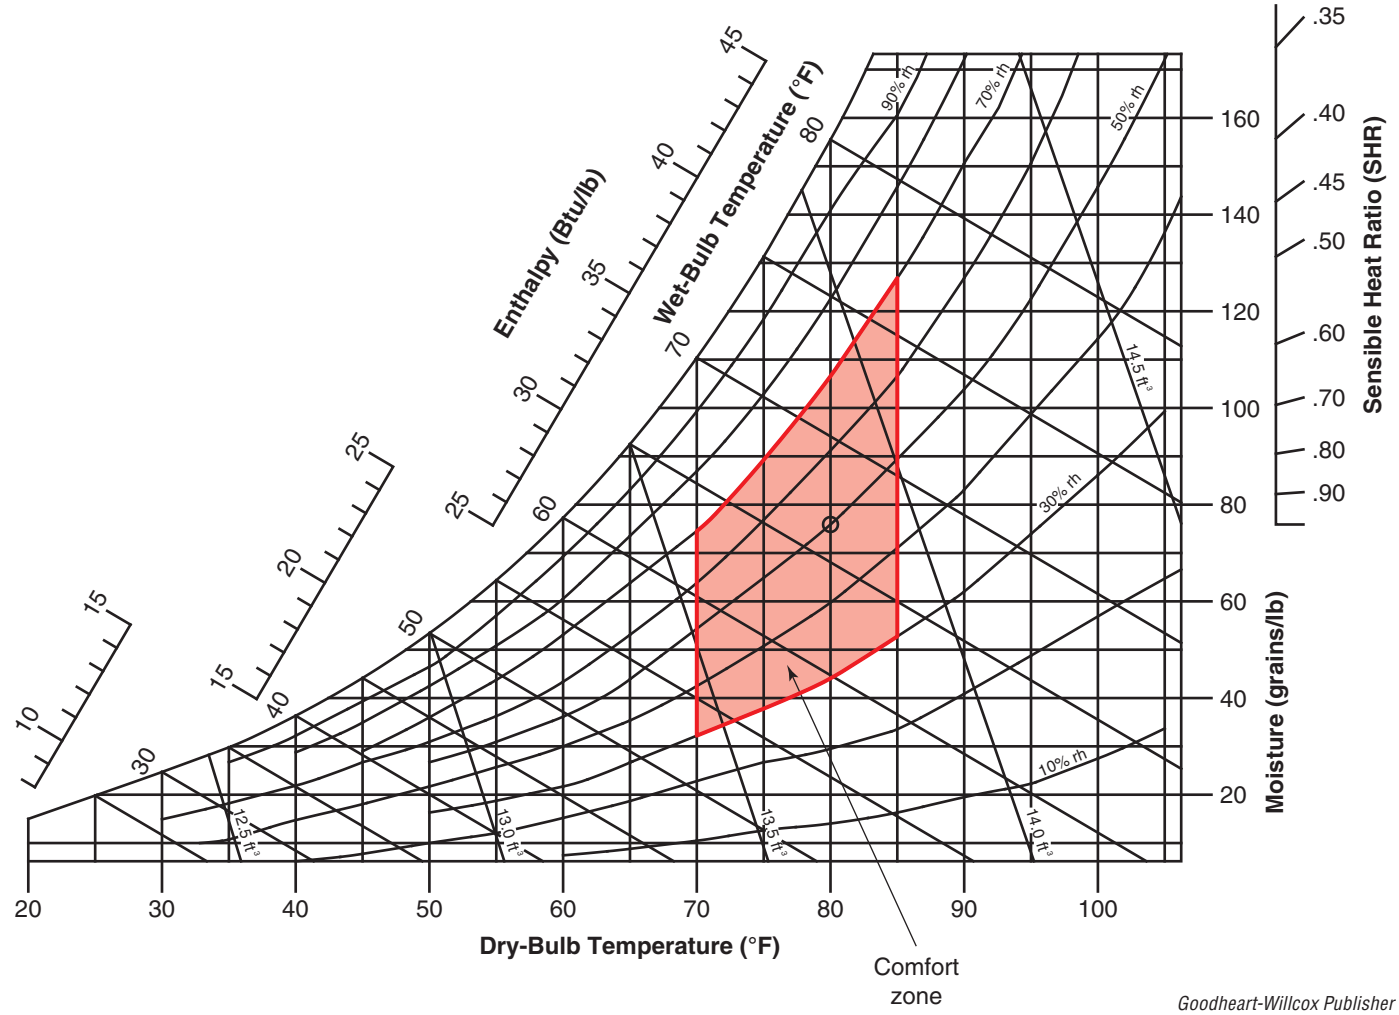


Figure 27-20. The four extremes of the human comfort zone are plotted on this psychrometric chart. Any combinations of temperature and humidity that falls within the red lines can be considered comfortable.

The HVAC industry exists because nature does not always provide these ideal conditions. HVAC systems must modify existing air conditions to bring them into a comfortable range. To accomplish this, air-conditioning systems use a combination of heating, cooling, humidification, and dehumidification processes.

These processes can be modeled on the psychrometric chart. See **Figure 27-21**. For example, Point A in the figure shows a dry-bulb temperature of 40°F and a relative humidity of 10%. The desired condition is Point B, 75°F and 50% relative humidity. The HVAC system must increase the temperature of the air by 35°F (red line) and increase the humidity by 50 grains per pound of air (blue line), which would result in a relative humidity of 50%. Plotting the air conditions at key stages in the air-conditioning process provides a good visual model of the changes that occur during the process.

A psychrometric chart can be used to plot the actions of the evaporators, heaters, and chillers in an HVAC system. Advanced psychrometrics can provide equations representing all the processes used in the conditioning of air. This gives scientists and engineers the data they need to design and evaluate new HVAC systems.

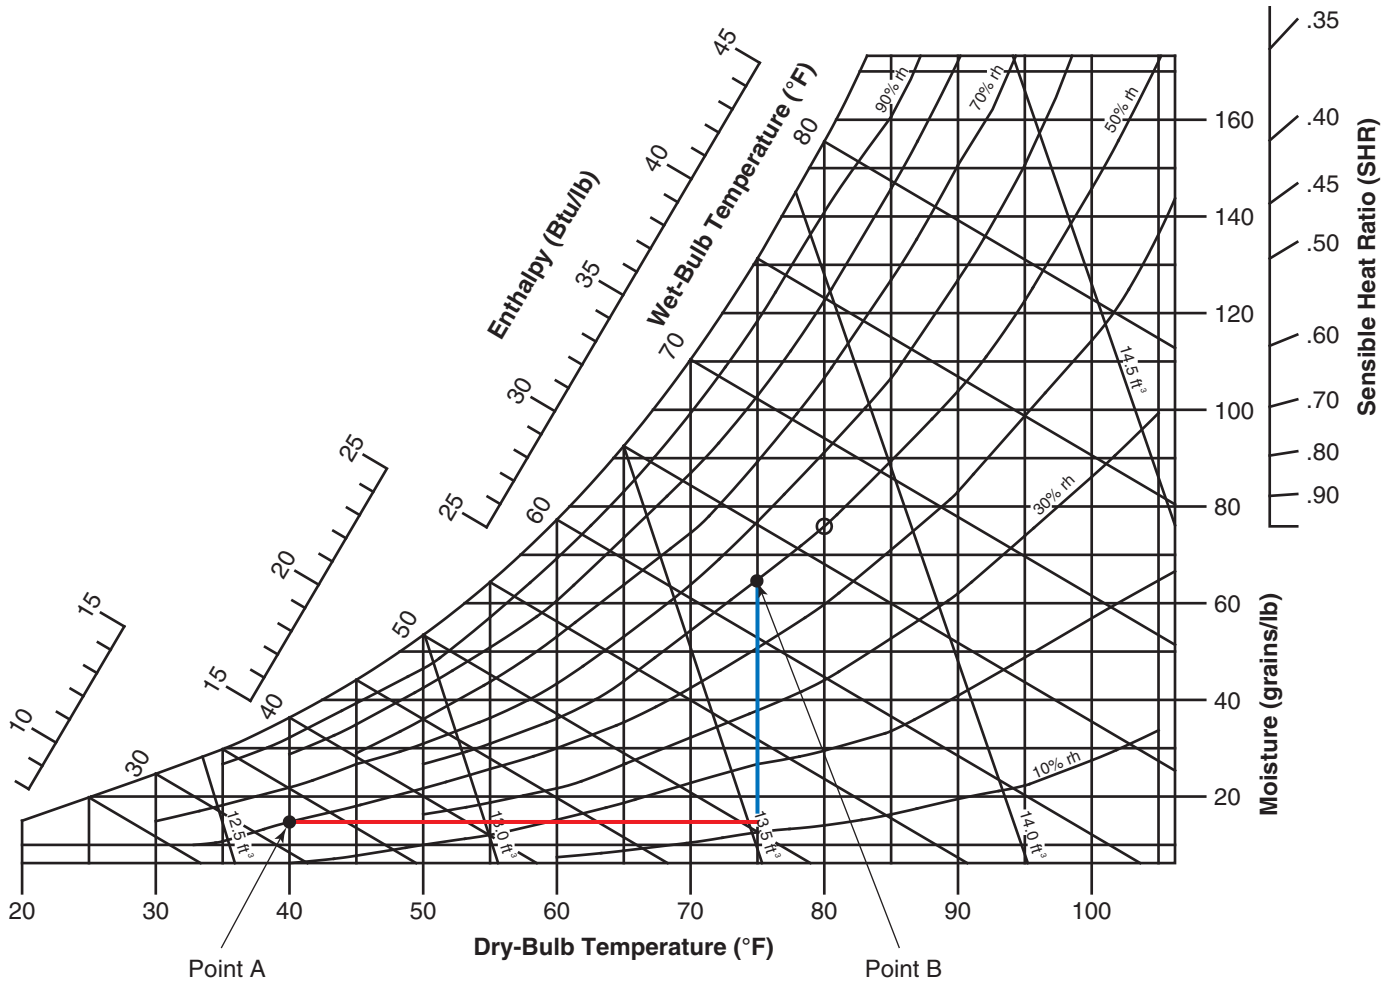
27.3 Comfort Conditions

A more technical graph showing the comfort zone is provided in **Figure 27-22**. This comfort zone represents a considerable area. However, any point in this area provides relative comfort under equal conditions of clothing and work. A room that is 75°F with a high relative humidity will feel basically the same as a room that is 80°F with a lower relative humidity. This means both rooms have the same effective temperature.

27.3.1 Effective Temperature

Effective temperature is the combined effect of dry-bulb temperature, wet-bulb temperature, and air movement that provides an equal sensation of warmth

Copyright Goodheart-Willcox Co., Inc. 2017



Goodheart-Willcox Publisher

Figure 27-21. If the current air conditions are represented by Point A and the desired air conditions are represented by Point B, the red line indicates how much the temperature must increase. The blue line represents the amount of moisture that must be added to the air.

or cold. Therefore, on a psychrometric chart, the effective temperature is the temperature at 50% relative humidity that yields the same heat loss as actual environment.

In the summertime, air conditioned buildings are usually kept at temperatures approximately 10°F to 15°F (5.6°C to 8.4°C) below the outside temperature. Some people are quite sensitive to thermal shock when entering or leaving an air conditioned space. This shock is lessened if the difference between inside and outside temperatures is reduced. Wearing a sweater or coat when indoors also reduces the shock.

The comfort range for most people varies from season to season. In summer, the comfort zone ranges between 72°F (22°C) db (dry-bulb temperature) at 90% rh up to 87°F (31°C) db at 23% rh. In winter, it is between 66°F (19°C) db at 70% rh up to 80°F (27°C) db at 20% rh.

Typically, people are most comfortable if their skin surface temperature is 91°F (33°C). This skin temperature is usually maintained in cold weather by wearing adequate clothing. In hot weather, it is maintained by the evaporation of moisture (sweat) and by heat radiation from the skin's surface.

27.3.2 Temperature-Related Illnesses

Temperature-related illnesses are called thermal disorders. In cold climates, it is possible for body temperature to drop a few degrees below normal due to lower metabolism. If body temperature drops too far below normal, hypothermia results. Hypothermia causes disorientation, numbness, loss of motor control, and eventually tissue damage, organ failure, and death.

High temperatures can also cause illness, especially if there is also high humidity. Jobs involving high air temperatures, radiant heat sources, high humidity, direct physical contact with hot objects, or strenuous physical activity have a high potential for causing heat stress. OSHA provides examples of methods to reduce heat stress hazards in the workplace. These methods include wearing light clothing, drinking one pint of

water (preferably 50°F to 60°F) per hour, scheduling frequent rest periods in shaded or air-conditioned recovery areas, reducing the physical demands of the job, rescheduling strenuous activity to a cooler time in the day, blocking out direct sunlight and heat sources, and avoiding beverages containing alcohol or caffeine.

27.3.3 Comfort-Health Index (CHI)

The American Society of Heating, Refrigerating and Air-Conditioning Engineers (ASHRAE) recognizes a ***Comfort-Health Index***, which lists effective temperatures, the sensation associated with each temperature, and the effects that each temperature have on human physiology and health. This chart indicates that the human body attempts to adjust to very hot conditions by increasing sweating and the flow of blood. These physiological conditions may result in an increased danger of heat strokes and cardiovascular difficulty, **Figure 27-23**.

At comfortable temperatures, the chart also shows that there is no sensation of either warmth or cold. Also, there are no apparent physiological effects. Moving down in temperature to very cold conditions, the body is uncomfortable. Physiologically, the body attempts to correct this condition by shivering. In extremely cold conditions, the body attempts to maintain its core temperature by shutting down circulation to the extremities. Extreme cold can cause an increased risk of death, particularly in older people.

27.4 Air Movement

Air movement affects comfort. Cool, dry air circulated past a warm body will speed heat flow from the body. Evaporation will increase, which cools the

Comfort-Health Index

New T_{eff} Scale	Temperature Level	Comfort Range	Physiological Response	Health Effect
°C °F	Limited tolerance	Limited tolerance	Body heating Failure of regulation	Circulatory collapse
40				
100	Very hot	Very uncomfortable	Increasing stress caused by sweating and blood flow	Increasing danger of heat strokes
35	Hot			Cardiovascular embarrassment
90	Warm	Uncomfortable		
30	Slightly warm		Normal regulation by sweating and vascular change	
80				
25	Neutral	Comfortable	Regulation by vascular change	Normal health
70	Slightly cool			
20	Cool	Slightly uncomfortable	Increasing dry heat loss	
60			Urge for more clothing or exercise (behavioral reg.)	Increasing complaint from dry mucosa and skin (water vapor pressure <10 mm Hg)
15	Cold		Vasoconstriction in hands and feet	
50	Very cold	Uncomfortable	Shivering	Muscular pain Impairment of peripheral circulation

body. During cold days, a person exposed to outdoor atmospheric conditions often feels much colder than the thermometer shows. This chilling effect is due to wind velocity and relative humidity. The term *windchill* describes this uncomfortable feeling.

27.4.1 Wind

The Beaufort Scale is frequently used by the United States Weather Bureau for indicating wind velocity. It is divided into a series of levels, from zero for calm winds to twelve and above for hurricanes. Each value represents a classification of wind velocity along with descriptions of its effects. Wind velocity values and effects according to the Beaufort Scale are shown in **Figure 27-24**.

An increase in wind velocity increases the heat loss of a heated structure, thereby impacting the efficiency of a heating system. The calculated heat load for a structure should include the maximum wind velocity expected for the area.

During the winter months, the ***windchill index*** (chill factor) is used to describe the combined effect of temperature and wind speed. The windchill index chart is published and maintained by the United States Weather Bureau. The chill factor is based on both temperature and wind speed. For example, at a temperature of 0°F (–18°C) and a wind speed of 10 mph, the windchill index temperature is –16°F (–26°C), **Figure 27-25**.

People exposed to air temperatures below freezing are at risk for frostbite, which is essentially a freezing of the skin. The exposure time required for frostbite to occur gets shorter as wind speed increases or temperature decreases. In addition, the body's physiological response to the cold is to reduce blood flow to the exposed areas, causing those areas to cool even faster while reducing overall heat loss from the body's core.

Beaufort Scale of Wind Velocity

Beaufort Number	Wind Velocity		Observed Wind Effects	Terms Used in NWS Forecasts
	Mph	Knots		
0	Less than 1	Less than 1	Calm; smoke rises vertically	Light
1	1–3	1–3	Directions of wind shown by smoke drift; but not by wind vanes	
2	4–7	4–6	Wind felt on face; leaves rustle; ordinary vane moved by wind	
3	8–12	7–10	Leaves and small twigs in constant motion; wind extends light flag	Gentle
4	13–18	11–16	Raises dust and loose paper; small branches are moved	Moderate
5	19–24	17–21	Small trees in leaf begin to sway; crested wavelets form on inland waters	Fresh
6	25–31	22–27	Large branches in motion; umbrellas used with difficulty	Strong
7	32–38	28–33	Whole trees in motion; inconvenience felt walking against wind	
8	39–46	34–40	Breaks twigs off trees; generally impedes progress	Gale
9	47–54	41–47	Slight structural damage occurs; leaves and branches blown from trees	Severe Gale
10	55–63	48–55	Seldom experienced inland; trees uprooted; considerable structural damage occurs	Storm
11	64–72	56–63	Very rarely experienced; accompanied by widespread damage	
12 or Higher	73 or Higher	64 or Higher	Very rarely experienced; accompanied by widespread damage	Hurricane–Typhoon

27.4.2 Air Velocity Measurement

Outside air velocity, or wind, is measured in miles per hour (mph) or knots. Indoor air velocity is usually expressed in feet per minute (fpm). It is possible to calculate the volume of air flowing through a duct in cubic feet per minute (cfm). To do this, multiply the air velocity by the cross-sectional area of the duct.

Maintaining the proper rate of air movement in a conditioned space is very important. Air movement is necessary to supply fresh air to the space. If the air moves too fast (a draft), a person feels uncomfortable. If the air movement is too slow, the air becomes stale (contaminated) and lacks oxygen.

If air flows through an occupied space at more than 15′ to 20′ per minute (4.5 m/min to 6 m/min), occupants of the space will feel a draft. It is difficult to develop accurate instruments to measure drafts. The usual method is to use a smoke generator and a stopwatch. The flow of the smoke through the space is timed. If the smoke moves at a rate exceeding 15′ to 20′ per minute, a draft is indicated.

Several different instruments can be used to measure air velocity. The following devices are most commonly used:

- Vane anemometer
- Hot-wire anemometer
- Swinging-vane anemometer
- Manometer and pitot tube (measures velocity pressure)

Pro Tip

Measuring Air Velocity

Note that the vane anemometer, the swinging-vane anemometer, and the pitot tube are used to measure air velocity, but they are not accurate at very low air velocities.

Anemometers

Vane anemometers measure airflow velocity using a small propeller. When the propeller is placed in an airstream, it revolves as air flows past the blades. The revolution of the propeller is directly proportional to the velocity of the airstream. An electronic instrument connected to the propeller monitors the rotation of the propeller. It then calculates the distance traveled by the air based on the number of degrees the propeller rotates. Next, it divides this distance by the time elapsed and then converts the value to standard units and displays the velocity of the airflow. The electronic instrument performs these calculations many times per second and averages the results to provide an accurate reading, **Figure 27-26**.

Some anemometers include a function that allows the users to enter the cross-sectional area of the duct, which the meter then multiplies by the air velocity to determine the rate of airflow in cubic feet per minute.

To use a vane anemometer, carefully place the propeller in the airstream at a right angle to the airflow. Measurements can be taken in areas such as vents, returns, registers, and exhausts. Allow it to reach a constant speed (after about one minute), then trip the registering mechanism.

Another type of anemometer is placed over the duct grille. The technician inputs the cross-sectional area of the duct into the instrument. The LCD readout displays the airflow exiting through the grille in cubic feet per minute (cfm). With this data, the operator can calculate the number of Btus going into the space through each grille by multiplying the volume of airflow by the appropriate temperature factor, **Figure 27-27**.

A ***hot-wire anemometer*** has a small wire element often made of tungsten. Current is passed through the element to heat it. As the temperature of the element increases, so does its resistance. Airflow passing over the element cools the wire and reduces its resistance. By measuring the current draw through the element, the anemometer can calculate the velocity of airflow over the wire, **Figure 27-28**.

A ***swinging-vane anemometer*** operates on the principle that incoming air will push on a small vane, causing it to deflect at different angles as the air velocity

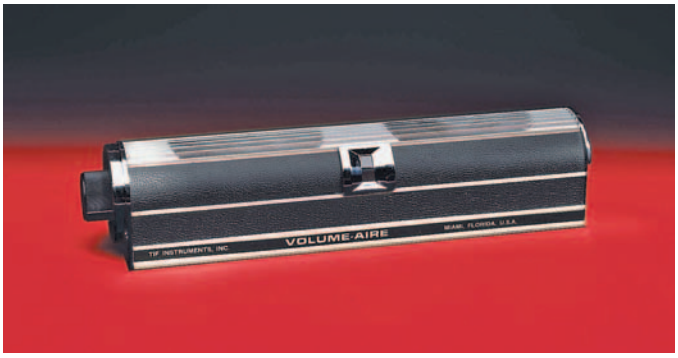
It is designed to measure airflow rate even under extreme temperature conditions.

changes, **Figure 27-29**. To measure airflow, the instrument or connections from it are put directly in the airstream. Long pitot tube probes are often used to extend the reach of the instrument in cases where it is difficult to place the instrument directly in the airstream. The tips of these tubes are placed in the airflow and divert a small column of the airflow into the meter, **Figure 27-30**.



TIF Instruments, Inc.

Figure 27-27. Anemometer that reads air velocity and automatically calculates airflow volume.

Swinging-vane anemometers are entirely mechanical. Because they have no mechanisms that are likely to spark, they are very safe in environments where electronic meters pose an explosion risk. However, as the temperature of the air being measured changes, the sensing mechanism in the instrument expands and contracts, which can throw off the instrument's readings. The instrument is calibrated for use at a temperature of 68°F (20°C). Corrections must be made if the duct temperature is not at 68°F (20°C).

Formula used to correct airflow velocity calculations for temperature deviations:

$$\text{airflow velocity in fpm} = \frac{460 + T}{460 + 68°\text{F}} \times \text{instrument reading}$$

where

T = Fahrenheit temperature of air in duct

9

Pitot Tube and Manometer

A ***pitot tube*** is an instrument used to measure total air pressure and static air pressure. A pitot tube is always positioned so the open end of the tube is pointed directly into the airflow, **Figure 27-31**.

Air passing through the nose of the pitot tube represents the total air pressure. The total air pressure equals

Dwyer Instruments, Inc.

Figure 27-31. Pitot tubes come in a variety of styles. This pitot tube has a handle and telescoping tubing.

Copyright Goodheart-Willcox Co., Inc. 2017

the static air pressure plus velocity pressure. Remember that static air pressure is based on the density of the air. Velocity pressure is the force exerted by the air's movement. The outer tube, with the holes on the side, measures just the static pressure. The difference between the total pressure and the static pressure is the velocity pressure. This pressure difference is measured in inches of water. The pressure can be measured by connecting the ends of the pitot tube to the ends of a manometer. This technique is typically used for measuring air pressures inside of ductwork, **Figure 27-32**.

If the air is in motion, the total pressure is always greater than the static pressure. This pushes the fluid in the manometer toward the static pressure side. At first glance, the concept of velocity pressure may seem to violate Bernoulli's principle. However, velocity pressure is measured by bringing the airflow to a stop inside the manometer. The still air inside the manometer is pressurized as additional air tries to enter the pitot tube, compressing the air that is already there. The faster the air is moving, the more air tries to squeeze into the tube, and the more it pressurizes the air that is already inside. In other words, the velocity pressure is exerted when the airflow is slowed or stopped, not when it is moving without resistance through the duct. See **Figure 27-33**.

Formula for using velocity pressure to calculate velocity:

Velocity (V) = Velocity conversion factor × Square root of velocity pressure in inches of water (P_v)

where

Velocity conversion factor = 4005 (for standard conditions)

$$V = 4005 \sqrt{P_v}$$

Example:

If the velocity pressure is 1″ of water, what is the velocity?

Solution:

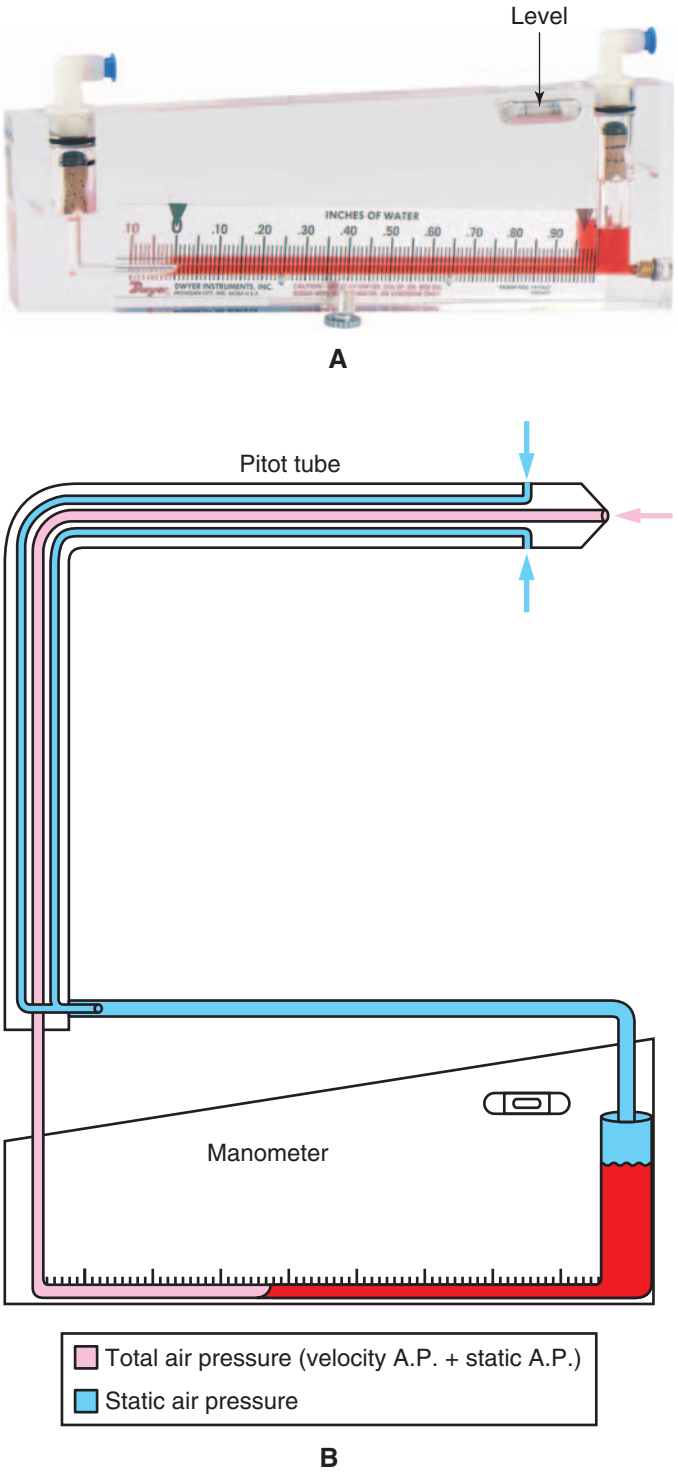
$$V = 4005 (\sqrt{1''})$$
$$= 4005 \times 1$$
$$= 4005 \text{ ft/min}$$

Example:

If the velocity pressure is 0.25″ of water, what is the velocity?

Solution:

$$V = 4005 \text{ ft/min } (\sqrt{0.25''})$$
$$= 4005 \text{ ft/min} \times 0.5$$
$$= 2002.5 \text{ ft/min}$$



Dwyer Instruments, Inc.

Goodheart-Willcox Publisher

Figure 27-33. Velocity pressure. A—With no airflow, the pressure on both sides of the pitot tube is equalized. B—When the air is moving, static pressure is reduced. Pressure on the right side of the tube is increased due to velocity pressure.

The conversion factor of 4005 shown in the equations is accurate for standard conditions. However, the velocity conversion factor changes based on the specific volume (density) of the air. You can find the specific volume for any set of conditions by using a psychrometric chart. You can then cross-reference the specific volume with the conversion factors listed in a chart such as the one shown in **Figure 27-34**.

To obtain correct velocity readings, take several readings in various parts of the duct and then average the readings. The American Society of Heating, Refrigerating and Air-Conditioning Engineers (ASHRAE) has determined a recommended pattern of testing location points for measuring pressure in both rectangular and circular ducts as shown in **Figure 27-35**.

Turbulent airflow can affect the ability of a pitot tube to accurately measure pressures. A pitot tube should be used only where the duct is very long. The length of the duct downstream of the measuring location should be a minimum of 10 times the duct diameter. If precise measurements are required, air straightening vanes should be located upstream from the pitot tube.

Velocity Conversion Factors	
Specific Volume (ft^3/lb)*	Velocity Conversion Factor
11.5	3720
12.1	3818

27.4.3 Ventilation

Ventilation is a term applied to changing the air in a building. In any space occupied by people, breathing reduces the oxygen content. Activities in the space may add some pollutants to the environment. The most economical way to maintain health and comfort conditions is by replacing the air. This is done by bringing in outside air to ventilate the space.

Sometimes it is desirable to quickly replace all the air in the confined space. This is done by opening windows and doors, flushing the space completely with 100% outside air.

Most heating systems provide continual replacement of air. A small percent of the air in the conditioned space is continually replaced. This is done by slowly exhausting some of the air and bringing in fresh air from outside. In homes, the gradual change may not be noticeable. There is always a small amount of air entering and leaving the home. This movement of air occurs through the cracks around windows and doors. It also takes place through doorways each time doors are opened.

Some building materials are porous (contain many tiny holes). Thus, a large amount of air may filter in and out of a building. The amount of infiltration depends on the wind velocity and temperature difference between the inside and the outside of the building. Air tends to enter the building on the upwind side and leave the building on the downwind side.

Since warm air is lighter than cold air, it tends to rise in a room. In buildings with more than one story,

Figure 27-35. Rectangular and circular duct cross-sections identifying the recommended locations for measuring pressure in a duct. An average of the readings will produce average duct velocity.

the warm air rises from the lower floors to the upper floors. The rising air slightly raises the pressure in the upper areas of the house and slightly lowers the pressure in the bottom parts of the house. The increased pressure causes some warm air to escape through the upper surfaces of the building. This lost air is replaced by cold air, which enters at the lower levels because of the reduced pressure there. See **Figure 27-36A**.

During the summer cooling season, the opposite situation occurs. Cold air tends to flow downward and may leave the building at the lower levels. The cold air is replaced by warmer air entering at the upper levels. See **Figure 27-36B**.

Whenever air is exhausted from a space, it must be replaced. The air brought in from outdoors should be cleaned and adjusted to have the same temperature as the indoor air. Replaced air is conditioned to provide a comfortable room environment. This conditioned air brought into the room is called make-up air.

Goodheart-Willcox Publisher

Figure 27-36. Indoor airflow is affected by the differences between density and temperature of indoor and outdoor air. A—Heating season. B—Cooling season.

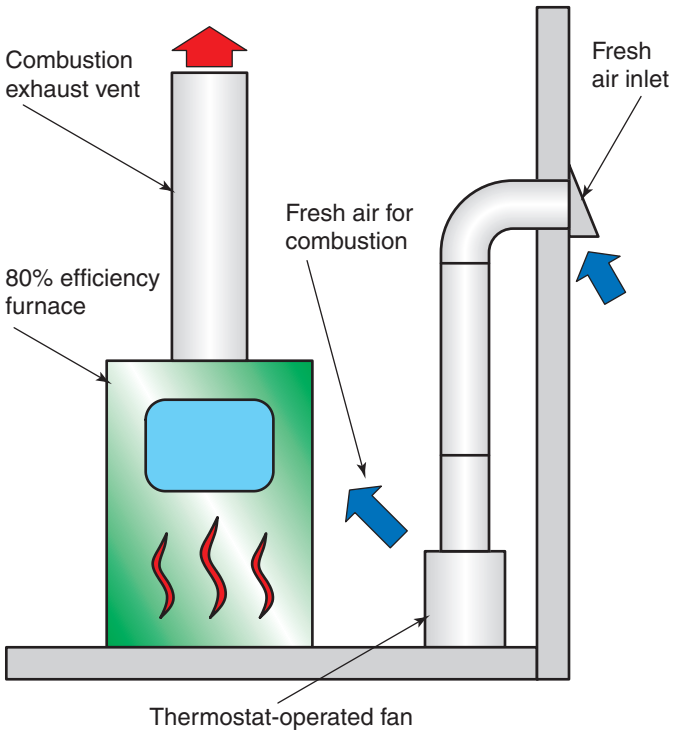
Thinking Green

Make-Up Air

In some buildings, one area of the building may require localized exhaust because of poor air quality while the other areas of the building remain relatively clean. For the dirtier areas, it may be more energy efficient to supply make-up air from clean, air-conditioned spaces of the building than to bring in outdoor air and condition it.

A structure that keeps inside air pressure slightly above atmospheric pressure has a positive pressure. A structure that maintains an air pressure slightly below atmospheric pressure has a negative pressure. Depending on stratification and airflow through a building, upper rooms in tall, heated structures may be slightly above atmospheric pressure. The lower rooms may be slightly below atmospheric pressure because warm air rises.

The process of combustion requires oxygen from the air, which can reduce its oxygen content. The operation of fuel-burning furnaces, stoves, water heaters, and fireplaces tend to cause a negative pressure, as it takes in fresh air for combustion and exhausts it out of the building. The negative pressure resulting from this could cause a considerable amount of air leakage into the house through the walls and cracks. To maintain positive pressure, use dedicated ductwork and a fan or blower of some kind to bring in fresh air, **Figure 27-37**.



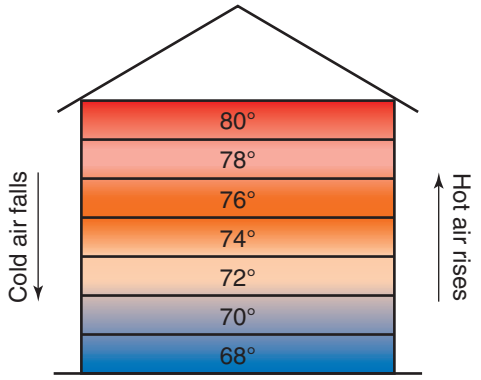
Goodheart-Willcox Publisher

Figure 27-37. This thermostat-operated fan turns on whenever the furnace turns on. It draws in air from outdoors to provide fresh air for combustion. This helps to keep the furnace operating at high efficiency and prevents the building from having negative pressure.

27.4.4 Stratification

If there is no air movement within a room, the air may tend to settle into layers of differing temperatures. Cold air will sink to the floor, and the warmer air will rise to the ceiling. This will result in a gradual difference in air temperature from the floor to the ceiling, which is known as ***stratification***, **Figure 27-38**.

Copyright Goodheart-Willcox Co., Inc. 2017



Goodheart-Willcox Publisher

Figure 27-38. Stratification occurs in rooms with little air movement. Warm air rises to the top of the room, while heavy colder air falls to the bottom of the room.

Stratification tends to make smoke haze hover in layers. The layers make it difficult to get rid of smoke. Because of stratification, if a thermostat is located in the upper part of a room with no air movement, the temperature difference between the thermostat setting and the air the occupants feel will be more noticeable. A certain amount of air movement is needed in the room to prevent stratification.

27.5 Factors Affecting Indoor Air Conditions

The temperature and humidity levels in a conditioned space can be affected by the materials inside and surrounding the conditioned space. Appliances and other electrical devices generate heat. Dark objects absorb sunlight during the day and release it at night when the temperature falls. Plumbing fixtures and potted plants can add humidity to the air.

Heat and humidity can be transferred into or out of the conditioned space through windows or poorly insulated walls. Different building materials and techniques result in different rates of heat transfer. In the summertime, heat from outdoors tends to migrate through the walls, windows, doors, ceilings, and floors into the house. In the winter, heat from inside the house tends to transfer to the outside. Proper insulating materials and weatherproofing techniques can minimize heat transfer.

27.5.1 Sun Heat Loads

Radiant heat (light) from the sun furnishes a tremendous amount of heat energy. If a glassed-in surface is exposed to this light energy, the energy will enter a space and become heat. Glass is a rather poor conductor of heat. However, it freely allows light to pass through it. In this way, energy that enters a building as a light ray becomes trapped in the room as heat.

The surfaces of buildings exposed to sunlight are also heated by the sun's rays. This heat source must be considered when calculating the heating and cooling requirements of air-conditioning systems. Many building materials are poor conductors of heat. Because of this, there is a lag or delay between the time the radiant heat energy strikes the building surface and the time the heat enters the conditioned space.

Color has a considerable effect on the amount of heat absorbed from the sun's rays. Black and red absorb much more heat than white and yellow. Likewise, surfaces designed to radiate heat are much more efficient if they are painted with dark rather than light colors. Light-reflecting surfaces, such as polished metal, chrome, and nickel plate, do not absorb heat easily and do not radiate heat efficiently from their surfaces.

27.5.2 Heat Sinks

A warm body radiates heat rays. When heat rays strike another surface, there are two common effects:

- Heat rays that strike another surface of the same temperature will reflect back. There is no increase or decrease in heat in the body being struck by the radiation. Imagine that a body giving off heat rays is totally surrounded by a surface at the same temperature as that body. Then all the surfaces, including the central body, receive back as much radiation as they give off. All the surfaces and the central object remain at the original temperature.
- If radiant heat strikes a surface colder than the radiating body, the heat rays do not all bounce back. Some of the radiant heat is absorbed into the colder surface. This surface becomes what is called a ***heat sink***.

On cold days, heat flows from a heated room to a cold window surface. A person sitting close to a window under such conditions will feel cold. This is due to the loss of some of their heat into the heat sink. The same will also be true if the walls of the room are not well insulated. If the walls are cold, they become a heat sink.

27.5.3 Vapor Barriers

Water vapor flows easily through all porous substances. Water in vapor form remains a vapor as long

Copyright Goodheart-Willcox Co., Inc. 2017

as its temperature is above the dew point. However, when its temperature drops to the dew point, the water vapor condenses into droplets.

In modern housing, water vapor is kept from passing through walls and toward surfaces where it might condense. This is done by using moisture-proof materials, such as aluminum foil and plastic sheeting, to form a vapor barrier. The barrier keeps water vapor from passing from warm surfaces to cold surfaces. Vapor barriers should always be installed on the warm side of a heated space.

Lack of proper vapor barriers is often indicated by peeling paint near kitchen and bathroom areas. The moisture from these areas travels through the walls. When it contacts the cold undersurface of the paint, droplets of water are formed, causing the paint to peel.

27.5.4 Heat Insulation

In extremely hot or cold climates, it is desirable to use materials that do not transfer heat readily. Reducing heat conductivity helps maintain desired air-conditioning temperatures more economically. Usually, spaces in the structure can be filled with insulating material to help prevent the flow of heat through the structure. Modern buildings are usually insulated with mineral wool, expanded mica, balsam wool, urethane, and sometimes cork in either sheet or granular form.

Chapter Review

Summary

- Weather describes atmospheric conditions. In reference to outdoor conditions, the term *climate* refers to the long term weather trends for a region. In reference to indoor conditions, it describes the typical conditions maintained in the space.
- Air-conditioning systems simultaneously control temperature, filter airflow, and adjust humidity to maintain desired conditions inside a space.
- The atmosphere, or air that surrounds the earth, is composed of several distinct layers. Air is composed mostly of nitrogen, oxygen, argon, and carbon dioxide, with other gases present in smaller quantities. Air exerts a pressure on everything it surrounds. At sea level, the pressure (atmospheric pressure) is 14.7 psia (101 kPa) at a temperature of 69.8°F (21°C).
- Humidity is the moisture vapor contained in air. The quantity of humidity in the air affects evaporation rates. Drier air results in more rapid evaporation, which in turn provides more cooling effect. Air at a given temperature can hold only a certain amount of moisture. The warmer the air is, the more moisture it can hold.
- Relative humidity is the expression of the quantity of moisture in air compared to the maximum amount of moisture the air can hold at the current temperature. Relative humidity is usually expressed as a percentage.
- Dew point is the temperature at which the current amount of moisture in the air would result in complete saturation of the air (100% relative humidity). At dew point, moisture in the air begins to condense.
- A hygrometer is an instrument that measures moisture in the air. Palm-held electronic hygrometers can use the power of mobile devices and PCs to display, record, document, annotate, and report measurements. These units typically can measure relative humidity, temperature, dew point, wet-bulb temperature, and more.
- Air temperature can be expressed as a dry-bulb temperature or a wet-bulb temperature. A dry-bulb temperature is a measurement of the air's temperature without adjusting for the effect of humidity. Wet-bulb temperature is a measurement of the air's temperature that is adjusted for the effect of the air's humidity on evaporative cooling.
- Psychrometry is the science studying the thermodynamic properties of air and water vapor. Psychrometers measure dry-bulb and wet-bulb temperature and are used to determine the relative humidity in the air. Psychrometric charts are a graph of the interrelationships between dry-bulb temperature, wet-bulb temperature, specific humidity, relative humidity, specific volume, dew point, and enthalpy in air mixtures. A technician that knows any two of these values can use a psychrometric chart to look up the others. Each stage in an air-conditioning process can be plotted on the chart so the technician can see the demands placed on the system.
- A wide range of temperature and humidity combinations provide a comfortable environment for humans. People perceive different combinations of humidity, airflow, and temperature as equivalents. This perceived temperature is called effective temperature. The Comfort-Health Index lists different effective temperatures and the physiological responses to those temperatures.
- Air movement affects comfort. Cool, dry air circulated past a warm body will speed heat loss from a body. Evaporation will increase, which cools the body. The chilling effect due to wind velocity and relative humidity is referred to as windchill.
- Indoor airflow must be great enough to provide effective ventilation and prevent temperature stratification, but must not be so strong that it makes the space feel drafty. Ventilation in the form of make-up air is necessary to maintain oxygen levels, minimize or eliminate negative pressure in a building, and provide combustion air for fuel-burning appliances, such as gas furnaces, stoves, water heaters, and ovens.
- Various types of anemometers are used to measure air velocity. A pitot tube is an instrument that measures total air pressure and static air pressure. The difference between the total pressure and the static pressure is the velocity pressure.
- Indoor air conditions can also be affected by sun loads, heat sinks, and heat and humidity migration. Vapor barriers prevent infiltration of moisture into a building, and heat insulation reduces heat transfer between indoors and outdoors.

Review Questions

Answer the following questions using the information in this chapter.

1. The conditions that are normally maintained in an indoor space are referred to as its _____.
   A. climate
   B. effective temperature
   C. psychrometry
   D. weather
2. According to ASHRAE, the process of treating air so as to control simultaneously temperature, humidity, cleanliness, and distribution is called _____.
   A. air conditioning
   B. dew pointing
   C. heat sinking
   D. ventilation
3. Earth's atmosphere contains about 23% _____ by weight.
   A. argon
   B. nitrogen
   C. oxygen
   D. sulfur dioxide
4. When air temperature reaches 100% relative humidity, it is at its _____ point.
   A. desiccant
   B. dew
   C. hygrometric
   D. wet-bulb
5. Air with 75% relative humidity contains _____ of the moisture it is capable of holding.
   A. one-fourth
   B. one-half
   C. two-thirds
   D. three-fourths
6. Starting at sea level and rising higher in altitude through the troposphere, atmospheric pressure _____.
   A. drops
   B. remains the same
   C. rises
   D. weighs more
7. A hygrometer is an instrument that measures _____.
   A. air pressure
   B. enthalpy
   C. moisture in the air
   D. wet-bulb temperature
8. Degree day calculations are based on a temperature of _____.
   A. 32°F (0°C)
   B. 50°F (10°C)
   C. 65°F (18°C)
   D. 98.6°F (36°C)
9. The science of studying the thermodynamic properties of air and water vapor is called _____.
   A. stratification
   B. hygrometry
   C. enthalpy
   D. psychrometry
10. The Beaufort scale _____.
    A. lists windchill factors
    B. indicates levels of wind velocity
    C. is a psychrometric chart
    D. lists average daily heating and cooling demands for a period of time
11. Which of the following instruments is used to measure air velocity?
    A. Psychrometer.
    B. Chilled mirror hygrometer.
    C. Anemometer.
    D. All of the above.
12. Which type of anemometer is entirely mechanical?
    A. Vane anemometer.
    B. Swinging-vane anemometer.
    C. Hot-wire anemometer.
    D. None of the above.
13. Changing the air in a building is called _____.
    A. stratification
    B. desiccation
    C. ventilation
    D. None of the above.
14. For a building to maintain positive pressure with various fuel-burning appliances operating, a(n) _____ should be used.
    A. fan or blower
    B. heat sink
    C. psychrometer
    D. swinging-vane anemometer
15. When radiant heat strikes a surface that is colder than the radiating body, _____.
    A. some of the radiant heat is absorbed into the colder surface
    B. the heat rays will reflect back
    C. the radiating body becomes a heat sink
    D. Both A and C.

CHAPTER 28 Air Quality

Learning Objectives

Information in this chapter will enable you to:

- Identify the agencies and standards that regulate indoor air quality.
- Categorize indoor air pollutants as solid or gas pollutants and provide examples of each.
- Recall the factors that affect indoor air quality.
- Recognize the main sources of pollutants that adversely affect residential and commercial indoor air quality.
- Summarize the processes used to assess residential and commercial indoor air quality.
- Summarize the steps that can be taken to prevent indoor air quality problems.
- Differentiate between sick building syndrome, building-related illness, and multiple-chemical sensitivity.
- Compare the different types of air filters available.
- Summarize the different air cleaning methods used to improve indoor air quality.
- Explain the operation and maintenance of ultraviolet air treatment system.
- Differentiate between heat recovery ventilators (HRVs) and energy recovery ventilators (ERVs).

Chapter Outline

28.1 Indoor Air Quality Standards and Guidelines
28.2 Air Pollutants
28.2.1 Solid Pollutants
28.2.2 Gaseous Pollutants
28.3 Indoor Air Quality
28.3.1 Residential Indoor Air Quality
28.3.2 Indoor Air Quality in a Commercial Setting
28.3.3 Preventing IAQ Problems
28.3.4 Classifications of Indoor Air Quality Issues
28.4 Air Cleaning
28.4.1 Air Filters
28.4.2 Electronic Air Cleaners
28.4.3 Ionizing Air Purifiers
28.4.4 Ultraviolet Light
28.5 Indoor Air Quality Systems

Review of Key Concepts

Reviewing these concepts from earlier chapters will help you understand new concepts presented in this chapter:

- When an atom has an imbalance of electrons and protons, it is ionized. If an atom has more electrons than protons, it is a negatively charged ion. If an atom has more protons than electrons, it is a positively charged ion. (Chapter 12)
- There are two kinds of static charges—positive and negative. An object with a negative charge has accumulated more electrons than protons, and an object with a positive charge has more protons than electrons. (Chapter 12)
- Objects with the same kind of charge repel each other. Objects with different charges attract each other. (Chapter 12)
- In any space occupied by people, activities in the space may add some pollutants to the environment. The most economical way to maintain health and comfort conditions is by replacing the air. This is done by bringing in outside air to ventilate the space. (Chapter 27)

Introduction

A good air-conditioning system delivers clean air to the space being conditioned. Air quality control includes more than just the removal of contaminants. ***Indoor air quality (IAQ)*** includes the status of indoor air as measured by temperature, humidity, fresh airflow, pollutants, and chemicals in an enclosed space.

9

Copyright Goodheart-Willcox Co., Inc. 2017

28.1 Indoor Air Quality Standards and Guidelines

ASHRAE Standard 62 is a widely recognized standard relating to indoor air quality. ASHRAE Standard 62 offers equipment and system requirements, as well as minimum ventilation rates, which should result in indoor air quality that would be acceptable to human occupants. Standard 62 establishes the IAQ-related standard for the design, construction, startup, operation, and maintenance of ventilation systems used in commercial structures.

Standard 62.1 ties ventilation rates to the number of occupants in a given space. For example, the rate for office space where smoking is not allowed is 20 cubic feet per minute (cfm) per person.

Code Alert

IAQ Standards

The National Institute for Occupational Safety and Health (NIOSH) has developed specific criteria and exposure limits for pollutants. The Occupational Safety and Health Administration (OSHA) also sets permissible exposure limits (PELs) for hazardous substances.

28.2 Air Pollutants

A ***pollutant*** is a substance that is in some way a detriment to comfort, health, and a desirable environment. The Federal Clean Air Act of 1970 gave the Environmental Protection Agency the power to establish and enforce standards for clean air.

Three common indoor air pollutants are asbestos, bioaerosols, and radon. Asbestos was often used in the past as a form of insulation. Bioaerosols are airborne microorganisms that breed in humid conditions. Radon is a naturally occurring gas that has been found to cause cancer. Asbestos, bioaerosols, and radon will be discussed further below.

28.2.1 Solid Pollutants

Solid air pollutants are particles of various sizes that are suspended by air currents. They are classified into the following general groups: dust, fumes, smoke, bioaerosols, and asbestos, **Figure 28-1**.

Dust

The term ***dust*** refers to the small particles that become temporarily airborne from wind, a sudden earth disturbance, or mechanical work on a solid. The origin of dust can be animal, vegetable, or mineral. Dust particles are usually 1–200 microns in size.

Fumes

Fumes are small, solid particulates suspended in the air. They form by the condensation and solidification of gaseous materials. These materials ordinarily are solids but have been put into a gaseous state, usually by an industrial or chemical process. These particles are about 1 micron in size.

Smoke

Smoke is composed of solid particles carried into the atmosphere by gaseous products of incomplete combustion. Particles vary in size from 0.1 to 13 microns.

Bioaerosols

Bioaerosols are airborne microorganisms, such as viruses, bacteria, fungi, protozoa, mold, rust, dust mites, mildew, and yeasts. They are found both indoors and outdoors. Excessive moisture indoors increases the growth of some microorganisms.

Certain types of humidifiers, water spray systems, and wet porous surfaces act as breeding grounds for the microorganisms found in bioaerosols. For instance, humidifiers kept at a lukewarm temperature may provide an excellent breeding place for bacteria. Also, surfaces of dehumidifiers may become breeding places for bacteria and fungi. These surfaces should be

Comparative Micron Sizes	Examples of Typical Contaminants
10+ microns	Heavy atmospheric dust Ash Particles visible to the naked eye
5–10 microns	Average atmospheric dust Pollen Mold
1–5 microns	Light atmospheric dust Bacteria Pollen
0.3–1 microns	Oil fumes and smoke Bacteria Suspended dust particles

Goodheart-Willcox Publisher

Figure 28-1. Relative sizes of common air contaminants.

Copyright Goodheart-Willcox Co., Inc. 2017

sterilized from time to time to maintain a safe operating condition.

Bacteria

Bacteria are simple, single-cell microorganisms that are responsible for the transfer of many diseases. Many manufacturing processes, health care environments, and food service environments require the removal of bacteria. Several techniques can be used to control bacteria.

The FDA recommends the use of one teaspoon of chlorine bleach to one quart of water to disinfect home surfaces, such as counters, that may be contaminated by bacteria. Use bleach with caution, since it may discolor some surfaces. Studies have shown that a high water heater temperature of at least 140°F (60°C) is effective in controlling Legionella bacteria in single-family residences.

Mold

Mold is a growth of minute fungi that forms on vegetable and animal matter. Many typical air conditioning applications provide a favorable environment for their growth and development. This is particularly true if moisture is present. The spores from certain molds can cause illness.

Pollen

The term ***pollen*** refers to the small particles released by plants as part of their reproductive cycle. During certain seasons, plants (most notably ragweed, timothy grass, goldenrod, and roses) release pollen grains into the atmosphere, creating irritating symptoms and ailments for many people. These ailments include hay fever, rose fever, and other respiratory difficulties. For this reason, removal of pollen from the air is an important function of air conditioning. Pollen grains vary in size from 10 to 100 microns.

A ***pollen count*** is a measurement of the amount of pollen in a given space. The amount of pollen can be measured by exposing an adhesive-coated surface to the atmosphere for 24 hours. The number of pollen grains in a square centimeter determines the pollen count for the previous 24 hours.

Asbestos

Asbestos is a naturally occurring mineral that forms fiber bundles. It is known for its strength and fire resistance. It was once used in the construction of commercial buildings, such as in furnace insulation materials, tiles, and in various coatings. Exposure to asbestos normally occurs in four settings: during acquisition (mining), manufacturing (insulation, brake linings), installation, and removal. Sampling for asbestos is accomplished through environmental monitoring, including visual assessment and, if needed, bulk sampling.

Safety Note

Asbestos

Asbestos is a carcinogen (cancer-causing agent). Breathing asbestos fibers can also cause serious lung diseases, such as asbestosis, which may result in loss of lung function, disability, and even death. Removal of asbestos should only be done by professional asbestos abatement companies.

28.2.2 Gaseous Pollutants

Common gaseous pollutants include carbon monoxide (CO), carbon dioxide (CO_2), sulfur dioxide (SO_2), photochemical oxidants, and nitrogen oxides (NO_X). Photochemical oxidants result from the effect of sunlight on hydrocarbons and nitrogen oxides. They react and produce smog. Terpene, a hydrocarbon released from growing trees, is sometimes considered a pollutant, as is methane, which is produced by the decomposition of vegetable matter.

In addition to the pollutants already mentioned, chlorine, paints, insecticides, and volatile solvents release polluting vapors. Many vapor-caused illnesses are difficult to identify. However, illnesses often disappear after patients are removed from the polluted environments.

Sulfur-Based Gaseous Pollutants

Sulfur dioxide (SO_2) is a common gaseous pollutant. It is produced by burning coal, gas, or oil. Hydrogen sulfide results from some industrial processes, particularly papermaking. Depending on the makeup of these gases, they may contain carcinogens, which are harmful to human health.

Carbon Monoxide (CO)

Carbon monoxide (CO) is a deadly poison. It is an odorless, colorless gas that leaves a metallic taste in the mouth. Carbon monoxide replaces the oxygen in red blood cells. Health effects from exposure to carbon monoxide are shown in **Figure 28-2**.

Carbon monoxide is produced by the incomplete combustion of fuel. A common source is automobile engine exhaust. Fuel-burning furnaces also produce carbon monoxide. It is present in the combustion chamber, heat exchanger, flue, and stack. Carbon monoxide may be found inside homes or offices due to poorly vented combustion appliances, faulty chimneys, or cracked heat exchangers.

Copyright Goodheart-Willcox Co., Inc. 2017

Effects of Carbon Monoxide Exposure	
Parts Per Million (ppm)	**Health Effects**
200–400	Slight headache
1000–2000	Heart palpitations (within .5 hours of exposure)
1000–2000	Staggering (within 1.5 hours of exposure)
1000–2000	Mental confusion, headache, nausea, and vomiting (after 2 hours of exposure)
2000–2500	Unconsciousness (within .5 hours)
2500	Collapse; death will occur prior to any warning symptoms

Goodheart-Willcox Publisher

Figure 28-2. Breathing carbon monoxide can result in unconsciousness and death.

Carbon Dioxide (CO_2)

Carbon dioxide (CO_2) is a gaseous, nontoxic combination of carbon and oxygen that results from combustion and respiration. The concentration of CO_2 in exhaled breath is fairly constant, approximately 3.8%. Once the CO_2 leaves the mouth, it mixes with the surrounding air.

When people exhale CO_2, they also exhale other gases, odors, bacteria, and viruses. When these build up in a space due to poor ventilation, poor air quality results. When this occurs, occupants often complain of fatigue, headaches, and general discomfort. Carbon dioxide (CO_2) does not create these symptoms. However, high CO_2 concentrations indicate that these other pollutants may also be present.

Nitrogen Oxide (NO_X)

Nitrogen and oxygen atoms combine to form ***nitrogen oxide (NO_X)*** compounds. Nitrogen oxide is formed at high temperatures, such as those developed during combustion in an automobile engine. Nitrogen oxide is one of the substances common in the photochemical oxidants that produce smog. It is unstable and changes back to nitrogen and oxygen easily at lower temperatures.

Ozone (O_3)

Ozone (O_3) is a form of oxygen photochemically produced in nature. The chemical formulas for oxygen (O_2) and ozone (O_3) are similar, differing by only one additional atom of oxygen per molecule. In the upper atmosphere, ozone is made by ultraviolet light reacting with oxygen. It may also be produced by an electric discharge in the air, such as lightning.

Ozone is a substance that can be either beneficial or detrimental to health. Ozone is a disinfectant and is sometimes used to purify water or to maintain a sterile atmosphere. It also removes odors in such places as cold storage rooms and hospitals. In these applications, a very small amount of ozone is used. However, in larger concentrations, it may be harmful to health. Symptoms that ozone can induce include chest pain, coughing, throat irritation, and congestion. It can also worsen current respiratory conditions.

An ozone concentration of 0.1 parts per million (ppm) is generally considered the maximum level permissible for an eight-hour exposure. For continuous occupancy, ozone should not exceed 0.01 ppm. The effect doubles for each 15°F (8°C) increase in temperature. The use of some electronic air cleaners may slightly increase ozone content. Ozone concentration is measured with ozone monitors. See **Figure 28-3**.

Radon (Rn)

Radon (Rn) is an odorless, tasteless, radioactive, inert gas that occurs naturally in soil and rocks. It is formed from the natural decay of uranium and is found in some industrial wastes.

Radon has been shown to cause lung cancer. When inhaled, it settles in a person's lungs. The radioactive particles then begin to damage the lung tissue. Radon gas comes from the soil and rock upon which a building is built. It may enter a building through small cracks in concrete floors, floor drains, sump pumps, and pores in hollow-block walls. See **Figure 28-4**.

Radon can be detected using a charcoal canister or a small container called an alpha track detector,

Ozone Solutions, Inc.

Figure 28-3. Wall-mounted ozone sensors are very sensitive and allow for two adjustable set points. Ambient ozone levels from outside are detected.

Goodheart-Willcox Publisher

Figure 28-4. Potential sources of radon.

Figure 28-5. The detectors are usually placed in the living areas of the house, where they absorb contaminants in the air over a period of time. At the end of the testing period, the detectors are sent to a laboratory for analysis. If the results show the presence of radon, the entry points of the gas must be located and repaired.

Steps to Reduce Radon Exposure

Steps can be taken to reduce radon exposure in residential homes. To stop gases from entering the home, a gas permeable layer, which often consists of a four-inch layer of clean gravel, can be placed beneath the floor or slab of the house. Plastic sheeting can be placed on top of the gas permeable layer and under the floor or slab. A PVC pipe can be run from the permeable layer, through the house, and vented out the rooftop. In this manner the gases are allowed to vent out without entering the home. An electrical junction box is often needed for the installation of an electric venting fan (an in-line fan). The fan draws the radon from beneath the home and through a pipe where it is then exhausted outdoors.

Large cracks can be filled with cement grout. Caulking compounds suitable for concrete can be used for small cracks. Painting basement walls and floors with two coats of an epoxy paint is recommended.

Organic Vapors

Organic vapors are a major source of air pollution. Portable odor monitors use a highly sensitive metal-oxide thermal conductivity sensor. Vapors that can be measured by such instruments include acetic acid, formaldehyde, ammonia, anesthetic gases, hydrogen peroxide, mercury vapor, nitrogen dioxide, nitrous oxide, and ozone. Numerous readings are initially made to set the quality standards or acceptable odor levels. Once this is established, the monitor will then identify the odor level at any time.

Volatile organic compounds (VOCs) include a variety of chemicals, some of which have short-term and long-term negative health effects. Organic chemicals are used in many household products. VOCs are emitted by a wide variety of products, including cleaning and disinfecting supplies, pesticides, furnishings, and office equipment. These products can

release organic compounds while in use, as well as to some degree when stored.

28.3 Indoor Air Quality

Indoor air quality (IAQ) has become an increasing concern as a result of the unforeseen consequences of improved building standards. Building design, construction, and synthetic building materials have made buildings tighter. The resulting reduced infiltration of outdoor air and the vapors released from the new building materials have diminished the quality of indoor air. As building standards and construction methods evolved, building occupants began reporting building-related symptoms at a growing rate. Building-related symptoms include headache; fatigue; eye, nose, and throat irritation; confusion; dizziness; and skin rashes.

28.3.1 Residential Indoor Air Quality

According to studies by the American Lung Association, US residents spend about 65% of their time at home and stay indoors 90% of that time. As a result, there is a growing awareness of the importance of indoor air quality to good health. According to the U.S. Department of Health and Human Services and the Surgeon General's Office, approximately one-quarter of preventable illness worldwide is a result of poor environmental quality. The following are primary causes of poor IAQ in homes:

- Decreased fresh air infiltration due to tight construction and weatherproofing measures. Homes must be equipped with adequate and appropriate ventilation systems. If drafts are eliminated, another means of bringing fresh air into the house must be provided.
- Fumes and volatile organic compounds (VOCs) released from adhesives, paints, and synthetic building materials. Building and finishing materials must be used properly. Materials intended for outdoor use should not be used indoors unless such use is approved by the manufacturer.
- Moisture infiltration and seepage. Homes must be properly sealed to prevent moisture infiltration. Any moisture- or flood-related problems should be corrected as quickly as possible. Ventilation should be provided for bathrooms, kitchens, and other areas where steam or excessive humidity is generated.
- Occupant habits. Environmental tobacco smoke is a major cause of indoor pollution with a great potential for adverse health effects. A home should be cleaned regularly to prevent the buildup of excessive dust and unpleasant or unhealthy air contaminants.
- Lack of maintenance to the home and its HVAC system. Filters in the ventilations system should be changed regularly. HVAC ducts should be cleaned periodically. Any moisture-related issues should be corrected as soon as possible to prevent mold problems. The furnace and gas appliances must be properly vented and in good working order.

Indoor air pollutants can come from many sources, including household chemicals, pets, and dirt brought in from outside the home. Allergens and molds may form inside the house due to high humidity levels. Modern homes are built to be energy-efficient. In order to make the home energy-efficient, much of the natural ventilation in the home is eliminated. Such homes rely on the HVAC systems to bring in an adequate amount of fresh air.

Thinking Green

Controlling Indoor Air Quality

The most energy-efficient method of relieving IAQ problems is to identify the source of pollutants and reduce them at their source. Although increasing ventilation can often improve indoor air quality, doing so typically also increases energy usage. Limiting the number of pollutants in the air improves indoor air quality without increasing energy consumption.

Indications of IAQ Problems

Sensitivity among people to indoor air pollutants varies, often making it difficult to determine if a residential dwelling truly has an IAQ problem. When a resident complains about odors, health problems, or lack of comfort, an IAQ problem may be indicated. If an IAQ problem is suspected, the technician should attempt to uncover the cause and extent of the problem. Health complaints related to poor IAQ tend to diminish when the person leaves the residence.

Potential sources of indoor air pollutants include smoke (cigarette, cigar, or pipe), unvented gas appliances (stove, dryer, or hot water heater), pesticides used indoors, hobbies (such as model making or jewelry making), exhaust from motor vehicles left running in an attached garage, stored chemicals, pets with fur, below-ground living areas, and insulation made of urea-formaldehyde or asbestos. Questionnaires, such as the one in **Figure 28-6**, help the technician identify potential indoor air pollutants.

High-Risk Individuals

Some individuals have an increased susceptibility to indoor air pollutants. People with increased risk factors include the following:

- Children younger than four years of age.
- People older than sixty years of age.

Copyright Goodheart-Willcox Co., Inc. 2017

Potential Sources of Indoor Air Pollutants—Residential

Discuss each of these items with the homeowner and circle Yes or No. Yes answers identify potential sources of indoor air pollutants.

Do any residents smoke?	Yes	No
Are there any unvented gas appliances, such as a stove, dryer or hot water heater?	Yes	No
Are pesticides used indoors?	Yes	No
Do any residents have hobbies such as woodworking, jewelry making, pottery, or model making?	Yes	No
Is there an attached garage where motor vehicles are left running or chemicals are stored?	Yes	No
Are there any furry pets living inside?	Yes	No
Is any part of the living area below ground?	Yes	No
Is the residence insulated with urea-formaldehyde or asbestos?	Yes	No
Are the burner or pilot flames on gas appliances yellow instead of blue?	Yes	No
Are scented candles used indoors?	Yes	No
Was the building constructed or remodeled recently?	Yes	No
Was pressed wood furniture or paneling installed recently?	Yes	No
Are air fresheners or deodorizers used indoors?	Yes	No
Are there musty odors present?	Yes	No
Are clothes dry cleaned frequently and stored in closets?	Yes	No
Are toilet bowl deodorizers or mothballs containing paradichlorobenzene used indoors?	Yes	No

Chart based on data from AERIAS Air Quality Science IAQ Resource Center

Figure 28-6. Checklist of potential sources of indoor air pollutants.

- People confined to the home for more than twelve hours per day.
- People undergoing chemotherapy.
- People with a compromised immune system.
- People with asthma, allergies, bronchitis, emphysema, or a heart condition.

Maintaining a good indoor air quality is especially important if an individual who has one of these risk factors is living in the residence. A high-risk individual is more likely to develop building-related illnesses. Poor indoor air quality could also threaten an individual's health by aggravating a preexisting condition.

Home and Residential Inspection

If a resident complains of an indoor air quality issue, the building should be thoroughly inspected. Areas of the home that generate IAQ complaints and typical causes of those complaints are shown in **Figure 28-7**.

Prior to completing a home inspection, the technician should listen to the occupant's IAQ complaints. Next, the technician should walk through the home and visually inspect areas of the home that are likely to cause the IAQ issues. During the inspection, the technician should complete a checklist similar to the one shown in **Figure 28-8**. The technician will need the occupants' input in order to complete such a checklist.

Indoor air quality problems are often linked to health and comfort issues. Complaints regarding temperature and humidity may offer clues to indoor environmental problems. Such complaints may include one or more of the following:

- Drafty or stale areas of the residence.
- Humidity levels above 60% or below 40%.
- Interior areas that seem stuffy or musty.
- Areas that are too hot or too cold.
- Noticeable lack of air movement.
- An odor of mold or mildew.

Residential Assessment

Complaints regarding IAQ generally fall into four major categories:

- Ventilation-related complaints. Symptoms appear to be related to inadequate ventilation, and no strong emission sources are noted.
- Source-related complaints. Timing of symptoms coincides with the presence of a source of pollution or contamination.
- Chemical or biological hypersensitivity. The individual reacts to the presence of small quantities of chemicals or bioaerosols, which does not appear to affect others.
- Perceived IAQ problems. Symptoms are unrelated to IAQ, but may be due to other factors such as dust-, water-, or food-borne illnesses, skin contact with

Figure 28-7. IAQ problems common in the various areas of a home.

Home and Residential Building Inspection

The items below refer to residences. Facility managers of multifamily residential buildings should view inspection checklists for commercial and educational buildings for applicable entries. Yes answers identify potential sources of IAQ problems.

Is dust visible on the furniture?	Yes	No
Is dust or dirt staining the walls, ceilings, furniture, or draperies?	Yes	No
Are cleaning and vacuuming put off or not done regularly?	Yes	No
Does the vacuum system use filters that are not high-efficiency particulate air (HEPA) filters?	Yes	No
Is food kept out overnight?	Yes	No
Is there evidence of pests such as cockroaches, rats, or mice?	Yes	No
Can people smell chemicals or other odors when they enter the residence?	Yes	No
Do cooking odors linger for several hours?	Yes	No
Are there leaks around or under sinks?	Yes	No
Is there condensate on windows, window sills, or window frames?	Yes	No
Do the cold water pipes have condensation on them?	Yes	No
Do the walls have condensate on them?	Yes	No
Does water get backed up in the drains?	Yes	No
Do toilet leaks occur?	Yes	No
Are there brown stains or discoloration of ceilings, walls, or furnishings?	Yes	No
Is mold growing anywhere in the residence?	Yes	No
Is soot present around the furniture, boiler, or hot water heater?	Yes	No
If residence is heated with gas or oil furnace, can the odor of gas or oil fumes be detected?	Yes	No
If residence is heated with wood, can the smell of wood smoke be detected?	Yes	No
Are any paint or furnishing odors noticeable when entering the residence after being away?	Yes	No

Chart based on data from AERIAS Air Quality Science IAQ Resource Center

toxic materials, infectious disease, or psychological or sociological influences such as stress.

The initial interview of the occupant will identify IAQ complaints. The technician should discuss the concerns with the occupant and perform an inspection in an effort to identify obvious causes. In many cases, the cause of the IAQ complaint can be quickly identified and corrected. If the cause of the IAQ complaint cannot be identified during the inspection, further tests are required.

In some cases, an in-depth investigation by an IAQ expert will be necessary. The consultant may follow a process to diagnose the IAQ issue and recommend potential solutions. This process may include identification of complaint patterns, assessment of the HVAC system, determining and prioritizing of sources of pollution, testing of air pollutants, and making conclusions and recommendations.

28.3.2 Indoor Air Quality in a Commercial Setting

Poor indoor air quality can also be a problem in the workplace. Building-related symptoms have been proven to negatively affect productivity. Studies have shown that productivity can be increased by improving the working environment. Lack of adequate environmental control (such as temperature and humidity) and elevated pollutant levels contribute to poor IAQ.

Confirmation of an indoor air quality problem can be difficult because the sensitivity to indoor pollutants varies from person to person. If the occupants of a building complain about building-related symptoms, a trained technician should perform a systematic investigation to determine if an IAQ problem exists. A form like the one shown in **Figure 28-9** can help to iden-

Potential Sources of Indoor Air Pollutants—Commercial

The items below refer to offices. Yes answers identify potential sources of IAQ problems.

Is the office dirty or dusty?	Yes	No
Is the office not cleaned or vacuumed (with HEPA system) thoroughly and regularly?	Yes	No
Can debris be seen falling from the air supply?	Yes	No
Does the air supply outlet have condensates or black soil on it?	Yes	No
Are there any new furnishings or electronic equipment in the office?	Yes	No
Are scented cleaners used to clean the office?	Yes	No
Does trash sit in the office for more than eight hours?	Yes	No
Does the office have pests such as cockroaches, rats, or mice?	Yes	No
Are pesticides used in the office?	Yes	No
Are chemicals used in the office?	Yes	No
Can people smell chemicals or other odors when they enter the office?	Yes	No
Has a fluid spill been allowed to stand?	Yes	No
Are permanent markers or other graphic materials used in the office?	Yes	No
Are photocopiers, laser printers, or photo processing equipment used in the office?	Yes	No
Are perfume, aftershave, or other strong odors present?	Yes	No
Does water back up in the drains?	Yes	No
Do toilet leaks occur?	Yes	No
Are there leaks around or under office sinks and/or water fountains?	Yes	No
Is there condensate on windows, window sills, or window frames?	Yes	No
Are there musty odors?	Yes	No
Has there recently been a remodeling project that produced dust or chemical odors?	Yes	No
Do the cold water pipes have condensation on them?	Yes	No
Has condensate been present on the indoor side of exterior walls?	Yes	No
Are there brown stains or discoloration of ceiling tiles or walls?	Yes	No

Chart based on data from AERIAS Air Quality Science IAQ Resource Center

Figure 28-9. A form can help a technician identify possible causes of IAQ complaints in a commercial building.

Copyright Goodheart-Willcox Co., Inc. 2017

tify potential sources of IAQ problems in a commercial setting. The technician is able to answer many of the questions by performing a visual inspection. The remaining questions can be answered by interviewing the building's occupants.

The technician should examine both the indoor ventilation system and the total ventilation system. When evaluating the systems, the technician should answer the following questions:

- Are the outside air intakes located near a source of pollution?
- Are any of the vents (supply or return) blocked?
- Do the air ducts have fiberglass liners?
- Is vehicle exhaust seeping inside?
- Are odors from restrooms noticeable outside the restrooms?
- Is there an odor of mold or mildew?
- Is there an odor of chemicals?
- Are fume hoods being used correctly in areas where chemicals are being used?

Health problems associated with indoor air pollution include the following: headaches, itchy eyes, confusion or dizziness, breathing problems, sore throat, nasal congestion, drowsiness, skin rash, fatigue, and increased allergy or asthma attacks. If several people, especially those who work in a particular area, have similar complaints, there may be an indoor air problem.

Complaints about temperature and humidity are often clues to indoor air problems. Such issues may include any of the following: drafty or stale air in the office, humidity levels above 60% or below 40%, temperature too hot or too cold, or complaints of noise or crowding.

Commercial IAQ Assessment

Assessment of IAQ problems in commercial buildings is similar to the assessment of IAQ problems in residential settings. Investigations are often prompted by complaints regarding odors, health concerns, or comfort concerns. Complaints may be ventilation-related, source-related, the result of chemical or biological hypersensitivity, or perceived IAQ problems that are actually caused by other factors.

A more in-depth, thorough investigation may need to be conducted by an IAQ expert. This expert will attempt to identify complaint patterns, assess HVAC systems, determine pollutant sources, test air pollutants, and develop conclusions and recommendations.

Educating Occupants and Staff

Residents and building maintenance staff should be educated regarding the causes and remedies of IAQ issues. The importance of regular maintenance and inspection should be stressed. If the building's staff takes a proactive role, potential indoor environmental issues can be alleviated or reduced. Recommendations to staff may include the following:

- Use fewer toxic supplies and materials.
- Use only the exact amount of chemicals needed.
- Do not use chemicals in air ducts.
- Do not use ozone-generating air cleaners.
- Conduct activities, such as roofing, painting, and remodeling, after hours.
- Clean the living/working spaces regularly.
- Use vacuum cleaners with HEPA filters.
- Clean carpets one to two times each year to remove allergens, mold, and dust.
- Control sources of moisture by eliminating or preventing them.
- Use air filters with a MERV rating of 12. ***MERV*** is the Minimum Efficiency Reporting Value, a measurement scale developed by ASHRAE to rate the effectiveness of air filters.
- Develop maintenance and inspection plans for HVAC system.

28.3.3 Preventing IAQ Problems

To effectively deal with IAQ issues, HVAC technicians must become familiar with the various causes and effects, **Figure 28-10**. Prevention of IAQ problems in residential and commercial buildings requires a four-step approach:

1. Controlling indoor pollutants and sources.
2. Providing adequate ventilation and filtration.
3. Maintaining acceptable indoor environmental conditions.
4. Educating occupants, such as residents and maintenance staff.

Control of Indoor Pollutants

Indoor pollutants can be controlled using a variety of measures. The following are some actions that can be taken to control pollutants at their source. When discussing IAQ complaints with customers, explain that these simple actions can improve the quality of the air inside their home or business:

- Select and use nonaerosol and nontoxic products whenever possible.
- Coat pressed-wood products with polyurethane to reduce formaldehyde emissions.
- Maintain a moderate temperature and humidity.

Copyright Goodheart-Willcox Co., Inc. 2017

IAQ Problems and Solutions			
Source of IAQ Problem	**Symptoms**	**Ideal Levels**	**Possible Solutions**
Volatile Organic Compounds (VOCs)	• Respiratory difficulties • Allergies	Minimal VOCs	• Install a heat recovery ventilator (HRV) • Install an energy recovery ventilator (ERV) • Install an air purification system
Bioaerosols and other airborne particulates	• Respiratory difficulties • Allergies	Minimal particle count	• Use high efficiency (MERV-13 or higher) filter • Install a germicidal light on evaporator coil
Humidity	• Discomfort • Increased fungal growth	25%–55%	• Humidifiers • Dehumidifiers
Temperature	• Discomfort	68°F–81°F	• Install a better thermostat • Instruct customer on proper system operation
CO_2 (poor ventilation)	• Stale air • Sick building syndrome	700 PPM CO_2	• Install a heat recovery ventilator • Install an energy recovery ventilator • Replace filters regularly
CO	• Illness • Death	Zero PPM	• Repair furnace or gas appliance • Do not operate vehicles or gas-powered equipment in an attached garage • Install a CO detector

Goodheart-Willcox Publisher

Figure 28-10. Symptoms associated with poor IAQ, the likely causes, and their solutions.

- Install and use exhaust fans in bathrooms, kitchens, and other areas that produce excessive humidity.
- Repair any plumbing leaks immediately.
- Remove lint around and under the clothes dryer on a regular basis.
- Use fragrance-free, nonaerosol personal care products.
- Clean the carpet and upholstered furniture on a regular basis using a HEPA vacuum system.
- Use a dehumidifier to reduce humidity, if necessary.
- Have the HVAC system and chimney inspected each year and perform proper maintenance of HVAC system.

Providing Adequate Ventilation and Filtration

To maintain adequate ventilation and filtration, the technician should ensure that the design and operation of the HVAC system is in accordance with ASHRAE Standard 62.1, *Ventilation for Acceptable Indoor Air Quality*, and ASHRAE Standard 129, *Measuring Air Change Effectiveness*. Air filters with a Minimum Efficiency Reporting Value (MERV) of 13 should be used. Be certain that filters fit correctly and are changed regularly. There should be a maintenance and inspection plan for the HVAC system, including at least the two following steps:

- Ensure that outdoor air intakes are free of obstruction and potential pollutant sources.
- Provide exhaust ventilation in rooms with higher pollutants, such as bathrooms and kitchens.

Maintaining Acceptable Indoor Environment Conditions

To maintain acceptable indoor environmental conditions, temperature, humidity, and airflow must be kept at acceptable levels. Keep humidity levels between 40% and 60% by running the cooling system when humidity is high or by using humidifiers and dehumidifiers to maintain proper levels. Maintain temperature between 72°F and 76°F (22°C and 24°C) by properly programming the thermostat. Make sure adequate ventilation is maintained by programming the thermostat to operate the fan occasionally if it has that capability. Also, make sure furnace filters are replaced on schedule. Locate and eliminate unwanted drafts. Drafts can bring in unwanted humidity, transfer heat between the indoors and outdoors, bring in dust and other contaminants, and make occupants uncomfortable.

28.3.4 Classifications of Indoor Air Quality Issues

Problems with indoor air quality can cause a variety of symptoms in occupants. Often these symptoms lead to the diagnosis of one of three classified

Copyright Goodheart-Willcox Co., Inc. 2017

conditions: sick building syndrome (SBS), building-related illness (BRI), or multiple chemical sensitivity (MCS). The majority of IAQ concerns stem from poor ventilation, poor filtration, and contaminated HVAC systems.

Sick Building Syndrome (SBS)

One of the most commonly diagnosed IAQ conditions is ***sick building syndrome (SBS)***. It can usually be confirmed when approximately 20% or more of a building's occupants complain of drowsiness, fatigue, eye and skin irritations, or respiratory problems. SBS health problems appear to be due to the building. The symptoms frequently disappear when individuals are removed from the environment. In cases of sick building syndrome, a specifically diagnosable illness is not identified.

OSHA describes sick building syndrome as a reaction to chemical, physical, or biological stimuli. According to NIOSH (National Institute of Occupational Safety and Health), a deficiency in the ventilation system is the largest single cause of SBS. Sick building syndrome can be caused by any combination of the following factors:

- Poor temperature/humidity control.
- Poor ventilation and lighting.
- Improper maintenance and system design.
- Airborne chemicals or pollutants.
- Excessive noise.

Building-Related Illness (BRI)

Building-related illness (BRI) is a diagnosable illness caused by exposure to airborne agents. BRI symptoms do not disappear when the occupant moves to a more favorable environment. BRI differs from SBS in that SBS has no specific cause and no identifiable illness.

Examples of BRI include colds, flu viruses, tuberculosis, measles, and smallpox. BRI illnesses can permanently damage health and, in extreme cases, may be fatal. In BRI cases, the services of a qualified health professional should be sought immediately. There are numerous causes of BRI, including viruses spread by the airflow system, stagnant water, toxins and allergens, radon, and microscopic airborne biological agents, such as spores and fungi.

A specific example of a building-related illness is ***Legionnaires' disease***. Symptoms include headache, high fever, and respiratory problems. This disease is caused by the Legionella bacteria, which can live in cooling towers, evaporative condensers, and domestic water systems.

Inadequate preventive maintenance can provide the nutrients that bacteria such as Legionella need to thrive. Proper equipment design and proper maintenance of systems may reduce the risk of bacteria growth. Periodic disinfecting also helps to prevent the bacteria's growth.

The HVAC system should be checked whenever evidence indicates the presence of diseases, such as humidifier fever, allergic asthma, and allergic rhinitis. The system must be checked to determine if any microorganisms are present. An initial walk-through is recommended, with visual inspection for possible reservoirs and sites of contamination. If a suspected site is located, a sample should be obtained and analyzed.

Multiple Chemical Sensitivity (MCS)

A small portion of the population has experienced ***multiple chemical sensitivity (MCS)***. This is a condition that is unexplained, manifesting itself in reported sensitivities and adverse reactions to low levels of chemicals, bioaerosols, and other irritants. Individuals that develop multiple chemical sensitivity appear to have abnormal sensitivity to contaminants in the environment. MCS can also be referred to as *chemical hypersensitivity* or *environmental illness*.

28.4 Air Cleaning

Many IAQ problems can be solved or avoided by cleaning the air in an enclosed space. Filtering is one of the most common methods of cleaning the air. It is possible to remove almost 100% of air contaminants; however, doing so can be expensive. Removal of 90% to 95% is much more common and practical.

28.4.1 Air Filters

An ***air filter*** is a device made of fibrous materials used to remove solid particulates, such as dust, pollen, mold, and bacteria, from circulating air. Having an air filter in series with an air handler allows the filter to passively remove contaminants from the air. Air filter efficiency is measured by the following three factors:

- Total weight of dirt collected.
- Size of the smallest particle that can be removed.
- Degree of discoloration on the exhaust side of the filter being tested.

Air filters and electronic air cleaners are rated by ASHRAE Standard 52.2, which determines efficiency by the size of particle that the filter will capture, **Figure 28-11**. Manufacturers often rate their air filters as 90–98% efficient. This usually refers to an air filter's ability to capture only large particles (3.0–10.0 microns). See **Figure 28-12**.

Copyright Goodheart-Willcox Co., Inc. 2017

Air Filter Efficiency		
Particle Type	**Class**	**Particle Size (Microns)**
Small	E1	0.3–1.0
Medium	E2	1.0–3.0
Large	E3	3.0–10.0

Goodheart-Willcox Publisher

Figure 28-11. Air filter efficiencies are usually a measure of the percentage of class E3 large particles the filter is capable of capturing.

Minimum Efficiency Reporting Values and Applications		
MERV	**Typical Contaminant**	**Typical Application**
13 through 16 (0.30 to 1.0 microns)	All bacteria Most tobacco smoke Droplet nuclei Cooking oil Copier toner Face powder Paint pigment	Hospital inpatient care General surgery Smoking lounges Superior commercial buildings
9 through 12 (1.0 to 3.0 microns)	Legionella Lead dust Milled flour Coal dust Auto emissions Nebulizer drops Welding fumes	Superior residential buildings Better commercial buildings Hospital laboratories
5 through 8 (3.0 to 10 microns)	Mold Spores Hair spray Cement dust Snuff Powdered milk	Commercial buildings Better residential buildings Industrial workplaces Paint booth inlets
1 through 4	Pollen Spanish moss Dust mites Sanding dust Paint spray Dust Textile fibers	Minimum filtration Residential Window air conditioners

Goodheart-Willcox Publisher

Figure 28-12. Chart of MERV ratings and typical contaminants found in various applications.

There are five basic types of air filters:

- Disposable filters.
- Washable filters.
- Electrostatic filters.
- Carbon filters.
- HEPA filters.

Each type of air filter serves the same basic function of removing pollutants from the air. The major difference is the amount of pollutants each removes from a specific volume of air over a given period.

Code Alert

Air Filters

Local building codes may dictate the way central heating and air conditioning systems are to be filtered. Codes may dictate what media can be used, airflow requirements through the filter, and the flammability limits of any treatment (such as an adhesive or static spray) that is to be applied to the filter element.

Disposable Filters

As their name implies, disposable filters are meant to be discarded when they become dirty. There are several different types of disposable filters available on the market. Two common types of disposable filters are fiberglass panel filters and pleated media panel filters. These filters generally consist of a cardboard frame, filter material, and sometimes a thin metal grille, **Figure 28-13**.

In most residential applications, these disposable filters have a thickness of 1″. Disposable filters for commercial use can be several inches thick. The efficiency rating of this type of filter is usually low to medium.

Washable Filters

Washable filters are designed to be used repeatedly. The filters can be removed, cleaned as directed, dried, and reinstalled. Washable filter media materials include synthetic media, such as polyester and foam, aluminum expanded metal mesh, and wire cloth.

Electrostatic Filters

Static electricity, a buildup of charged particles, is the reason dirt and dust cling to walls, drapes, and ceilings. Static electricity also attracts dirt and dust to vertical and overhead surfaces.

Static electricity is often generated when two surfaces rub together and are then separated. For example, rubbing a cloth on a rubber ball will build up surplus electrons on the ball, giving it a negative charge. The cloth will lack electrons, giving it a positive charge. This imbalance of electrons is called static electricity.

Figure 28-14. A variety of materials and their abilities to generate static electricity. Materials nearer the top of the list will tend to have a positive (+) charge, while materials nearer the bottom will tend to have a negative (–) charge. The farther apart the substances are on the list, the greater their combined ability to generate static electricity when they are touched together.

If the imbalance of electrons is great enough, the electrical charge will jump an air gap and create a spark. Under the right conditions, this spark could cause a fire or explosion. Different materials have different potentials for generating static electricity, **Figure 28-14**.

Basically, an ***electronic air cleaner*** puts a static electrical charge on all particles in the air that pass through it. These charged particles are then attracted to collector plates with an opposite electrical charge. Electronic air cleaners are also called electrostatic air cleaners, electronic filters, or electrostatic filters.

Thinking Green

Passive Electrostatic Filters

In many cases, a passive electrostatic filter can be installed in an HVAC system to improve filtering capability without increasing energy consumption. The electrostatic charge is produced by the friction of air blowing across the fibers in the filter, so no outside power source is required. Several manufacturers produce electrostatic coating that can be sprayed onto a disposable filter to give it an electrostatic charge.

Copyright Goodheart-Willcox Co., Inc. 2017

Carbon Filters

An air filter made of activated carbon can remove solid particles, odor-causing gases, and bacteria. In activated-charcoal form, the carbon can be made from various substances, including coconut shells and petroleum refining by-products. The activated charcoal will adsorb as much as 50% of its weight in foreign gases. Because of its ability to reduce odors, this type of air filter is often used in air conditioners and in refrigerators. **Figure 28-15** shows an activated carbon filter assembly.

It is possible to recycle used carbon filters. However, this is usually done by the manufacturers. They remove and process the carbon for reuse.

HEPA Filters

A HEPA (high-efficiency particulate air) filter removes a high percentage of particles in air as the air passes through an air purifier. To qualify as a HEPA filter under US government standards, a filter must capture 99.97% of airborne particles 0.3 microns or larger. A micron is one-millionth of a meter.

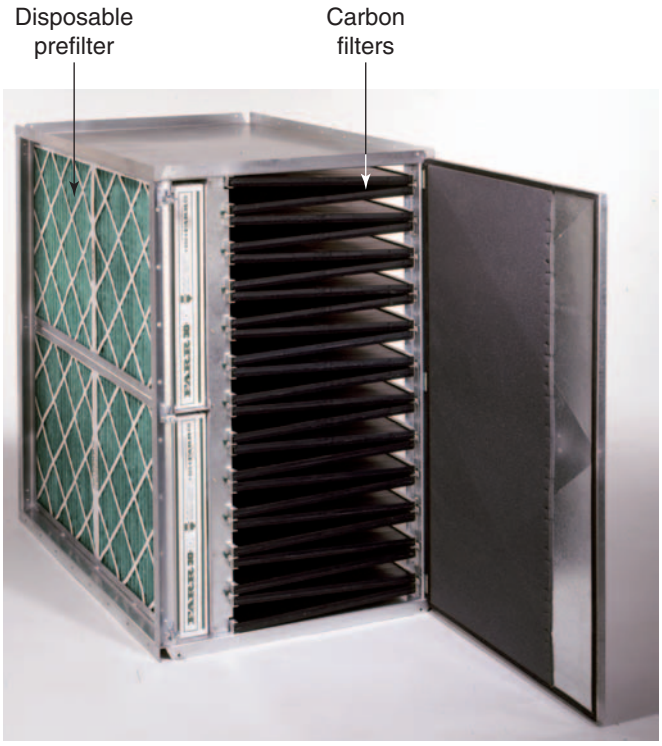
HEPA filters perform significantly better than ionic and electronic air cleaners. They also often improve in performance over time, whereas dirt accumulation on the plates causes a decrease in performance in the ionic and electronic air cleaners. HEPA filters are used in a variety of applications, including medical facilities and aircraft, **Figure 28-16**.

Air Filter Maintenance

Air filters tend to unload excess contaminants once their capacity has been reached. These contaminants are then released downstream in the system, dirtying heat exchange surfaces, covering the inside of ductwork, and entering the conditioned spaces. This can result in sooty soil on ceilings, diffusers, and wall surfaces. A dirty air filter can also affect energy cost due to inefficient heat transfer at coil surfaces and a resulting increased fan run time. Air filters should be changed at approximately 80% of design final resistance, as energy cost rises sharply with resistance.

When installing air filters, check the support of the air filter frames. Also look for leaks around frames. Be sure there is no light showing around the frame, which may allow unfiltered air to leak by. The fit of air filters in frames should be plumb and square.

Visually check the condition of the filter media. If there are any tears, rips, or holes, replace the filter. Filters have design specifications providing both initial and recommended final resistance to airflow. These are usually stated in inches of water. A manometer can be used to measure pressure drop across the filters in inches of water. The two manometer openings are



Camfil Farr Co.

9

Copyright Goodheart-Willcox Co., Inc. 2017

connected to measure the airflow on the two opposite sides of the filter. These measurements will indicate the pressure drop across the air filter.

A ventilation system is usually designed to allow the filter pressure drop (resistance) to be about one-fourth of the total pressure drop (pressure rise across the blower fan). For example, if the total pressure rise across the fan is 4.0″ (10 cm) of water column, then the allowed pressure drop across the filter is 1.0″ (2.5 cm) of water column.

Measuring Air Filter Efficiencies

Air filters are tested in laboratories. They can also be tested on the job. One test determines how many 0.3 micron-size particles the filter can remove. This test is made by measuring the interference with diffused (scattered) light. To increase filtering surface or area in air filters, many different designs are used. A popular method to increase the area is to use pockets or pleats to trap the air.

As described in ASHRAE Standards 52.1 and 52.2, three common methods are used to measure air filter performance:

- Atmospheric dust spot efficiency.
- Synthetic dust weight arrestance.
- Fractional efficiency.

Atmospheric dust spot efficiency measures the ability of an air filter to remove atmospheric dust by evaluating the flow rates on both sides of the filter and the quantity of material it captures. This test is used to assess medium efficiency air filters and air cleaners. Special filter paper targets are located on both sides of the tested filter. The efficiency is calculated based on the quantity of air drawn through the target filter, the amount of light transmitted through the target filter, and the difference in light transmission for the two paper filter targets. The amount of air and light transmitted through the target filter papers decreases during the test due to a buildup of dust.

Synthetic dust weight arrestance is a measure of a filter's ability to remove synthetic dust from test air. It is calculated by comparing the weight of the synthetic dust that gets caught in the filter being tested and the weight of the amount of dust fed into the filter.

Another air filter efficiency test is called the ***DOP HEPAP Method***. The name of the test comes from the name of the testing particles, dioctyl phthalate. This test is used mainly with high-efficiency filters. Particles of 0.3 microns are sprayed into the inlet duct of the filter being tested. Small, white, sample filters collect some of this dust from the airstreams ahead of the test filter. Other sample filters collect dust from the air leaving the test filter. The difference in the sampling filters, by color or weight, determines the efficiency of the test filter. For example, if the outlet sample filter collects only 1% of the amount of particles as the inlet sample filter, the test filter has a 99% efficiency.

The ***fractional efficiency test*** is the most advanced and accurate of the techniques for measuring air filter performance. It uses high-tech equipment to count the number of particles trapped by an air filter. The test then classifies the particles based on their size. A challenge aerosol is chosen that will be able to accurately measure the particle sizes. A particle count is taken both upstream and downstream of the filter. The efficiency of the filter is calculated based upon each size range.

28.4.2 Electronic Air Cleaners

Electronic air cleaners have four main parts:

- Frame.
- Power supply.
- Prefilter and airflow distributor.
- Electronic cell (electronic grid).

Electronic air cleaners are available as stand-alone units or for installation in ductwork. Stand-alone units can be installed on ceilings or in a portable cabinet, **Figure 28-17**. In addition to the four basic components already described, stand-alone electronic air cleaners are usually equipped with a fan to draw in and expel air.

Figure 28-18 shows an electronic air cleaner that is designed to be installed at the inlet of the return air ductwork. Many electronic air cleaners are installed closer to the air handler, just before the inlet to the blower. These can be installed in several ways depending on the orientation of the air handler and

General Filters, Inc.

Figure 28-18. Electronic air cleaner installed at the inlet of the return air duct.

the available ductwork, **Figure 28-19**. Regardless of the type of electronic air cleaner being used, the purpose is the same—to remove airborne particles, such as smoke, dust, mold spores, pollen, and bacteria from the air.

In most electronic air cleaner designs, the air first passes through a washable filter, often referred to as the prefilter. The prefilter is usually made of metal mesh and removes most of the larger particles of dirt, which helps extend the capacity of the device. After going through the prefilter, the air passes into the electronic part of the filter, called the electronic grid or electronic cell. In the electronic cell, a wire with a high positive voltage is positioned between two negative ground wires. This creates a strong electrical field between the wires.

As particles in the air pass through the electrical field, they lose electrons, giving the particles a positive charge. These particles are then drawn to the grounded collector plates, which have a negative potential relative to the wires, **Figure 28-20**.

A common design variation has both positively charged and negatively charged plates. In these designs, the positive plates repel the positively charged particles as the negatively charged plates attract and trap them. Since the plates work together, the particles are moved to the negative collector plates more quickly. This design is better than the negative plate–only design in high-airflow applications because it reduces the chances that a charged particle can pass all the way through the filter before being captured by the collector plates. A typical household electronic air cleaner is shown in **Figure 28-21.**

Goodheart-Willcox Publisher

Figure 28-20. A simplified drawing shows how an electronic air cleaner works. The prefilter traps large particles. The small particles that pass through the prefilter become positively charged when they pass between the positive and negative wires in the electronic cell. Positively charged particles are attracted to and captured by the negatively charged collector plates.

Honeywell, Inc.

Figure 28-21. A whole house electronic air cleaner is capable of removing 93% of medium size particles (1.0–3.0 microns) and 98% of large particles (3.0–10.0 microns).

Safety Note

Electronic Air Cleaners

Electrical potentials as high as 12,000 V are developed between the wires in the electronic cell. Due to the high voltages used to ionize pollutants, electronic air cleaners can be dangerous. Always disconnect the unit from its electrical supply before servicing. In addition, it is important that the unit be cleaned according to the recommended schedule. If excess dirt is allowed to build up inside the unit, the high voltages in the electronic cell may cause arcing, which could result in a fire or explosion.

The electronic cells and prefilter must be cleaned every two to three months. Most electronic air cleaners have cleanable filters. To clean the electronic cell and screens, disconnect the power and then remove the filter. Clean the filter with a mixture of warm water and mild detergent. Rinse the filter with hot water until the water runs through clean. Dry the filter thoroughly and return it to its proper position. Turn on the power. With proper care and maintenance, these filters last indefinitely.

Electronic air cleaners must be installed level and plumb to provide efficient airflow. Airflow should be evenly distributed across the face of the air cleaner for maximum efficiency. If the unit is installed near an airflow elbow, movable air vanes or baffles should be installed inside the duct to help the air flow smoothly around the bend. A fine-mesh screen or filter should be installed ahead (upstream) of the filter to prevent excessive lint from entering the unit. Excessive lint interferes with electronic air cleaner operation.

28.4.3 Ionizing Air Purifiers

If charged particles are allowed to pass from the ventilation system into a room, they will stick to walls, furniture, and other surfaces. Ionizing the air in the room can neutralize the static electrical charges that cause dirt and dust to stick to walls and other surfaces. Ionizing means

Copyright Goodheart-Willcox Co., Inc. 2017

to give a positive or negative charge to atoms or molecules by adding or removing electrons. When the air is ionized, electrons are exchanged between the negatively charged air and the positively charged dirt and dust. When electrons are added to the dust particles, they lose their electric charge. The electrically neutral dirt and dust is no longer attracted to the walls and other surfaces, so it settles to the floor. The dirt and dust can then be collected with a HEPA vacuum system.

Caution

Air Purifiers and Ozone

Some ionizing air purifiers produce ozone as a by-product. In excessive concentrations, ozone can irritate eyes and the respiratory system. The manufacturer's instructions should be followed closely when using an ionizing air purifier.

28.4.4 Ultraviolet Light

Wavelengths within the short wave, or C band, of UV light (UVC) are effective germicidal light wavelengths. UVC lamps use electrical discharge through low-pressure mercury vapor enclosed in a glass tube. The lamp transmits UVC light, primarily at the mercury wavelength of 254 nanometers. This wavelength has been found to be efficient in the killing of microorganisms. Therefore, UVC from mercury lamps also is referred to as ***UVG*** (ultraviolet germicidal). When used appropriately, UVGs destroy viruses, bacteria, and fungi. The type of microorganisms and quantity killed depends on the length of exposure to the ultraviolet rays and the output or intensity of the lamps.

Safety Note

Ultraviolet Light

Avoid looking at or being exposed to ultraviolet light rays. Ultraviolet lights are harmful to eyes and skin. The risk of skin and eye damage increases with the length of exposure.

Ultraviolet light duct fixtures may be used for residential and commercial applications. Residential units are often a single or double ultraviolet ray tube assembly. A common location for UV lights is in the return air duct just upstream of the air handler, **Figure 28-22**.

Near an UV light installed, any access door to the ductwork must be equipped with a safety shut-off switch that turns off the lamps if someone opens a door. When the lamps are on, the rays must cover the full cross-section of the duct to be effective.

UV lights may be installed in different locations, depending on the system and the objective of the installation. Return air duct installations are common and purify all return air before it is warmed or cooled and distributed throughout a building. During cooling operation, evaporator coils often condense moisture from the air. The moisture and air temperature can turn an evaporator coil into a breeding ground for mold and bacteria. For this reason, an HVAC system may need a UV light installed near its evaporator coil, **Figure 28-23**.

Field Controls, LLC

Figure 28-23. Reference manufacturer literature for recommended installation locations of UV lights.

Commercial HVACR systems may also use UV lights. Always check manufacturer recommended locations for a UV light before installation. Location may depend on the type of system and its orientation. A commercial HVAC rooftop unit installation is shown in **Figure 28-24**.

UV lights should be cleaned quarterly and replaced annually. Sealed lamps contain mercury, so caution must be taken.

Safety Note

Ultraviolet Operation

To verify that lights are in operation, check the lamp light indicator on the lamp knob. Never look directly at the lamps while they are illuminated.

Steril-Aire, Inc.

Figure 28-24. Technician installing a single UV light tube in an ultraviolet light assembly on a commercial unit.

Cleaning an Ultraviolet Air Treatment System

Ultraviolet lamps should be cleaned regularly to maintain an air treatment system. Cleaning recommendations are as follows:

1. Disconnect the power to the HVAC system.
2. Unplug the ultraviolet air treatment system cord from the electrical outlet and allow the lamps to cool for at least 15 minutes.
3. Rotate the lamp knob counterclockwise and gently pull the lamp knob to remove the lamp(s).
4. Holding only the lamp knob, wipe the lamp glass using a soft cloth with window cleaner applied to it. Do not touch the lamp surface with your hands. Use only the cloth.
5. To ensure that the lamp indicator continues to function, use a moistened cotton swab to gently remove any dust that may have collected between the lamp light indicator on the base and the black lamp base.
6. Wipe the lamps with a clean, dry cloth.
7. Put the clean lamps back into the unit base.
8. Plug the cord into the electrical outlet.
9. Verify the operation of the ultraviolet lamp(s) by viewing through the lamp light indicator on the lamp knob.
10. Reconnect the power to the HVAC system.

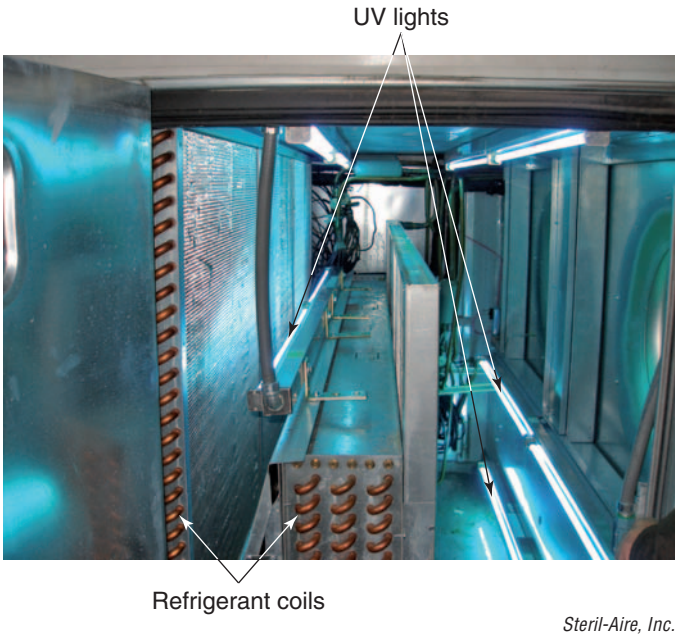
High-volume commercial systems often contain multiple lamps, which are used inside large air handling equipment. Units should be equipped with lamps

Copyright Goodheart-Willcox Co., Inc. 2017

that do not produce ozone. These units provide both odor control and germicidal protection, **Figure 28-25**.

Lamp installation is needed in cooling coils and drain pan areas, since these are areas of high contamination. Use of UV lights in these locations can reduce the need for chemical cleaning agents. Additional light fixtures may be installed in the ductwork if heavy contamination exists there.

Lamps should remove 80–90% of the bacteria in domestic and commercial systems. They should remove at least 99% in hospital operating and recovery rooms. Systems that remove more than 99% of the bacteria are more expensive but may be required in some applications. Since these lamps are stronger than their commercial and residential counterparts, no human exposure to the light generated can be permitted. The useful life of a lamp varies with output, but may be as high as 9000 hours.



Steril-Aire, Inc.

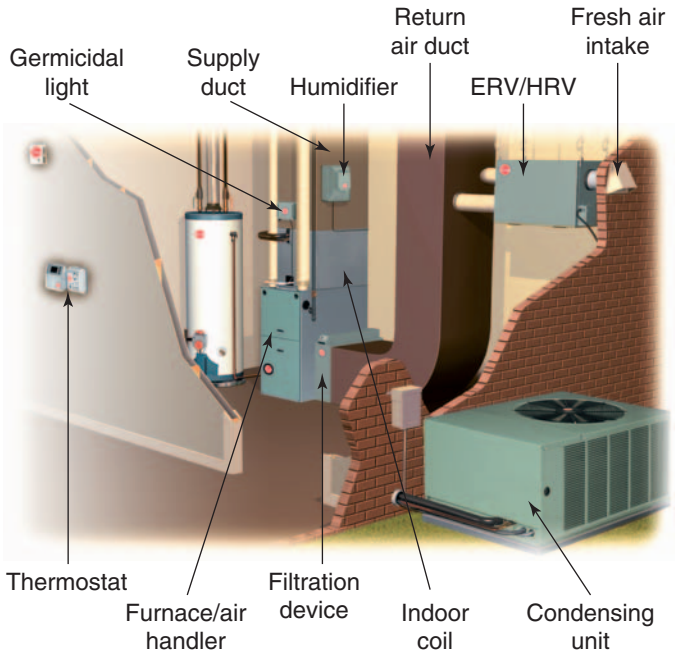
Figure 28-25. This commercial air handler has rows of ultraviolet lights. Additional lights increase the system's ability to remove pollutants.

28.5 Indoor Air Quality Systems

In the past, natural air exchange through ***infiltration*** (leakage of air into a building) and ***exfiltration*** (air leaving a building through doors, windows, and other construction joints) was assumed satisfactory. Additional exchange of air was provided by the opening of doors and windows. Today, systems that provide ventilation and increase air quality are recommended due to the increasingly tight envelope of newer home construction, through increased insulation and sealing.

An important responsibility of a residential home's HVAC system is maintaining the quality of the air. Some residential homes are equipped with complete indoor air quality systems. An indoor air quality system is a controlled ventilation system that exhausts stale humid air and reduces pollen, dust, odors, and other pollutants. A complete system consists of numerous components, including an air conditioner, high-efficiency variable-speed furnace, humidifier, air purification system, UV germicidal light, and a heat recovery ventilator (HRV) or energy recovery ventilator (ERV). The components in this type of system are coordinated to ensure adequate ventilation, heating, and cooling, **Figure 28-26**.

To maintain indoor air quality, stale indoor air is exchanged with fresh outdoor air. However, while outdoor air may be fresh, it is often not at the same temperature and humidity as the conditioned indoor air. To reduce the energy loss that would be required to recondition incoming fresh air, HVAC systems route incoming fresh air through an HRV or an ERV. Heat recovery ventilators (HRVs) and energy recovery ventilators (ERVs) deliver fresh air into a home's interior and improve ventilation.



Rheem Manufacturing Company

Figure 28-26. The components of a complete home air quality system are shown here.

A ***heat recovery ventilator (HRV)*** is a heat exchanger that passes incoming fresh air and outgoing stale air through a series of parallel passages. As each airstream passes through the HRV, heat is exchanged, so the incoming air is closer to the temperature of the outgoing air, **Figure 28-27**.

Field Controls, LLC

Figure 28-27. Removing a side panel reveals this heat recovery ventilator's heat exchanger.

An ***energy recovery ventilator (ERV)*** is constructed and operates in the same manner as an HRV; however, an additional component allows ERVs to transfer heat and also humidity.

ERVs and HRVs are mechanical ventilation systems. HRV/ERVs are referred to as balanced systems. An HRV recovers some of the heat that would otherwise have been exhausted. Through the use of fans, HRV/ERVs provide a flow of fresh outdoor air into the house while exhausting out the same amount of stale indoor air. In a typical installation, fresh air is brought to the living room and bedrooms, and stale air is removed from bathrooms, the laundry room, and kitchen.

An ERV transfers both heat and moisture (usually the stale air in winter and the fresh air in summer) to the airstream that is drier. In colder climates, where heating is important, an HRV is appropriate. An ERV is used in warmer climates where humidity control is important. ERVs and HRVs are most commonly connected to the ductwork. Installations and arrangements may vary, **Figure 28-28**.

Chapter Review

Summary

- ASHRAE Standard 62.1 provides guidelines for indoor air quality. The National Institute for Occupational Safety and Health (NIOSH) and the Occupational Safety and Health Administration (OSHA) regulate indoor air quality in the workplace.
- Indoor air quality is a measure of the combined effects of temperature, humidity, airflow, pollutants, number of occupants, and other factors in an enclosed space.
- A pollutant is a substance that is in some way a detriment to comfort, health, and a desirable environment.
- Solid pollutants include dust, fumes, smoke, bioaerosols, and asbestos. Gaseous pollutants include sulfur dioxide, carbon monoxide, carbon dioxide, nitrogen dioxide, ozone, radon, and organic vapors.
- The amount of time people spend indoors in combination with newer energy-efficient building standards and new synthetic building materials has made indoor air quality a growing concern. In residences, poor indoor air quality can be caused by decreased ventilation, fumes, moisture, the habits of occupants, and lack of maintenance of the home or HVAC system.
- IAQ problems in commercial settings can be caused by inadequate ventilation, inadequate filtration, work-related chemicals, cleaning chemicals, pesticides, mold, mildew, air pollutants being brought in from outdoors, or overcrowding. To maintain acceptable indoor environmental conditions, temperature, humidity, and airflow must be kept at acceptable levels.
- Exposure to poor indoor air quality can cause sick building syndrome (SBS), building-related illness (BRI), or multiple chemical sensitivity (MCS). Symptoms of SBS are building-related and disappear when the occupant leaves the building. BRI is caused by exposure to airborne agents that lead to a diagnosable illness. MCS results in abnormally high sensitivities and adverse reactions to low levels of chemicals, bioaerosols, and other irritants.
- To improve air quality, air can be cleaned with air filters, ultraviolet lights, or a combination of these measures.
- Numerous types of air filters are available, including disposable filters, washable filters, electrostatic filters, carbon filters, and HEPA filters. Disposable air filters consist of a filter material with a thin metal grille mounted in a cardboard frame. This type of filter generally has a low-to-medium efficiency rating. Washable air filters can be cleaned and reused.
- Electrostatic air filters ionize particles in the air. The particles are then drawn to collector plates that have an opposite charge. Most electronic air filters have a prefilter that blocks large particles. The electronic cell captures smaller particles.
- Carbon filters use activated charcoal to filter out particles and adsorb odors and fumes. Because of its odor-reducing abilities, this type of filter is commonly used in refrigerators and air conditioners.
- HEPA filters capture 99.97% of particles 0.3 microns or larger as they pass through the air purifier.
- The rating of an air filter's efficiency is a reflection of its ability to filter out particles of a certain size. Air filter efficiency can be measured by atmospheric dust spot efficiency tests, synthetic dust arrestance tests, and fractional efficiency tests.
- Ultraviolet lights are used to reduce bacteria, mold spores, viruses, and other microorganisms. UV lights are frequently installed in ductwork or near an evaporator coil and/or drain pan. In commercial applications, multiple UV bulbs are often used.
- Complete air quality systems combine air conditioning, heating/cooling, air purifier, UV germicidal light, and heat recovery ventilator or energy recovery ventilator. System components work together to ensure that the temperature, humidity, and overall air quality are maintained at the proper levels.

Copyright Goodheart-Willcox Co., Inc. 2017

- A heat recovery ventilator (HRV) passes incoming fresh air and outgoing stale air through a series of parallel passages. As each airstream passes through the HRV, heat is exchanged, so the incoming air is closer to the temperature of the outgoing air. An energy recovery ventilator (ERV) operates in the same manner as an HRV but transfers humidity as well as heat.

Review Questions

Answer the following questions using the information in this chapter.

1. A standard that includes equipment and system requirements and minimum ventilation rates that result in acceptable indoor air quality is _____.
   A. ASHRAE Standard 52.2
   B. ASHRAE Standard 62
   C. ASHRAE Standard 90.1
   D. ASHRAE Standard 170
2. Which of the following is a gaseous pollutant?
   A. radon
   B. asbestos
   C. fumes
   D. bacteria
3. Carbon monoxide is _____.
   A. formed from the natural decay of uranium
   B. a nontoxic combination of carbon and oxygen
   C. a result of incomplete combustion of fuel
   D. photochemically produced in nature
4. Diminishing quality of indoor air is due to _____.
   A. reduced infiltration of outdoor air
   B. vapors released from new building materials
   C. Both A and B.
   D. Neither A nor B.
5. Fumes and volatile organic compounds (VOCs) are released from _____.
   A. paints
   B. adhesives
   C. synthetic building materials
   D. All of the above.
6. Which of the following statements is false?
   A. An individual with multiple chemical sensitivity reacts to small quantities of chemicals or bioaerosols.
   B. Complaints about temperature and humidity can offer clues to indoor environmental problems.
   C. People between the ages of five and sixty have an increased susceptibility to indoor air pollutants.
   D. Unvented gas appliances are a potential source of indoor air pollutants.
7. Two common types of disposable filters are _____.
   A. pleated media filters and carbon filters
   B. carbon filters and fiberglass panel filters
   C. fiberglass panel filters and HEPA filters
   D. pleated media filters and fiberglass panel filters
8. A(n) _____ filter is often used in refrigerators because of its ability to reduce odors.
   A. washable
   B. HEPA
   C. electrostatic
   D. carbon
9. Which of the following is a measure of air filter efficiency?
   A. Total volume of dirt collected.
   B. Total weight of dirt collected.
   C. Size of the largest particle that can be removed.
   D. Total weight of the particles that can be removed.
10. The most accurate of the techniques for measuring air filter performance is the _____.
    A. atmospheric dust spot efficiency test
    B. DOP HEPAP method
    C. fractional efficiency test
    D. synthetic dust weight arrestance test
11. In most electronic air cleaners, the larger particles and dirt are removed by a(n) _____.
    A. carbon filter
    B. electronic grid
    C. electronic cell
    D. prefilter
12. Ultraviolet lamps should be cleaned _____.
    A. daily
    B. quarterly
    C. every three years
    D. never

Copyright Goodheart-Willcox Co., Inc. 2017

13. Common installation locations for ultraviolet lights for germicidal protection include the following, *except* _____.
    A. above the evaporator coil
    B. inside the evaporator coil
    C. in the combustion chamber
    D. in the return air duct

14. Fresh air is delivered into a home's interior by _____.
    A. energy recovery ventilators
    B. heat recovery ventilators
    C. humidifiers
    D. Both A and B.

15. An ERV is _____.
    A. a heat recovery ventilator
    B. not a heat exchanger
    C. used where only heat is important
    D. used where humidity control is important

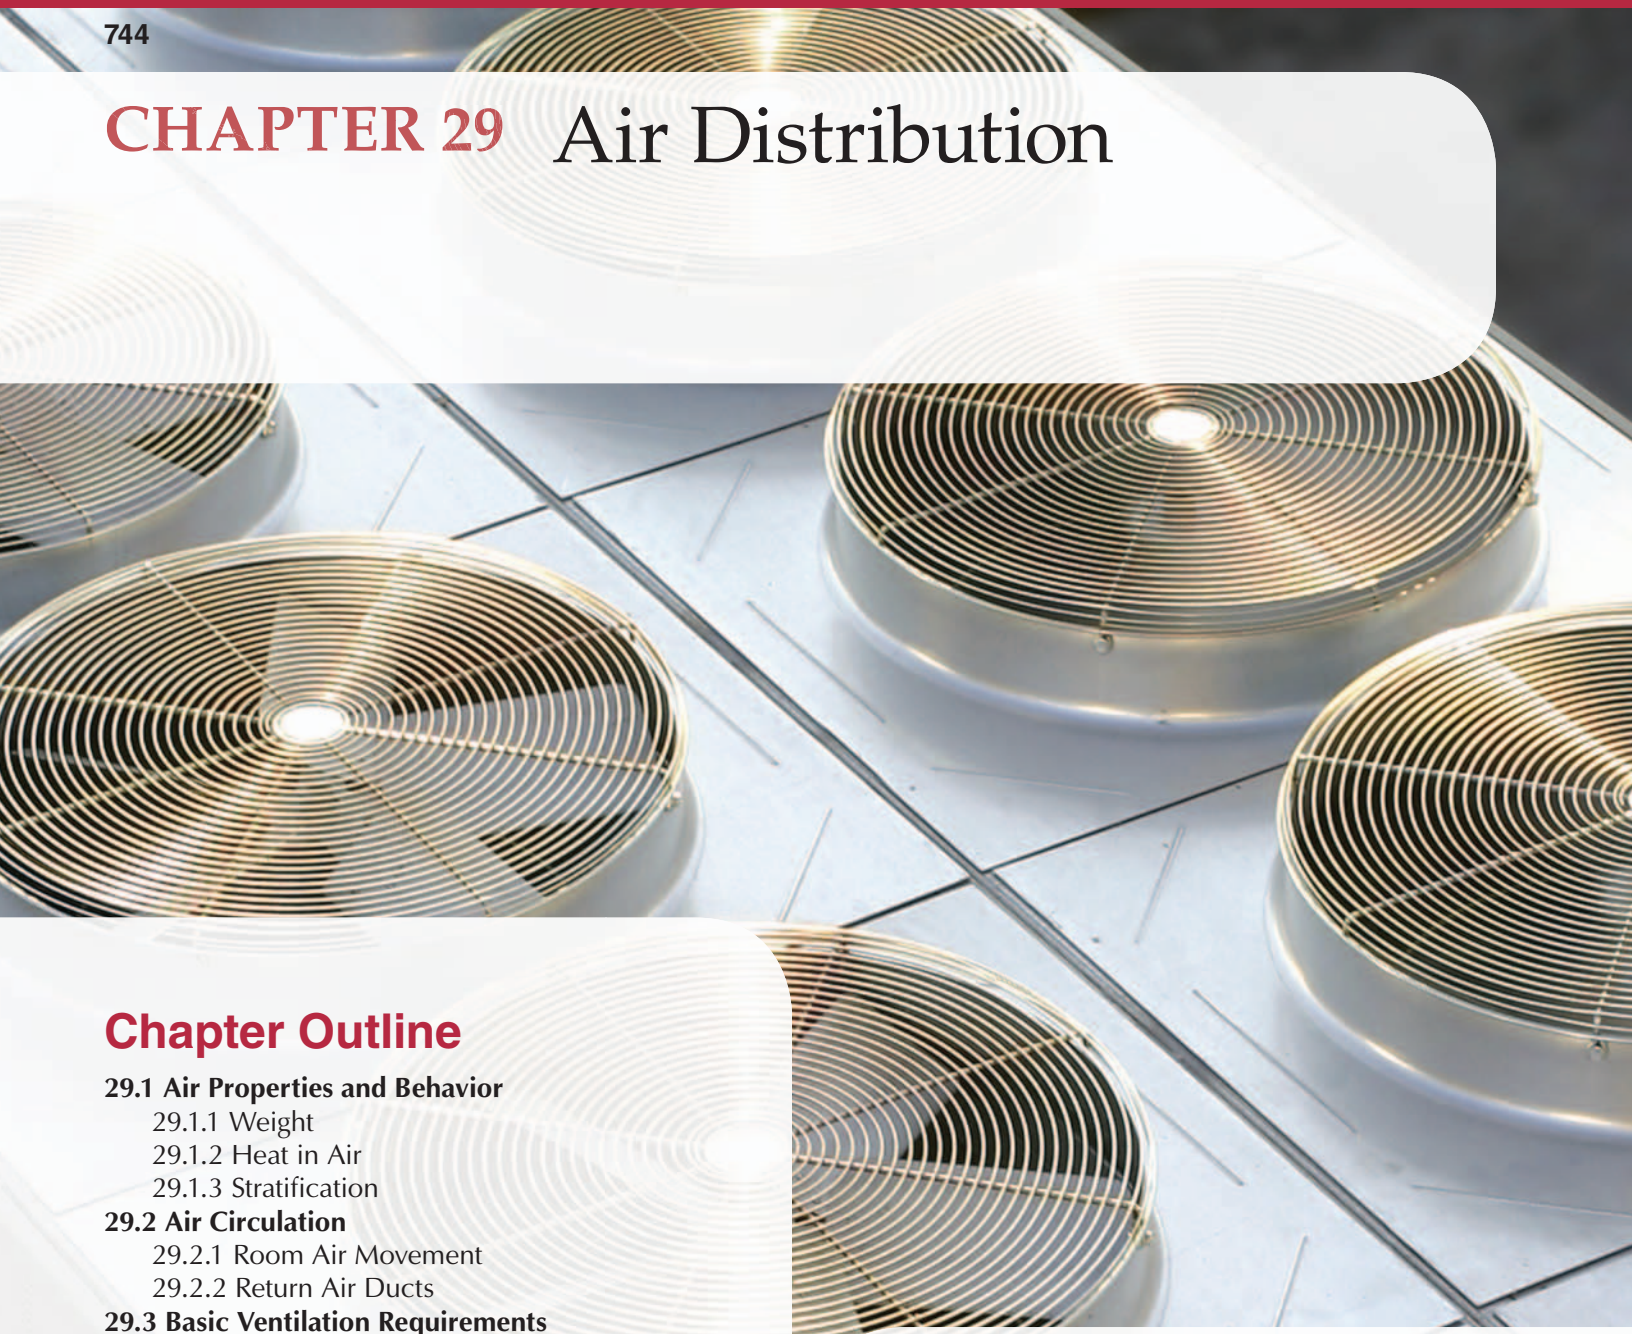
CHAPTER 29 Air Distribution



Chapter Outline

29.1 Air Properties and Behavior
- 29.1.1 Weight
- 29.1.2 Heat in Air
- 29.1.3 Stratification

29.2 Air Circulation
- 29.2.1 Room Air Movement
- 29.2.2 Return Air Ducts

29.3 Basic Ventilation Requirements
- 29.3.1 Calculating Air Changes
- 29.3.2 Attic Ventilation
- 29.3.3 Basement Ventilation

29.4 Air Ducts
- 29.4.1 Types of Duct Systems
- 29.4.2 Duct Construction
- 29.4.3 Fiberglass and Other Nonmetal Ducts
- 29.4.4 Duct Dimensions
- 29.4.5 Registers, Diffusers, and Grilles
- 29.4.6 Dampers
- 29.4.7 Elbows

29.5 Duct Sizing
- 29.5.1 General Duct Design Guidelines
- 29.5.2 Duct Sizing Procedure
- 29.5.3 ACCA Manual D

29.6 Fans

29.7 Air Curtains

Learning Objectives

Information in this chapter will enable you to:

- Recall the properties of air that affect air distribution system design or installation.
- Categorize air circulation systems.
- Determine the basic ventilation requirements for a given space.
- Identify the basic types of air duct systems.
- Explain the relationships between air distribution and duct sizing and design.
- Understand the procedure for correctly sizing ducts.
- Identify types and classifications of fans.

Review of Key Concepts

Reviewing these concepts from earlier chapters will help you understand new concepts presented in this chapter:

- Sensible heat is the heat energy absorbed or released to change the temperature of a substance. Heat that brings about a change of state with no change in temperature is called latent heat. (Chapter 4)
- Boyle's law states that the volume of a gas varies inversely to the pressure, provided the temperature remains constant. (Chapter 5)
- Charles' law states that at a constant pressure, the volume of a confined gas varies in direct proportion to the absolute temperature. (Chapter 5)
- Dew point is the temperature at which the current amount of moisture in the air would result in complete saturation of the air (100% relative humidity). At the dew point, moisture in the air begins to condense. (Chapter 27)
- Dry-bulb temperature is a measurement of the air's temperature without adjusting for the effect of humidity. Wet-bulb temperature is a measurement of the air's temperature that is adjusted for the effect of the air's humidity on evaporative cooling. (Chapter 27)
- Total air pressure is static air pressure (which is based on the density of the air) plus velocity pressure (which is the force exerted by the air's movement). (Chapter 27)
- A pitot tube measures total air pressure and static air pressure. Air passing through the nose of the pitot tube represents the total air pressure. (Chapter 27)

Introduction

Air-conditioning systems condition the air and distribute it. They are designed to distribute air to the proper space in amounts that provide the most comfort to the occupants of the conditioned space.

When a radiator or a room convector system is used, air distribution is simple. An example of this type of air distribution is a radiator. The heat exchange units are located along the outside walls. During the heating season, heated air rises from the radiator along the wall. It mixes with the cold air adjacent to the cold wall. Natural air currents (convection) then move the air mixture throughout the room. Many heating systems use motor-driven fans to help circulate the air.

A good air-conditioning system delivers clean air to the space being conditioned. Proper ventilation can also help control humidity levels in indoor air. Uncontrolled humidity from bathrooms, laundry rooms, and shower rooms can cause condensation on windows and walls. Proper ventilation can also control odors from cooking, smoking, or other household activities.

Copyright Goodheart-Willcox Co., Inc. 2017

29.1 Air Properties and Behavior

Before designing or installing an air distribution system, the basic properties of air must be understood. Failure to consider the behavior of air will result in a poorly designed system. Some properties to consider are the weight of air, the manner in which air absorbs heat, and the way air separates into layers (stratification).

29.1.1 Weight

Air has definite weight. Although they are invisible, the gases that compose air have a definite mass and, therefore, weight. **Figure 29-1** lists the density of air under various temperature and relative humidity conditions.

One pound (0.454 kg) of dry air at 70°F (21°C) at standard atmospheric pressure occupies a space of 13.35 ft^3 (0.378 m^3). If there is 50% relative humidity, one pound of air and moisture mixture takes up 13.51 ft^3 (0.383 m^3) of space. Because air is a gas, it obeys the gas laws (Boyle's and Charles'). Therefore, as the temperature rises or the pressure drops, air expands to fill a greater space. Also, as relative humidity increases, each pound of air will occupy a greater space. Each water molecule weighs less than each nitrogen or oxygen molecule. A gas made up only of water molecules would weigh a little more than half as much as an equal volume of dry air, provided that the pressure remains constant.

29.1.2 Heat in Air

Two types of heat can be added or removed from air—sensible heat and latent heat. When sensible heat is added into air, an increase of dry-bulb temperature occurs. Likewise, when sensible heat is removed, there is a decrease in dry-bulb temperature.

Latent heat in air is the heat or energy stored within the moisture in the air. When water vapor condenses, it changes from a vapor to a liquid. This process releases heat from the water. The latent heat in the air is the amount of heat that would be released if all of the moisture in the air condensed out of the air.

Since colder air is not capable of holding as much moisture as warmer air, the air is much drier during the winter season. A humidifier adds moisture to the air. Moisture is commonly added while air is being heated to bring the air as close as possible to the human comfort level, or approximately 70°F (21°C) db and 30% rh during winter months.

Relative humidity is much different from absolute or specific humidity. Relative humidity compares the air being treated to that same air that is completely saturated (100% relative humidity). Saturation is the point where no more moisture can be added to the air. It is the maximum amount of moisture that the air is capable of holding.

For example, assume that a volume of air at 80°F (27°C) is capable of holding 0.022 lb of moisture per pound of air or 0.022 lb/lb when the air is saturated. If this volume of air is actually holding only 0.011 lb/lb of moisture, then the air has a relative humidity of 50% (0.011 lb/0.022 lb × 100 = 50%). This air at this moment has only half the amount of water vapor that it is capable of holding.

Absolute humidity is the actual amount of moisture in the air, which would be the 0.011 lb/lb of moisture in the previous example. The moisture content is often expressed in grains of moisture per pound of air. There are 7000 grains for every pound of moisture. Thus, the absolute humidity of the air from the previous example would be 77 grains/lb (0.011 lb × 7000 grains/lb).

Another component that will add latent heat into air is an evaporative cooling system, typically

Density and Volume of Air

Air Temp (°F)	Dry Air		50% rh		100% rh	
	Density (lb/ft³)	Volume (ft³/lb)	Density (lb/ft³)	Volume (ft³/lb)	Density (lb/ft³)	Volume (ft³/lb)
0	0.08635	11.58	0.08632	11.585	0.08628	11.59
50	0.07786	12.84	0.0774	12.915	0.0769	12.99
70	0.07492	13.347	0.074	13.51	0.0731	13.68

Figure 29-1. The density of air at various temperatures and relative humidity. Water vapor weighs less than an equal volume of dry air.

Copyright Goodheart-Willcox Co., Inc. 2017

used in the southwest region of North America during the summer months. An evaporative cooling system adds moisture into the air to give a cooling effect. Because of the excessive sensible heat and the lack of moisture in the air, water will easily vaporize as it is introduced into the air. This will cause a cooling effect by increasing the rh level of the air while at the same time lowering its dry-bulb (sensible) temperature. Taking the 100°F db and 10% rh air and adding moisture brings the air closer to the human comfort levels for summer, which is about 75°F (24°C) db and 50% rh.

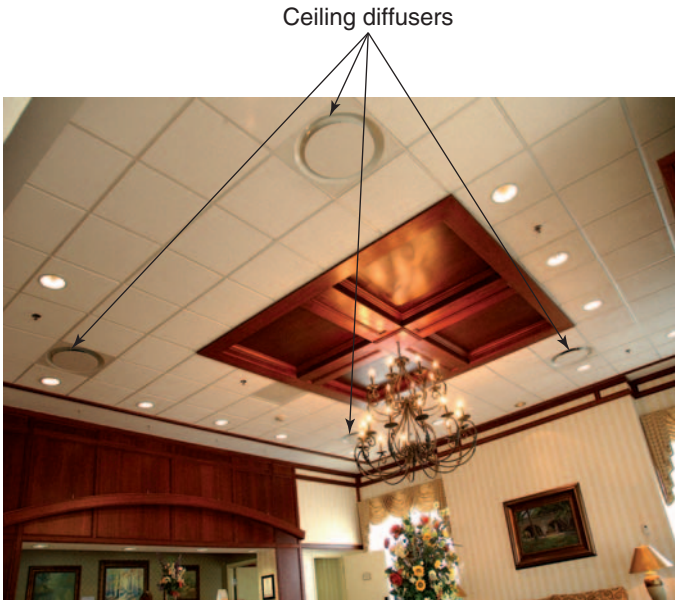
The evaporator coil in a comfort cooling system removes both sensible and latent heat from the air in regions that maintain higher relative humidity levels during summer months. As air circulates over the evaporator coil, the sensible temperature is reduced to the dew point temperature of the air. When the dew point temperature is reached as the air comes in contact with the evaporator coil, the moisture in the air condenses and is sent down a drain system. For each pound of moisture removed from the coil, about 970 Btus will be removed from the air. As both sensible and latent heat decreases, the air will move closer to its indoor target summer design db temperature of 75°F (24°C) and a relative humidity of 50%.

29.1.3 Stratification

In a given space with no drafts, warm air tends to rise and cold air tends to settle. If air is not deliberately moved, the air will settle at different heights according to its temperature. This condition is called stratification. To prevent stratification, the air in an occupied space must be kept moving.

If thermostats or humidistats are placed too high in a room, they may be exposed to air that is warmer and more humid than the air felt by the occupants. If thermostats or humidistats are placed too low in a room, they may be exposed to air that is cooler and less humid than the air felt by the room's occupants. For this reason, it is important that these devices be positioned at the proper level.

Proper placement of supply and return duct outlets is also an important factor in preventing stratification. Poor placement of supply duct outlets or return duct inlets could cause air to move only in certain parts of the room while becoming stagnant (not moving) in others. Furnishings can also obstruct air movement. To minimize the airflow blockage caused by furnishings, duct outlets are often located high up in the room or in the ceilings. In these locations, the outlets may be concealed or given an attractive appearance. See **Figure 29-2**.



Raymon-Donco Corp.

Figure 29-2. These ceiling-mounted air diffusers are barely noticeable. Diffusers are placed around the room to prevent air stratification.

29.2 Air Circulation

In warm air heating, three basic systems are used to circulate the air:

- Gravity.
- Intermittent forced-air.
- Continuous forced-air.

The gravity system is no longer popular. Too much energy is lost before the conditioned air reaches the room being heated. Most installations use an intermittent forced-air system, in which a thermostat controls the blower fan in the air handler or furnace plenum chamber. The thermostat turns on the blower whenever sensed temperature becomes too far above or below the setpoint. Continuous forced-air systems are growing in popularity. These provide a more constant temperature in rooms.

Air distribution systems designed to provide cooling as well as heating may need the ability to move different volumes of air depending on mode of operation. A cubic foot of cooled air will not change room temperature as much as a cubic foot of warmed air. This is because of the greater temperature differences produced. Warmed air comes out of the duct many degrees warmer than the room air it is replacing. Cooled air is not all that much cooler than the room air it is replacing. Therefore, greater quantities need to be moved into the room to achieve the desired effect. In average conditions, a 30% to 50% airflow increase is

Copyright Goodheart-Willcox Co., Inc. 2017

required. Either of the following two methods can be used to increase the airflow:

- Use of a two-speed or variable speed blower.
- Use of an adjustable pulley system for belt-driven blowers. A larger motor pulley is used during the heating season and a smaller pulley is used during the cooling season.

29.2.1 Room Air Movement

Air entering a conditioned space through ducts must circulate without causing annoying drafts. Air circulation depends on the number and size of the duct supply outlets and return inlets. It also depends on the velocity of the air moving through the supply outlets.

Air delivered to the room from the supply duct is called ***primary air***. Primary air pushes against and mixes with air already in a room. The outlet velocity is the speed of the air as it leaves the duct outlet. The distance the air travels from the duct outlet before it slows to 50 fpm is called the ***throw***.

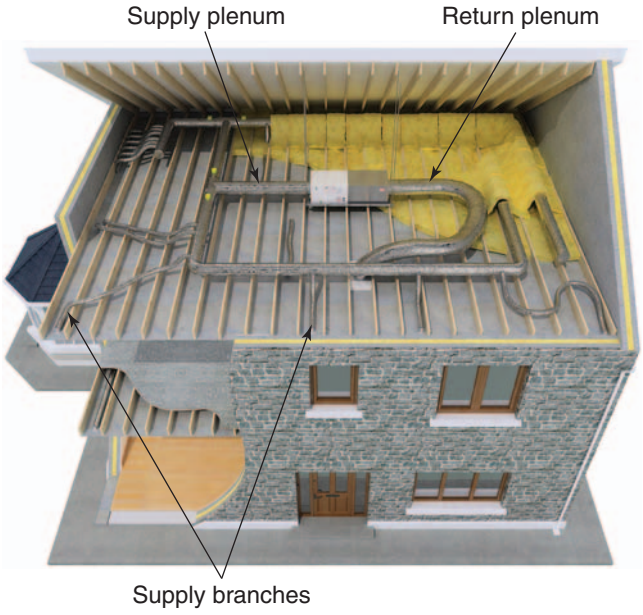
The overall size of the supply outlet is not important. The total area of the air openings in the fixture determines the fixture's capacity. The spread of the air that leaves the fixture is important.

29.2.2 Return Air Ducts

Airflow through ***return air ducts*** is almost always caused by the pulling action of a fan or blower. If the return airflow does not match the airflow into a room, the flow of air will not be properly balanced.

If there is more return air than supply air, the room will have a negative pressure. This condition is known as being starved for air. Rooms that are starved for air are cold during the heating season and warm during the cooling season. To correct the problem, more supply air must be delivered to the room.

Return duct inlets should be placed in the stratified (stagnant) air zone of a room. During the heating season, return air ducts would be located near the floor. During the cooling season, such ducts should be located near the ceiling. Ideally there would be two return duct inlets—one near the ceiling and one near the floor. The higher duct would be closed during the heating season, and the lower one closed during the cooling season. However, due to expense and practicality, most homes have only one return duct inlet. Therefore, placement of the return duct inlet is determined by the type of construction in a building or whether the primary usage will be cooling or heating. In all cases, return duct inlets should be located at the farthest distance from the supply duct outlets, **Figure 29-3**.



Hi-Velocity Systems

Figure 29-3. This small duct, high-velocity air distribution system shows supply air going to the inside perimeter of the building and the return air originated from the center of the building.

29.3 Basic Ventilation Requirements

Air normally contains about 21% oxygen. People need a certain amount of oxygen in the air in order to breathe comfortably. Depending how far below this level the oxygen content falls, people can experience a variety of symptoms including discomfort, breathing difficulty, drowsiness, disorientation, unconsciousness, and even death.

If a room is tightly sealed, anyone in that room will slowly consume the oxygen. As the oxygen is consumed, the amounts of carbon dioxide, water vapor, and various impurities increase. As the oxygen content in the air decreases and the carbon dioxide levels increase, the room begins to feel stuffy. Continued exposure to the oxygen-deficient air would cause people to experience progressive symptoms, beginning with drowsiness and ending in unconsciousness and death. For these reasons, living spaces must have air with a sufficient oxygen content. It is very important that fresh air be admitted to provide necessary oxygen. The air must also be kept at a reasonable temperature.

In the past, fresh air entered the space by infiltration through door and window openings and cracks in the structure. However, modern construction techniques reduce this air leakage. As a result, in modern homes and workplaces, an air-conditioning system must furnish fresh air. Modern air-conditioning systems should have a controlled fresh-air intake. This

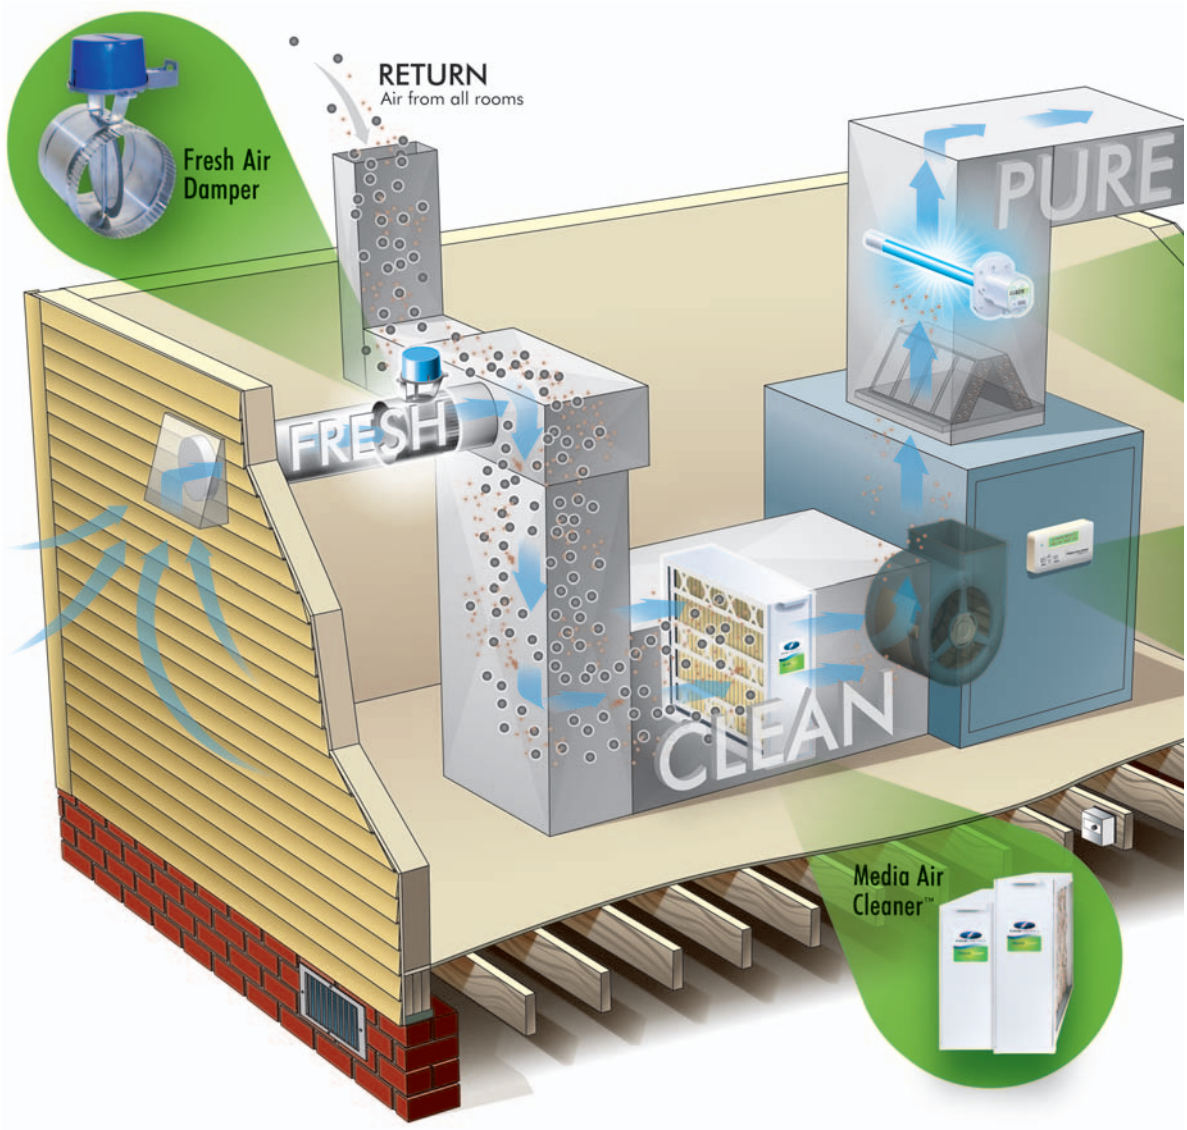
Copyright Goodheart-Willcox Co., Inc. 2017

fresh air is conditioned and mixed with the recirculated air before it reaches the room, **Figure 29-4**.

Fresh air can be brought into a building using a fresh air duct connected between outdoors and the return air ducts. When the air handler's blower is operating, fresh air can be drawn in and conditioned before being circulated through the conditioned space. A screen or mesh at the inlet to the fresh air duct prevents insects and other critters from entering. This fresh air duct connecting outdoors and the return air duct is usually regulated by a motorized damper or a barometric damper.

Another method of bringing in fresh air from the outside uses a heat recovery ventilator (HRV) or energy recovery ventilator (ERV). These devices have four air duct connections: fresh air inlet, fresh air outlet, exhaust air inlet, and exhaust air outlet. Two ducts connect to outdoors. One brings in fresh air, and the other exhausts stale indoor air to the outdoors. HRVs and ERVs transfer heat between incoming fresh air and outgoing exhaust air. The heat transfer helps to maintain steady indoor temperatures. HRVs and ERVs provide fresh air that has the least effect on indoor temperature. These units circulate air using a fan. HRVs and ERVs are covered in Chapter 28, *Air Quality*.

Some conditioned air leaves a building through exfiltration. Exhaust fans in bathrooms and kitchens also remove conditioned air. It is best to bring in



Field Controls, LLC

Figure 29-4. A duct to the outdoors is regulated by an automated damper. When the air handler is circulating air, the damper opens to allow fresh air to flow through the air filter and air handler and past the plenum's UVG light. Fresh air is cleaned, purified, and circulated into the conditioned space.

Copyright Goodheart-Willcox Co., Inc. 2017

replacement fresh air through an air system, where it can be cleaned and cooled or heated. Bringing in replacement air through an air-conditioning system also ensures that a definite amount of fresh air (makeup air) is brought in to provide a healthy oxygen level.

When fresh air is brought in by the air-conditioning system, a positive pressure can be maintained in the building to help keep out airborne dirt, dust, and pollen. Positive pressure is higher than atmospheric pressure. Negative pressure is below atmospheric pressure. In most cases, a negative pressure should be avoided, because it reduces the efficiency of exhaust fans and of fuel-fired appliances (furnaces, water heaters, etc.). Maintaining a negative pressure also tends to bring in outside contaminants.

Certain building areas should have slightly less positive pressure than the rest of the building. A lower positive pressure (10% to 15% less than the rest of the building) reduces the spread of odors. Such areas would include kitchens, bathrooms, and industrial areas where fumes are produced.

29.3.1 Calculating Air Changes

Air changes can be calculated by counting the people in a building or by calculating building volume. It is always necessary to choose the process that produces the greater number of changes per hour.

To calculate fresh air requirements and air changes per hour, the following factors must be considered:

- Number of occupants.
- Use of the space.
- Dry-bulb temperatures.
- Relative humidity.
- Amount of fresh air admitted by infiltration.
- Efficiency of the unit.

A system in a cooling mode should provide at least 15 cfm (cubic feet per minute) of air per person. This air exchange rate will provide enough oxygen and will remove carbon dioxide. In the example below, air changes are calculated by the number of occupants.

Formula for calculating required air exchange rate:

$$\text{Required air exchange rate} = \text{Number of occupants} \times 15 \text{ cfm}$$

Formula for calculating the time required for complete air exchange:

$$\text{Time for complete air exchange} = \frac{\text{Size of space}}{\text{Air exchange rate}}$$

Formula for calculating air exchanges per hour:

$$\text{Air exchanges per hour} = \frac{60 \text{ min}}{\text{Time for one exchange}}$$

Example:

Six people occupy a 10,000 ft^3 space. Calculate the necessary air exchange rate, the time required for one complete air exchange, and the number of air exchanges per hour.

Solution:

Required air exchange rate:

$$6 \times 15 \text{ cfm} = 90 \text{ cfm}$$

Time for complete air exchange:

$$\frac{10{,}000 \text{ ft}^3}{90 \text{ cfm}} = 111 \text{ min}$$

Air exchanges per hour:

$$\frac{60 \text{ min}}{111 \text{ min}} = 0.54$$

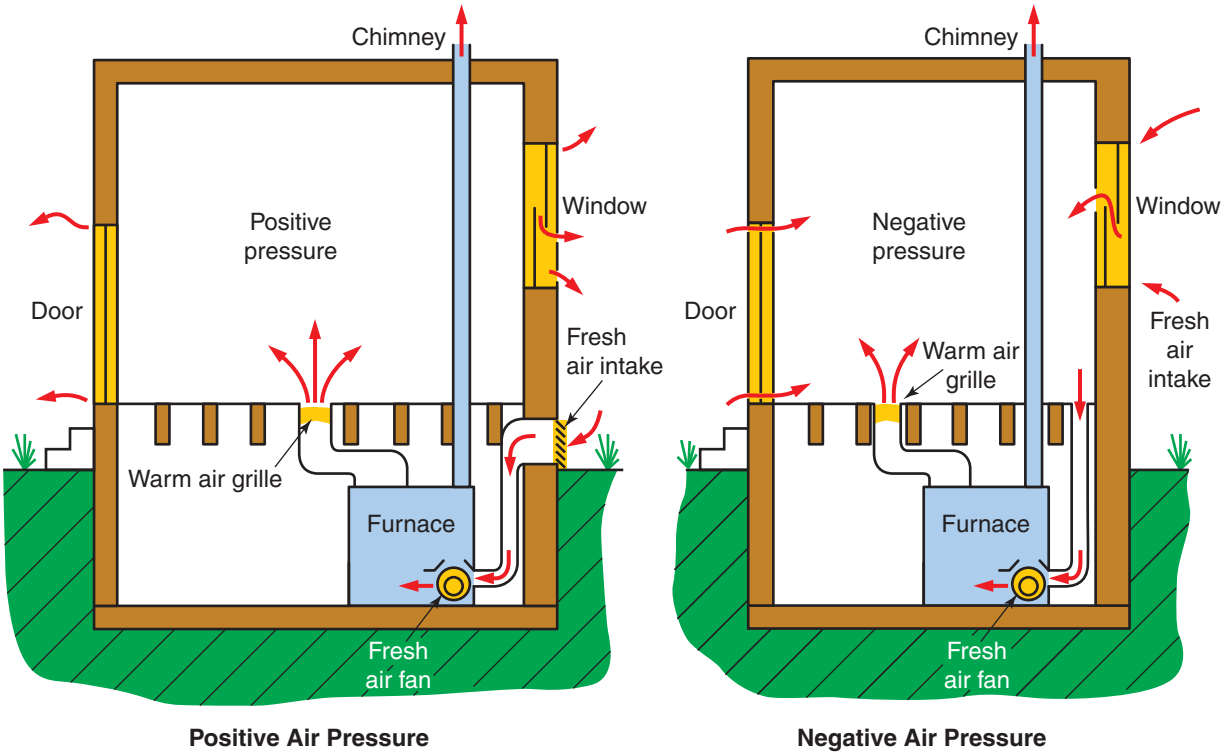
Based on the number of occupants, the required air exchange rate would be 90 cfm. At this rate, it would take 111 minutes (1.85 hours) to completely replace the air in the space, which translates to a little more than one-half of a complete air exchange per hour.

An air distribution system can produce positive or negative pressure in a building. A positive pressure eliminates infiltration of air from outside or from other spaces and ensures that all air entering a building can be filtered before reaching the occupied space. To produce a positive pressure, a special air intake draws outside air into the ventilation system. Negative pressure increases the infiltration at windows and doors. Air that enters by infiltration is untreated and may be dirty.

Residential homes that use fuel-burning appliances need a sufficient amount of air for proper combustion. This may not just be a gas-fired or oil-fired furnace but can also include gas stoves, gas clothes dryers, gas water heaters, and other appliances. For proper combustion, all fuel-burning appliances need sufficient amounts of oxygen from the air. If these appliances draw in combustion air from the inside of the house, the combustion exhaust leaving through the chimney might create a slightly negative pressure inside the house. See **Figure 29-5**.

Ventilation is usually based on air changes per hour for a conditioned space. Building volume can be used to calculate air changes per hour. For example, in a 1000 ft^3 space, three changes per hour would mean 3000 ft^3/hour or 50 cfm. Three changes every hour is the minimum for a residence during the heating

Copyright Goodheart-Willcox Co., Inc. 2017



Goodheart-Willcox Publisher

Figure 29-5. Airflow into and out of a building during the heating season. The red arrows in the diagram indicate airflow. If combustion air is taken from inside the house, negative air pressure may result.

season. As many as 12 changes per hour are recommended for cooling large public assemblies, such as crowded auditoriums. **Figure 29-6** shows typical air changes for both the heating and cooling seasons.

It is good practice to keep air blowers running all the time. They provide good ventilation to all parts of a building. Variable speed blowers may be used to provide more air movement when the heating or cooling system is running and less air movement when those systems are off.

An adequate air supply is the best way to control comfort. Body comfort is controlled by evaporation, convection, radiation, and respiration. Therefore, the temperatures of the walls, floors, and ceilings must be controlled. Enough air must also be supplied to promote good respiration, evaporation, and convection.

Typical Air Changes

Type of Space	Air Changes per Hour	
	Heating	Cooling
Homes	3–6	6–9
Office spaces	5–8	6–12
Public assemblies	5–10	6–12

Code Alert

Ventilation Recommendations

ASHRAE Standard 62 provides recommendations regarding ventilation. It provides basic equipment and system requirements and minimum ventilation rates that should result in indoor air quality that is acceptable to human occupants.

29.3.2 Attic Ventilation

There are two types of attics: unvented and vented. An ***unvented attic*** is closed off and essentially made into part of the conditioned space. The underside of the roof is usually heavily insulated to prevent heat loss and heat gain. However, many of the attics in North America are vented. A ***vented attic*** has vents or air openings between its inside and the outside. In the summer, these openings are intended to allow hot air to escape. In winter, the openings are intended to allow moisture to flow out and to maintain a cold attic temperature (to prevent ice dams from forming).

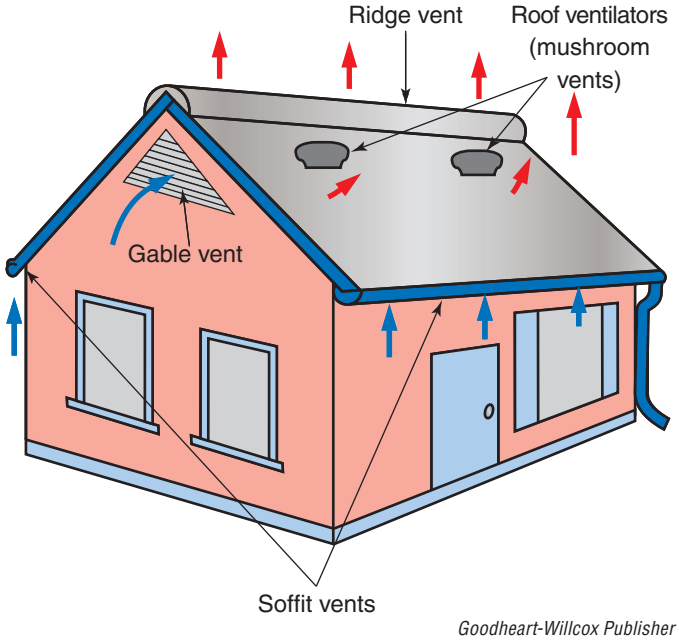
Copyright Goodheart-Willcox Co., Inc. 2017

A vented attic space must be properly ventilated. If not, an attic may develop a mildew odor and could become extremely hot. It could reach 150°F (66°C) on a hot summer day. This would make it difficult to maintain comfortable temperatures in the rest of the structure.

Attics are commonly ventilated using louvers or vents. Often a building will have upper and lower vents to allow the flow of natural convection. Upper vents may be ridge vents, gable vents, or different types of ventilators installed through the roofing. Lower vents are usually soffit vents. These methods allow fresh air to enter and internal air to escape. At the same time, through the inclusion of louvers and screens in these openings, water, insects, and other objects are prevented from entering the vented attic, **Figure 29-7**.

Ideally, a vented attic will have soffit vents and at least one of the other types of upper vents (gable, ridge, or ventilator). This arrangement takes advantage of natural convection, allowing hot air to flow out the upper vents and cooler air to flow in through the soffit vents.

Since not all buildings are constructed to have soffit vents, other methods may be employed to promote airflow. Fans may be used to increase the circulation of air through a vented attic. A ***gable fan*** is a fan installed at a louvered gable opening of a vented attic. It can be arranged to either blow into the attic or draw air out of the attic. If blown inward, a gable fan pressurizes the attic, so that hot air flows out of the vents, as cooler air is blown in through the gable. If arranged to blow outward, a gable fan draws hot air out of the attic, and cool air is drawn in from the other vents.



Goodheart-Willcox Publisher

Figure 29-7. Ridge vents, gable vents, soffit vents, and roof ventilators all work together to promote air circulation in a vented attic.

Another method of mechanically venting an attic uses a whole house fan. A ***whole house fan*** is a high-volume fan that is placed between the conditioned space and a vented attic. It may also be referred to as an *attic fan*. A whole house fan is generally used when outdoor air is cool but indoor air is warm or stuffy. This may occur in evenings after a sunny day during certain seasons. Occupants open the windows of the building and then turn on the whole house fan. The whole house fan blows indoor air into the attic. This removes the warm, stuffy air from the conditioned space and blows the hot air out of the attic. Cool air from outdoors is drawn into the building by the whole house fan.

Thinking Green

Free Cooling by Whole House Fan

During certain seasons under the right conditions, a whole house fan provides a building with free cooling. When outdoor air is cool and indoor air is warm or stuffy, a whole house fan can blow out the hot air and draw in the cool air. Running just the whole house fan (instead of the blower and compressor) is an economical way of managing indoor temperature.

Whole house fans have large capacities, ranging from 1000 to 4000 cfm. It is desirable to have a fan large enough to make the needed air changes. A complete change of air should be made in the attic every 8 to 10 minutes.

Example:

An attic measures 30′ × 60′ with an 8′ ceiling. An exhaust fan with a capacity of 1440 cfm is installed. Calculate the number of air changes per hour.

Solution:

$$\text{Volume of attic} = \text{Length} \times \text{Width} \times \text{Height}$$
$$= 60' \times 30' \times 8'$$
$$= 14{,}400 \text{ ft}^3$$

$$\text{Time for complete air change} = \frac{\text{Attic volume}}{\text{Fan capacity}}$$
$$= \frac{14{,}400 \text{ ft}^3}{1440 \text{ cfm}}$$
$$= 10 \text{ min}$$

$$\text{Air changes per hour} = \frac{1 \text{ hour}}{\text{Time for complete air change}}$$
$$= \frac{60 \text{ min}}{10 \text{ min}}$$
$$= 6$$

Copyright Goodheart-Willcox Co., Inc. 2017

The fan described in this example would completely change the air in the attic every ten minutes, providing six air changes per hour.

29.3.3 Basement Ventilation

Because basements tend to be cool and damp in the summer, mold and odors in those spaces are frequent problems. How to handle this situation is highly dependent on outdoor air conditions.

If outdoor air is dry, an exhaust fan can be installed in the basement to reduce dampness and mold growth. The fan should remove air from the floor level of the basement and exhaust it outdoors. One method of installing an exhaust fan is to remove a basement window pane and install the fan with an inlet duct leading down to floor level. However, running just an exhaust fan in this way could lead to negative pressure in the building. Also, if any resulting incoming air is hot, indoor temperature could rise. Remember that hot air naturally rises. Hot replacement air from outdoors that enters the basement could rise and affect temperature on the ground floor and upstairs.

If outdoor air is hot and humid, exhausting the basement could just replace the cool, damp air with hot, damp air. This would be a net loss and not solve the problem of high humidity. If the basement is already tied in with a forced-air cooling system, the air conditioning may be able to reduce the humidity. However, a cooling cycle may not run for a long enough period of time to reduce humidity levels in a basement. If this is the case, consider running a dehumidifier in the basement. This should reduce humidity and help to prevent mold growth.

While basement ventilation is necessary in many cases, every aspect and contributing factor to a given situation should be considered. These include outdoor air temperature, outdoor air humidity, type of HVAC system in the building, type of construction of the building, power consumption levels, initial investment costs of each available option, long-term cost of operating each option, and desired basement climate.

29.4 Air Ducts

Ducts are passageways that circulate and distribute air to and from a conditioned space. Ducts work on the principle of air pressure difference. If a pressure difference exists, air moves from higher pressure areas to lower pressure areas. The greater this pressure difference, the faster the air will flow.

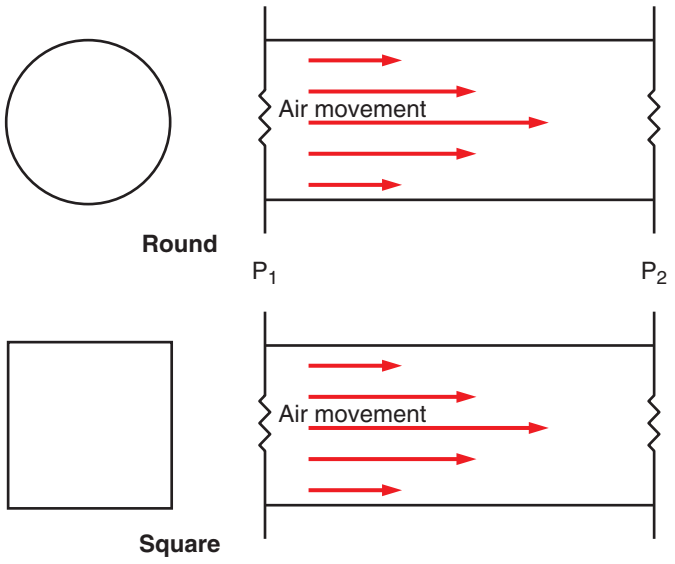
Ducts can be made of many different materials. They are usually constructed from sheet metal or some other noncombustible material. Air pressure in the ducts is small, so materials with a great deal of strength are unnecessary. Air ducts were originally made of thin, tinned sheet steel. Later, galvanized sheet steel, aluminum sheet, and insulated ducts were developed.

Ducts can have round, square, rectangular, or oval cross-sections. Round ducts are more efficient because less material is needed for the same capacity as square or rectangular ducts. The round design also reduces resistance to airflow. Since round ducts have less surface area, the air inside the ducts is less prone to heat loss or heat gain. However, square or rectangular ducts conform better to building construction. They fit into walls and ceilings better than round ducts. Also, it is easier to install rectangular ducts between joists and studs than it is to install round ducts with the same capacity, **Figure 29-8**.

Tables are available that compare the carrying capacities of rectangular and round ducts. There are several round duct equivalent sizes from which to choose. The one selected depends on the one-side dimension desired. For example, ducts 11″ high may be desired to improve appearance. They may be needed to fit in between joists (a 14″ distance), **Figure 29-9**.

29.4.1 Types of Duct Systems

Air ducts deliver air to a room or rooms. They then return the air to the heating (furnace) or cooling (evaporator) system. **Figure 29-10** shows a typical



Goodheart-Willcox Publisher

Figure 29-8. Duct shapes can vary. As indicated by the red arrows, the closer the air is to the duct wall, the slower the flow. P_1 and P_2 indicate pressure along a duct. To create airflow, P_1 must be greater than P_2.

residential air duct system. There are several types of supply duct systems. Some installations are a combination of different types. Supply duct systems can be categorized as follows:

- Radial duct system.
- Extended plenum system.
- Reducing trunk system.
- Perimeter loop system.
- SDHV (small duct, high-velocity) system.

Duct systems may be installed in basements, crawl spaces, attics, false ceilings, and other structural cavities. Ducts may be installed in concrete floors (slabs) of homes without basements. Ducts are usually insulated if the duct system is in a crawl space or attic. Otherwise, heat gain or loss would be too great, depending on the season. **Figure 29-11** shows the basic designs of conventional supply duct systems.

In basements, the main duct is run across and just under the floor joists. Branch ducts are then run between the joists to the diffuser openings. Return ducts usually use the joists and the floorboards for three sides of the branch ducts (panned joist space). Then the main return duct is run alongside the conditioned air duct.

Ducts installed in a concrete slab are usually made of metal, plastic, or ceramic. The ductwork can be laid out and the slab poured over it. The branch ducts usually connect to a perimeter duct. Diffusers are connected to the perimeter duct at intervals along the floor. Downflow furnaces are used with perimeter loop duct systems. In a downflow furnace, return air enters at the top of the furnace and supply air exits at the bottom of the furnace.

Supply and return air ducts and branches are often secured to a building's structural components. This can be done a variety of ways. Any method used should avoid constricting airways. Common supplies used to secure ducts in place include straps made of metal, iron, woven polypropylene, or wire, **Figure 29-12**.

Some buildings are designed with unit ventilators. The ventilator removes older stale air and replaces it with fresh oxygenated air by automatically drawing air from the conditioned space. The ventilator simultaneously brings in makeup air from the outside. These two streams of air pass by each other. In doing so, heat is transferred into the makeup air as it enters the building.

False ceilings are often used to conceal piping, wiring, heat exchangers, and ducts. The false ceiling may have holes to allow movement of conditioned air into the room below. Diffusers may also be used. Space between the false ceiling and the real ceiling may be used as a conditioned return air plenum chamber. Some systems use heated panels to provide radiant heating. See **Figure 29-13**.

29.4.2 Duct Construction

Ducts may be made of metal, wood, fiberglass, ceramic, or plastic materials. Metal ducts are used for warm air distribution and for exhaust air ducts. The metal is usually sheet steel coated with zinc, which is known as galvanized sheet metal. Galvanized sheet metal is used because it is inexpensive, strong, and corrosion-resistant. Some ducts are made of aluminum to reduce weight.

Code Alert

Duct Material

Some building codes do not approve of ducts made of aluminum, fiberglass, or plastic due to fire hazard. Many flexible ducts made of wire and fabric are also not permitted if fire could spread through them to other areas. Check with local authorities having jurisdiction for building codes before installing ductwork.

Sheet metal work is a specialty trade and is done by skilled sheet metal workers. Sheet metal brakes and formers are used for making ducts. While shops may use machines to form ductwork, some assembly and other work must still be done by hand. Sheet metal workers will need to become proficient in the use of various hand tools, such as snips and seamers, **Figure 29-14**.

Sheet metal ducts expand and contract as they heat and cool. Fabric joints are often used to absorb this movement. Fabric joints can also be used where ducts fasten to a furnace or air conditioner. This prevents most fan and furnace noise from traveling along the duct metal. However, most duct joints are made of sheet metal because fabric joints may present a fire hazard.

Round ducts are often made of flat sheets that are formed into a circular shape with ends locked together. Keeping these pieces as flat sheets saves space during transportation. Different seam locking methods makes assembly easy and quick, **Figure 29-15**.

To install a length of round duct as a branch supply, cut a hole in the plenum. Always begin by taking measurements and determining where everything will go prior to making any cuts, **Figure 29-16**.

Round ducts connect to plenum using ***starting collars***. These are couplings used to join round ducts to a square duct or plenum. Starting collars have a tabbed end that is inserted into the plenum and a crimped end over which is inserted the plain end of a round duct. The tabs are bent to grip the inside of the plenum. Use sheet metal screws to secure the starting collar and mastic to seal the joint, **Figure 29-17**.

Figure 29-17. A starting collar connects a round duct to a plenum.

Round ducts have a plain end and a crimped end. To join two lengths of round ductwork, the crimped end of one round duct is inserted into the plain end of another round duct, **Figure 29-18**.

Two lengths of round ducts are secured together using sheet metal screws that penetrate the overlap of the two ducts. Round ducts should be installed so that airflow is going in the direction of the crimped end of a round duct. This reduces the chance of air leakage if the ducts are not sealed with mastic. Elbows and other connections for branches are designed using geometric principles. Several types of duct connections are shown in **Figure 29-19**.

Though round ducts are often used as supply air branches, square ducts can also be used for branch supplies. Take measurements, determine locations, and mark out the cut before cutting, **Figure 29-20**.

Goodheart-Willcox Publisher

Figure 29-19. These typical branch duct designs are used to split or redirect airflow in the ducts.

Lengths of square ductwork can be connected using a variety of joints. This often depends on the sheet metal fabricator and the machines used in their shop, **Figure 29-21**. Joints should be airtight and strong. Joints may be riveted for added strength and tightness. **Figure 29-22** shows a pop rivet tool that can be used to rivet from one side only.

A pop rivet is often called a "blind" rivet. A—Riveting tool. B—Riveting procedure. When the pop rivet is fully expanded, the rivet pliers pinch or cut off the rivet stem. In some cases, the technician may need to finish breaking off the stem.

Copyright Goodheart-Willcox Co., Inc. 2017

Riveting a Joint Using a Pop Rivet Tool

To use a pop rivet tool to rivet a joint:

1. Align the two pieces of metal to be joined.
2. Drill a hole through both pieces of metal.
3. Place the rivet blank in the hole, with the nail-like stem facing outward.
4. Slide the nose of the tool over the rivet stem until the nose of the tool presses against the head of the rivet.
5. Squeeze the handle, which draws the expander toward the rivet head, expanding the rivet.
6. When the rivet is fully expanded, the rivet stem will break off flush with the rivet head.

Many air distribution systems are leaky, and conditioned air is often wasted by leaking into unconditioned areas. This is wasted energy for the building owner. However, this loss can be prevented by properly sealing ductwork.

Pro Tip

Sealing Ductwork

Never use duct tape to seal ductwork. Ductwork is often located in a home's unvented attic. High temperatures in summer can easily weaken the adhesive of duct tape, causing it to come loose and undoing any seal. Do not use duct tape. Use other stronger methods of sealing ducts, such as metal tape

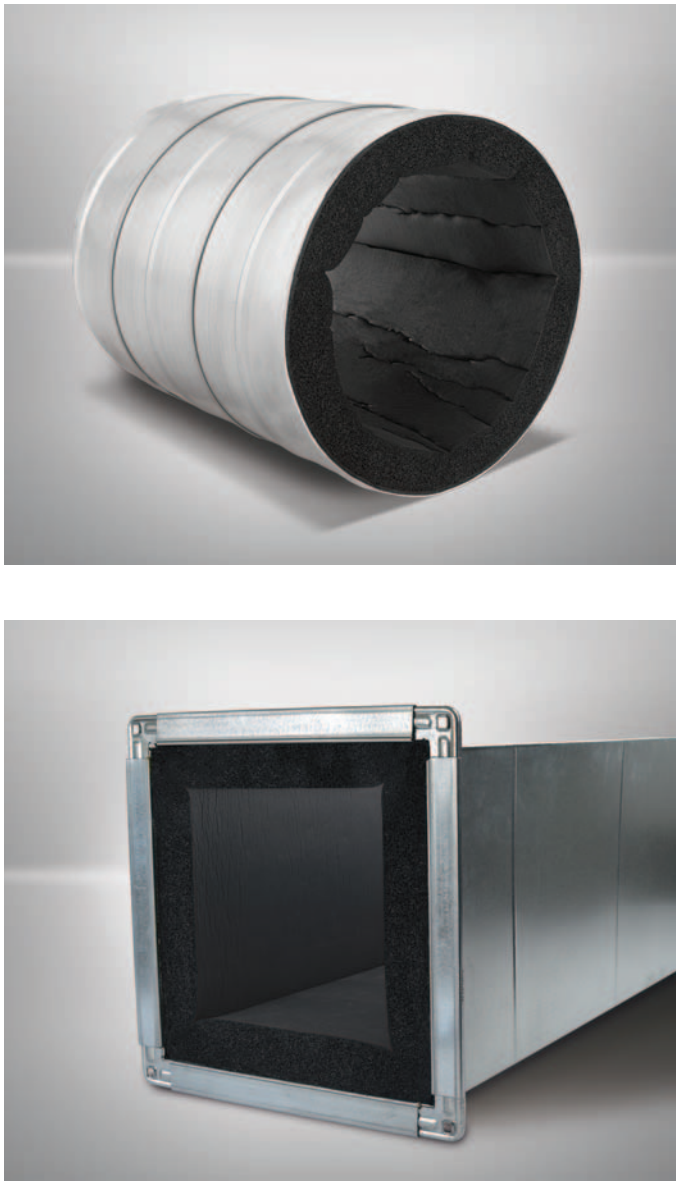
Ductwork should be sealed with mastic sealant or metal tape. These products are stronger and longer lasting than duct tape. They can endure the stress that is so often endured by components installed in unconditioned areas of a building, such as an attic or crawl space.

Using Mastic to Seal a Duct Joint

1. Clean off the surfaces to be joined. Wipe with a dry cloth. If any grease or oily residue is present, use a cleaning solution.
2. With a gap of 1/4″ or less, apply a layer of mastic on the joint and use a brush to work the mastic into the joint. Fill the entire joint with mastic.
3. Spread mastic across the joint about 1″ on each side of the joint.
4. If the gap is more than 1/4″, place a fiberglass reinforcing membrane over the joint. Then apply mastic to fill the gap and cover over the entire membrane.

Duct joints in forced warm air systems should be as leakproof as possible. Leaking joints cut down on the volume of air that is delivered at the end of long runs. Connect all duct sections with good sheet metal joints. Leaks may also make cold air ducts inefficient. Joints and seams in cold air ducts should be sealed the same way they are sealed in warm air ducts.

Many ducts are insulated (either on the inside or outside) to reduce noise as well as heat transfer. Insulation may be added to the inside of ducts of different shapes, **Figure 29-23**.



Armacell LLC

Figure 29-23. Insulation added to the inside of round and square ductwork.

Copyright Goodheart-Willcox Co., Inc. 2017

Installing Insulation into Square Ductwork

1. Take measurements of the ductwork.
2. Cut insulation to appropriate size.
3. Wipe ductwork surface dry. If any grease or residue is present, wash with a cleaner and wipe dry.
4. Apply adhesive to the insulation or to the ductwork. Consult insulation manufacturer literature for specifics.
5. Position the insulation into place straight, flat, and even. Apply pressure evenly to ensure good adhesion between insulation and duct surfaces.
6. Continue following these steps until all surfaces are dry, clean, and insulated to satisfaction, **Figure 29-24**.

When insulation is added to the outside of a duct, it may be fastened with adhesives or metal clips. Rolls of insulation can be wrapped around the outside, **Figure 29-25**.

Some ducts do not require the addition of insulation, because they are manufactured already insulated. These ducts are made with a metal inner wall and a metal outer wall. In-between each metal wall is insulation and sound absorbent material, **Figure 29-26**.

Figure 29-26. Round duct with insulation sandwiched between an inner and an outer metal jacket.

If duct systems are noisy, the air velocity may be too high, there may be turbulence, or the metal edges of the duct may be producing noise. Some ducts are lined with an acoustic material to provide a quieter duct system. Duct sections equipped with silencers are also available. Such units act as mufflers.

Recent years has seen a different style of metal ductwork being used more frequently. Spiral ducts are available in round, oval, and flat oval shapes. These metal ducts are formed to have a spiral seam that wraps around the outside of the duct its whole length. These ducts can be manufactured with fittings that provide a high level of air-tightness and a labor-savings advantage over some traditional ducts, **Figure 29-27**.

29.4.3 Fiberglass and Other Nonmetal Ducts

Some ducts are made of nonmetals, such as fiberglass, urethane, plastic, or sheetrock. ***Ductboard*** is a compressed fiberglass panel that can be easily cut with a knife and formed into a square or rectangular shape. The fiberglass provides good insulation and a fairly solid body to serve as ductwork, **Figure 29-28**.

Used by permission of Mestek Machinery

Figure 29-27. Round and flat oval spiral ducts.

Copyright Goodheart-Willcox Co., Inc. 2017

Some nonmetal ducts have a flexible nature that may be used for gradual bends. This is needed when connecting air ducts to diffusers or when routing air ducts through spaces with obstructions. Textile ducts may be used for high volume air movement in large commercial applications, **Figure 29-29**.

Safety Note

Nonmetal Duct Materials

Duct material must not release any loose material into the airstream. Ducts made of asbestos or fiberglass should be plastic-coated. Asbestos fibers and fiberglass particles released into the air are harmful to health.

Round ducts made of nonflammable plastic and spring-steel wire are often used. They need no elbows and are easily installed around other piping, beams, and joints. This type of duct generally relies on self-inflation.

Figure 29-29. This ice skating rink uses a combination of traditional sheet metal ductwork and textile ductwork.

The duct inflates when the blower is moving air through the systems. The duct deflates when no air is being moved, **Figure 29-30**.

29.4.4 Duct Dimensions

Any transition in the size of a duct should be tapered. When reducing the size of a round or rectangular duct, the taper should be approximately 1″ for every 4″ in length. When the duct is being enlarged, increase the cross-sectional dimensions of the duct 1″ for every 4″ to 7″ of length.

The sizes of rectangular ducts must be carefully chosen. The width and height dimensions should not be much different. The ratio of a duct's wide side to its

DuctSox Corporation

Figure 29-30. Textile duct being used in an underfloor application.

Copyright Goodheart-Willcox Co., Inc. 2017

narrow side is called the ***aspect ratio***. For example, if a duct is 18″ wide and 6″ tall, its aspect ratio is 18 to 6 (written 18:6), which can be reduced to 3 to 1 (3:1).

An aspect ratio of 1:1 provides the smallest perimeter for any given cross-sectional area. This is desirable because it maximizes the duct's capacity while minimizing its material requirements. Multiplying the cross-sectional area times the length of the duct yields the duct's volume. When you multiply the duct's perimeter by its length, you get the surface area of the duct. As you will recall, the surface area represents the amount of material required to construct the duct. Therefore, a rectangular duct with a 1:1 aspect ratio can hold the maximum amount of air using the minimum amount of material.

The following example shows how more metal is used as the aspect ratio increases: Assume a duct is 10″ × 10″ (aspect ratio 1:1). It has a cross-sectional area of 100 in^2 while the distance around (perimeter) is 10″ + 10″ + 10″ + 10″ = 40″. Another duct with a cross-sectional area of 100 in^2 is made 20″ wide and 5″ deep. The perimeter of this duct is 20″ + 5″ + 20″ + 5″ = 50″, or a 25% increase in metal for each unit of length. Sheet metal contractors classify ducts by their aspect ratios and estimate costs by class. **Figure 29-31** lists some common duct aspect ratios.

A duct should not be placed in a stud or joist space when its size is equal to the inside dimensions of the space. There must be room for fittings and clearance for alignment and expansion. The recommended clearance varies with the type of system. **Figure 29-32** illustrates a satisfactory duct clearance between floor joists. **Figure 29-33** lists the recommended gauge thickness for various sizes of round ducts and rectangular ducts.

Ducts going through floors should be protected on the corners by angle iron. Large sections of sheet metal or ducts must be cross-broken in the shop to reduce panel vibration. Cross-breaking the large panels prevents ***oil canning*** (the sound of expanding and contracting) when the blower starts and stops, **Figure 29-34**.

Duct Aspect Ratio

Duct Class (Aspect Ratio)	Wide Side (in)	Perimeter (in)
1 (1:1)	6–18	24–72
2 (2:1)	12–24	36–72
3 (3:1)	26–40	70–106
4 (4:1)	24–88	60–220
5 (5:1)	48–90	116–216
6 (6:1)	90–144	210–336

Continental Industries, Inc.

Figure 29-35. Registers generally have fixed vanes with movable deflectors to direct airflow.

29.4.5 Registers, Diffusers, and Grilles

The fixtures that cover duct openings serve two purposes. They control airflow out of the duct and prevent large objects from entering the duct. There are several different types of fixtures.

Registers deliver concentrated airstreams into a room. Many have one-way or two-way adjustable airstream deflectors. The deflectors can be adjusted to change the direction of the airflow into the room, **Figure 29-35**.

Thinking Green

Sealing Registers

Any registers with ductwork that passes from unconditioned spaces into conditioned spaces should be sealed to the drywall or subfloor. This will reduce heat leakage and improve system efficiency.

Diffusers are located on the supply side of the duct system. They diffuse, or spread, the air leaving the duct more uniformly than registers do. Diffusers deliver widespread, fan-shaped flows of air into a room. Some diffusers cause the duct air to premix with some room air before leaving the diffuser, and some diffusers have adjustable dampers. A ceiling-mounted air diffuser directs air in several directions along the ceiling, **Figure 29-36**.

Grilles are nonadjustable fixtures used to cover return duct inlets. Grilles offer some resistance to airflow, blocking about 30% of the air. For this reason, the duct cross section is usually enlarged at the grilles. This enlargement also slows air movement and reduces noise.

RectorSeal

Figure 29-36. Diffusers have fixed vanes that are designed to direct airflow in different directions.

Pro Tip

Registers, Diffusers, and Grilles

The terms register, diffuser, and grille are often used interchangeably. However, there are distinctions that should be noted. Be mindful when using these terms in conversation with HVACR professionals and customers. Make sure everyone understands to which component you are referring.

29.4.6 Dampers

Controlling airflow is necessary in forced-air systems. Without this control, some spaces would receive too much air, while others would receive too little. Airflow through ducts can be controlled and adjusted by duct dampers. Duct dampers can be adjusted to balance airflow. They can also open and close certain ducts for zone control. Three commonly used types of dampers are multiple-blade, butterfly, and split dampers.

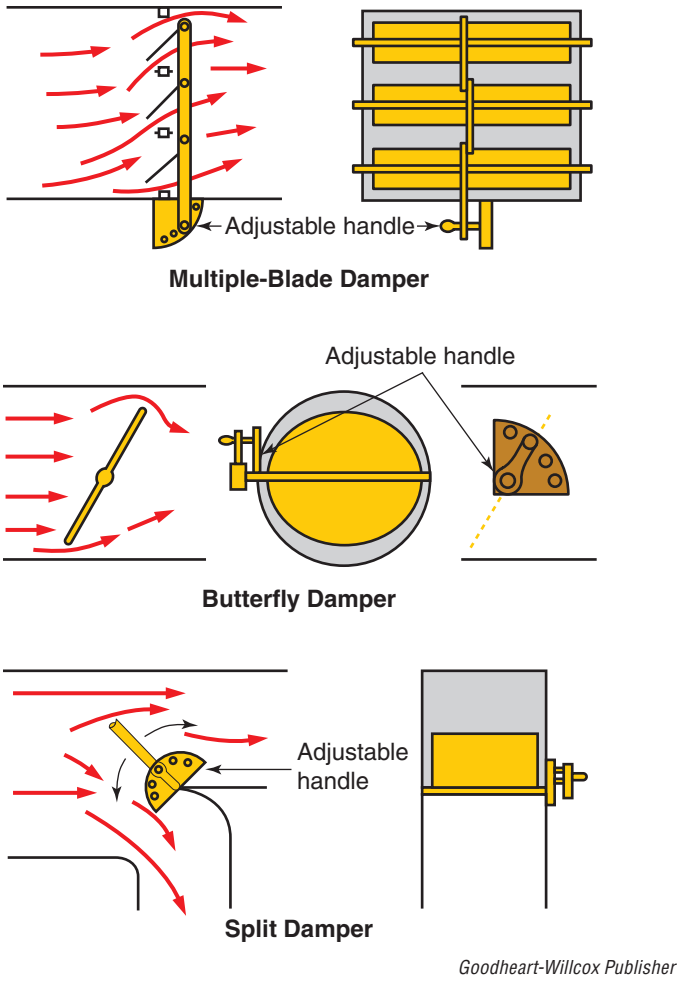
A ***multiple-blade damper*** is used primarily in square or rectangular ducts to restrict or completely shut off airflow to a room or zone. This type of damper can usually be operated manually or by using an electric or pneumatic actuator.

A ***butterfly damper*** is used in round ducts to control airflow. It is usually opened and closed using a manual control handle, but some may be operated by an automatic actuator. A ***split damper*** is used where an air path branches off (splits) in two directions. As the damper moves, it closes off one branch of the duct to airflow and opens the other branch. This decreases airflow in one branch while increasing airflow in the other branch. **Figure 29-37** illustrates examples of each type of damper.

Pro Tip

Damper Installation

When installing a damper, always draw a line on the end of the damper shaft that extends out of the duct, showing damper position. Labels may help show the position of the damper blades.



Goodheart-Willcox Publisher

Figure 29-37. Dampers adjust airflow volumes to help achieve a balanced system. These three types of dampers are butterfly, multiple-blade, and split.

Damper Controls

Many dampers are automatically controlled for either zone heating or cooling. Automatic controls are used for humidity control or for temperature control. Automatic controls are also used to mix two airflows for either fresh air or recirculated air mixes. These multiple dampers are interlocked by controls to provide different mixes and to maintain correct total airflow. **Figure 29-38** is a diagram of typical damper installations.

Automatically controlled dampers open and close based on a thermostat's signal. Damper position may be regulated by electric motors, pneumatic motors, hydraulic motors, or solenoids, **Figure 29-39**.

If outside air is too cold, thermostats cause power-operated devices to close the outside air damper. Thermostats also react if the recirculated air and outside air are out of balance. They operate actuators that open one damper and close the other just enough to produce the correct mix. These actuators are usually operated electrically or pneumatically.

Often dampers are held in a closed position by springs. When a damper must open, the thermostat controls a motor to open the damper as much as needed. The torque from the motor overcomes the spring pressure holding the damper closed. The motor continues to hold the damper open until the thermostat sends a signal to close the damper. Spring pressure then closes the damper. The motor operates the damper through a gear reduction train.

Control devices that regulate air volume in a distribution system are called variable air volume (VAV) controllers. These electronic devices are usually part of a larger computer-controlled HVAC system. On VAV systems, actuators use either pneumatic or electronic control for opening and closing of a damper, based on room temperature. The thermostat modulates the actuator to open or close the damper, allowing more or less heating or cooling to the conditioned space. The advantage is that the room will have less of a temperature swing, unlike with constant air volume systems.

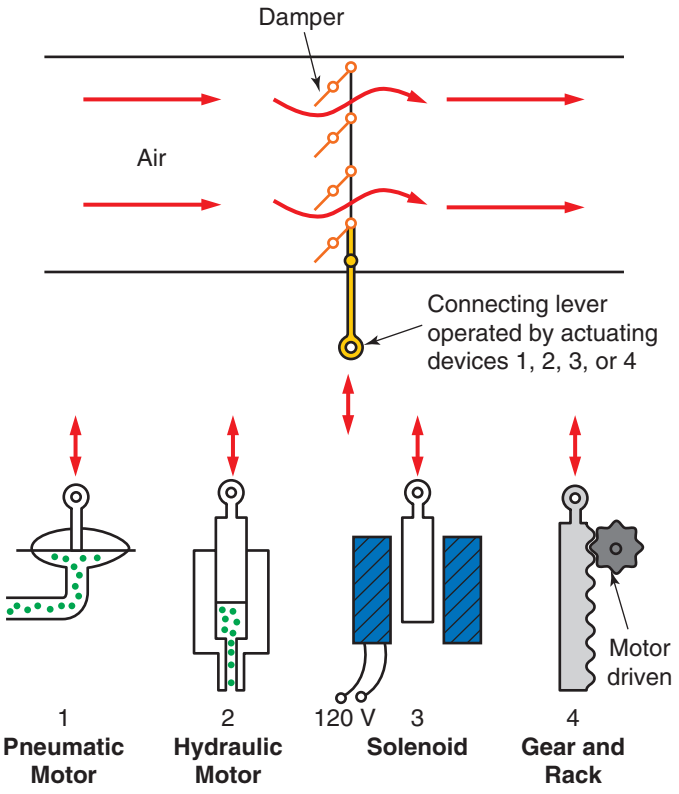
Goodheart-Willcox Publisher

Figure 29-38. Dampers can be used to control airflow for a variety of purposes. A—Dampers can open and close a bypass to control temperature and relative humidity. B—Dampers can control fresh air intake, exhaust air, and the blend of recirculated and fresh air. C—Dampers can control airflow over cooling or heating coils to maintain a precise temperature.



Goodheart-Willcox Publisher

Figure 29-39. A duct damper for controlling airflow can be operated by different types of power devices. Four ways to control damper action are shown.

Fire Dampers

Automatic fire dampers should be installed in all vertical ducts in commercial and industrial buildings. Ducts, especially vertical ones, will carry fumes and flames from fires. Fire dampers maintain the required rating of fire-related barriers, such as walls, doors, and floors, when they contain ductwork. These dampers are designed to close automatically on detection of heat. Airflow is stopped, and the passage of flames is limited. Automatic fire dampers should be inspected and tested at least once a year to ensure that they are in good operating condition.

Ducts passing through a firewall must have fire dampers. Hour ratings for fire dampers must be 75% of the hour rating for the wall, floor, or partition. For example, a fire damper rated for 1.5 hours is used in a fire barrier rated for up to 2 hours.

There are two types of fire dampers: static fire dampers and dynamic fire dampers. Static dampers are used in duct systems where there is little or no airflow when the damper closes. Dynamic fire dampers are required at locations in which fan pressure will be on during a fire. These units are expected to close against the air velocity and pressure produced by the system fan.

Fire dampers are assigned one of the following rating classifications based on their performance:

- Class A—This classification of fire dampers will hold back a fire indefinitely.
- Class B—This classification of fire dampers can be used when a two- to four-hour hold is required. This class is approved for most general installations.
- Class C—Fire dampers in this class are used where a one-hour hold is required.

SMACNA (the Sheet Metal and Air Conditioning Contractors' National Association, Inc.) publishes *Guideline on Through-Penetration Firestopping*. This document provides guidance regarding the installation of ductwork. Vertical ducts serving two or more floors must be enclosed in a fire partition. Fire dampers must be installed in the ducts. However, ducts of less than 20 in^2 (129 cm^2) area do not require a fire damper.

Copyright Goodheart-Willcox Co., Inc. 2017

Fire dampers are usually held open by a fusible link. Heat will melt the link. The damper will close either by gravity, weights, or springs. Some fire dampers have electronic sensors that operate a closing mechanism. The damper blade latches may use power to close the damper. Electric power devices may also be used to close the damper. Smoke dampers use a photoelectric device to detect smoke. An electronic device will trip a holding device and the damper will close.

Code Alert

Fire Dampers

Before installing ducts, check local fire damper regulations. Make sure that any necessary fire and smoke dampers are installed. Install the dampers in strict adherence to the manufacturer's instructions.

29.4.7 Elbows

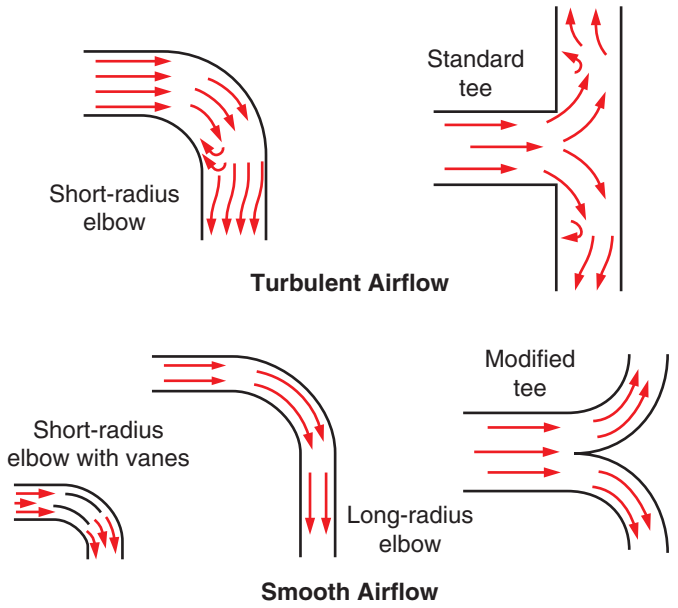
Elbows are 90° bends (unless otherwise specified) in the ducts. Airflow direction is diverted from a straight line using elbows. A variety of elbows are available for different types of ductwork. Round ducts often use adjustable elbows that can change bend angle by rotating the interlocking parts, **Figure 29-40**.

Air has inertia, which is to say it has mass and it obeys Newton's laws of motion. Once set in motion, air continues moving in the same direction until it is forced to change. In addition, air is compressible. On turns, therefore, it crowds toward the outer side of the elbow, as shown in **Figure 29-41**.

When airflow changes direction, it slows down, compresses, and becomes turbulent. The more abruptly the airflow changes direction, the more compressed and turbulent it becomes. The increased turbulence decreases the efficiency of the ventilation system. However, turbulence can be minimized and airflow velocity can be maximized by making the directional changes more gradual by installing long-radius elbows. If short-radius elbows must be used, turbulence can be minimized by using an elbow with built-in directional vanes.

Used by permission of Mestek Machinery

Figure 29-40. Round duct elbows have interlocking parts that can be twisted to change the direction and angle of the bend.



Goodheart-Willcox Publisher

Figure 29-41. To minimize turbulence and maximize airflow, make any directional changes in the ductwork as gradual as possible or use elbows that include guiding directional vanes.

29.5 Duct Sizing

In order for a heating or cooling system to function properly, the ducts supplying the conditioned air must be sized correctly. The duct sizes and damper settings determine the amount of conditioned air delivered to each room. The amount of air delivered must be balanced with the room's heating and cooling loads.

Another concern when designing a duct system is noise. Noise can become a problem if air travels through the ducts too quickly. A table of recommended maximum duct velocities is in **Figure 29-42**.

Code Alert

Duct Sizing

Both the *International Residential Code* (*IRC*) and the *International Mechanical Code* (*IMC*) require residential duct sizes to be determined in accordance with ACCA's *Manual D—Residential Duct Systems* or another approved method. This section provides only a simplified overview of duct sizing. Refer to ACCA's *Manual D* for complete duct sizing information.

Figure 29-42. Recommended maximum airflow velocities for the supply and return of main and branch ducts. This table shows values for various types of buildings.

29.5.1 General Duct Design Guidelines

When designing a duct system, keep the following general rules in mind:

- Install the air handler (blower) in a central location. By installing the air handler near the center of the building, the lengths of the longest supply and return ducts are minimized.
- Keep duct runs as short as practical. Position ducts to avoid obstacles and minimize the number of fittings required.
- Never install a duct in the end of a plenum. Always install ducts in the sides of a plenum. A duct in the end of a plenum will receive too much airflow.

29.5.2 Duct Sizing Procedure

The steps in the following duct sizing procedure are described in greater detail in this section.

Duct Sizing Procedure

1. Obtain room-by-room heating and cooling load calculations.
2. Obtain blower data "spec sheet" for the system equipment.
3. Determine the external static pressure (ESP) for the system using the blower data sheet.
4. Calculate the device pressure losses (DPL).
5. Calculate the available static pressure (ASP).
6. Prepare a rough sketch of the duct system, including register and grille locations, distances, and duct fittings.
7. Calculate the total effective length (TEL) for the duct system.
8. Calculate the design friction rate for the system.
9. Calculate the design air quantity for each room and each section of ductwork.
10. Use an airflow friction chart or duct calculator to determine duct sizes for each section of ductwork.
11. If needed, convert circular duct diameter to an equivalent rectangular duct size.

Pro Tip

Duct Sizing Tools

In practice, duct systems are typically sized using worksheets, spreadsheets, apps, and computer programs. These tools simplify the process of duct sizing. However, in order to use these tools correctly, you must understand the steps in the process and the information that determines the duct sizes.

Before sizing a duct system, you must first know the heating and cooling loads for the house and you must have information about the blower fan selected for the installation.

Copyright Goodheart-Willcox Co., Inc. 2017

Room-by-Room Heat Loads	
Room	**Heat Load (Btu/hr)**
Living room	25,000
Dining room	15,000
Kitchen	5000
Bathroom	8000
Bedroom #1	15,000
Bedroom #2	12,000
Total for house	**80,000**

Goodheart-Willcox Publisher

Figure 29-43. Example of heat loads for a small house.

Heating and cooling load calculation is discussed in Chapter 37, *Heating and Cooling Loads*. The heating and cooling loads for each room are added to determine the total load. The loads are expressed in units of Btu/hr. The total heating and cooling loads are used to select the correct size of the heating and cooling equipment. **Figure 29-43** shows an example of heating loads for a small house.

The airflow through the blower depends on the speed of the blower and the pressure difference between the blower inlet and outlet. The blower manufacturer provides a specification sheet listing the airflow of the blower under various conditions. **Figure 29-44** shows an example of the information provided on a specification sheet.

Pro Tip

Blower Specification Sheets

When using a blower specification sheet to determine the design external static pressure, use the medium blower speed airflow values.

The pressure difference between the blower inlet and outlet is the ***external static pressure (ESP)***. External static pressure is determined by the duct system. In turn, the external static pressure determines the volume of air delivered by the blower. Thus, the duct system must be designed to achieve the external static pressure that will result in the blower motor delivering the correct air volume.

If the external static pressure is too great, the blower will not deliver enough air to match the loads. If external static pressure is too low, the blower will deliver more airflow than is needed.

Pro Tip

External Static Pressure

You can think of external static pressure as the amount of resistance the air must overcome in traveling from the blower outlet, through the evaporator coil, supply duct, supply register, return grille, return duct, and filter before returning to the blower inlet. The greater the number of obstructions and distances along this path, the greater the external static pressure.

Example:

The blower with the specifications listed in **Figure 29-44** is being installed in a system with a design airflow of 1250 cfm. What external static pressure should be used for the duct system design?

Solution:

Use the medium fan speed row. Read across the row and find the design airflow of 1250 cfm. Then read up the column to find the corresponding external static pressure, which is 0.5 in. WC.

Determining Available Static Pressure

After the required external static pressure is determined based on the blower data, the next step in the duct sizing process is to determine the available static pressure. The ***available static pressure (ASP)*** is a measure of the amount of friction or resistance the ductwork is designed to provide to the flow of air. This is used to design the longest duct run.

Device pressure losses (DPL) are pressure losses in the duct system caused by devices other than ducts. **Figure 29-45** shows examples of some typical items considered when determining device pressure losses.

Blower Airflow (cfm)										
Blower Speed	**External Static Pressure [in. WC (water column)]**									
	0.1	**0.2**	**0.3**	**0.4**	**0.5**	**0.6**	**0.7**	**0.8**	**0.9**	**1.0**
Low	1284	1278	1254	1213	1154	1078	984	873	745	599
Medium	1423	1406	1370	1318	1250	1167	1068	953	823	677
High	1560	1525	1477	1416	1341	1253	1152	1037	909	768

Goodheart-Willcox Publisher

Figure 29-44. Manufacturers provide "spec sheets" showing the volume of air delivered by a blower at various speeds and at various external static pressures. When sizing ducts, use this chart to determine the required external static pressure, which is based on obtaining the design airflow at medium speed.

Copyright Goodheart-Willcox Co., Inc. 2017

Device Pressure Loss	
Item	**Typical Pressure Loss (in. WC)**
Filter	0.08–0.15
Evaporator coil	0.10–0.30
Air cleaner	0.20
Dampers	0.03
Registers, diffusers, grilles	0.03

Goodheart-Willcox Publisher

Figure 29-45. Table listing typical device pressure loss (DPL) values or ranges for air system components.

The available static pressure (ASP) is determined by subtracting device pressure losses (DPL) from the external static pressure (ESP).

$$ASP = ESP - DPL$$

Example:

A system with an ESP of 0.5 in. WC has the following device pressure losses:

- Evaporator coil, 0.15 in. WC
- Damper, 0.03 in. WC
- Air filter, 0.08 in. WC
- Supply register, 0.03 in. WC
- Return grille, 0.03 in. WC

What is the available static pressure for the duct system?

Solution:

Add the values for the various components to determine the device pressure losses (DPL):

$$\begin{aligned} DPL &= 0.15 \text{ in. WC} \\ &\quad 0.03 \text{ in. WC} \\ &\quad 0.08 \text{ in. WC} \\ &\quad 0.03 \text{ in. WC} \\ &+ 0.03 \text{ in. WC} \\ &= 0.32 \text{ in. WC} \end{aligned}$$

Then determine the available static pressure (ASP):

$$\begin{aligned} ASP &= ESP - DPL \\ &= 0.50 \text{ in. WC} - 0.32 \text{ in. WC} \\ &= 0.18 \text{ in. WC} \end{aligned}$$

Determining Total Effective Length

The available static pressure is a measure of the amount of resistance the ductwork is designed to provide to the flow of air. Resistance results from the air contacting the interior surfaces of the duct. The amount of this resistance in the system depends on the length of the duct.

Additional resistance to airflow occurs anytime the air flows through a passage that is not straight or has a change in cross section. For example, when air must pass through a reducer or "turn" as it passes through an elbow fitting, the airflow experiences increased resistance.

Duct systems are designed using the concept of ***effective length***. The effective length of a duct run is determined by adding the physical length of the duct work to effective length values for each fitting in the duct run. The table in **Figure 29-46** shows effective length values for some common duct fittings.

Code Alert

Effective Length for Duct Fittings

ACCA's *Manual D* provides effective length values for an extensive collection of fittings. Minor variations between fittings impact the effective length values. Always check this reference carefully to be sure the fitting being used in the field matches the selection used to determine effective length.

In order to determine the effective length for each supply and return duct run, you must first sketch out the duct system. This sketch must include the locations of all supply registers and return grilles. Also, all fittings required to route the ducts through the house must be included in your sketch. **Figure 29-47** shows a sketch of the supply duct system used to provide air to the rooms described in the earlier example.

Example:

Determine the effective length of the longest duct highlighted in **Figure 29-47**. The effective length of all fittings in the duct run is 114'.

Solution:

The effective length is the physical length of the duct run plus the effective length of all fittings:

Effective Lengths for Common Fittings	
Fitting	**Effective Length (feet)**
Round branch from trunk	20–50
Rectangular branch from trunk	20–75
Supply air boots	20–60
Return air boots	10–20
Return elbow	10–45

Goodheart-Willcox Publisher

Figure 29-46. Effective length ranges for common duct fitting types. Refer to ACCA's *Manual D* for effective length values for specific fittings.

Copyright Goodheart-Willcox Co., Inc. 2017

$$\begin{aligned}\text{Effective length} &= (12' + 2' + 8' + 2' + 4' + 8') + 114' \\ &= 36' + 114' \\ &= 150'\end{aligned}$$

Total effective length (TEL) is the greatest effective length for a supply duct run in a system added to the greatest effective length for a return duct run. The total effective length is the length of a straight duct run that would offer the same resistance to airflow as the most restrictive supply and return duct runs on a system.

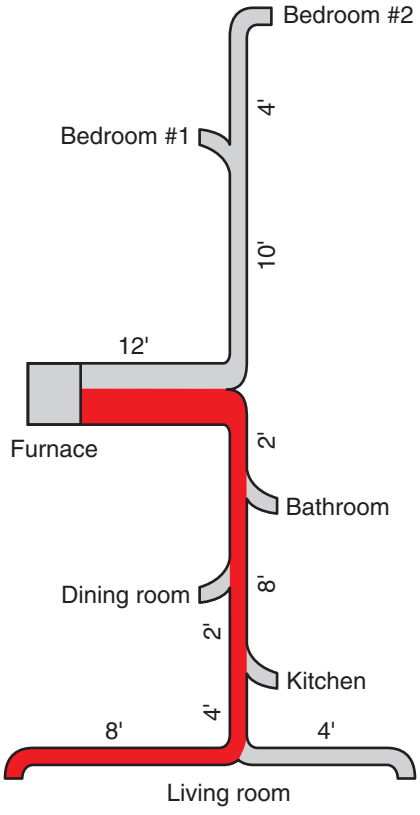
Example:

In the previous example, the effective length of the longest supply duct run was 150′. If the effective length of the longest return duct run in the system is 135′, what is the total effective length for the system?

Solution:

To find total effective length, add the effective lengths of the longest supply and return duct runs:

$$\begin{aligned}\text{TEL} &= 150' + 135' \\ &= 285'\end{aligned}$$



Goodheart-Willcox Publisher

Figure 29-47. A simple duct installation. The longest duct run is shown in red.

Determining Friction Rate

Friction loss in ducts is the pressure drop resulting from the air contacting the inside surface of the duct. For the purpose of duct design, friction loss is typically expressed in units of inches of water column per 100′ of duct.

The ***friction rate*** for a duct system is the friction loss along the total effective length that results in a pressure drop equal to available static pressure. The friction rate is calculated by the following formula:

$$\text{Friction rate} = \frac{\text{ASP (in WC)}}{\text{TEL (ft)} \times 100}$$

Example:

The system used in the previous examples has an available static pressure of 0.18 in. WC and a total effective length of 285′. Determine the friction rate for the duct system.

Solution:

Using the friction rate equation:

$$\begin{aligned}\text{Friction rate} &= \frac{\text{ASP}}{\text{TEL} \times 100} \\ &= \frac{0.18 \text{ in. WC}}{285' \times 100} \\ &= (0.18 \text{ in. WC} \div 285') \times 100 \\ &= 0.0006 \text{ in. WC} \times 100 \\ &= 0.06 \text{ in. WC per } 100' \text{ of duct}\end{aligned}$$

Determining Air Quantity for Each Room

Each duct run is sized based on the specific volume of air flowing through the run. The first step in determining the airflow in each branch is to determine the airflow required for each room. The required airflow for a room is found using the following equation:

$$\text{Airflow (room)} = \frac{\text{Heat load for room}}{\text{Total heat load}} \times \text{Design cfm}$$

This process simply divides the design airflow in proportion to heat loads.

Example:

Determine the room-by-room design air volume for the six rooms listed in **Figure 29-43**. The system has a design airflow of 1250 cfm.

Solution:

$$\begin{aligned}\text{Living room} &= \frac{25{,}000}{80{,}000} \times 1250 \text{ cfm} \\ &= 391 \text{ cfm}\end{aligned}$$

Copyright Goodheart-Willcox Co., Inc. 2017

$$\text{Dining room} = \frac{15{,}000}{80{,}000} \times 1250 \text{ cfm}$$
$$= 234 \text{ cfm}$$

$$\text{Kitchen} = \frac{5000}{80{,}000} \times 1250 \text{ cfm}$$
$$= 78 \text{ cfm}$$

$$\text{Bathroom} = \frac{8000}{80{,}000} \times 1250 \text{ cfm}$$
$$= 125 \text{ cfm}$$

$$\text{Bedroom \#1} = \frac{15{,}000}{80{,}000} \times 1250 \text{ cfm}$$
$$= 234 \text{ cfm}$$

$$\text{Bedroom \#2} = \frac{12{,}000}{80{,}000} \times 1250 \text{ cfm}$$
$$= 188 \text{ cfm}$$

Determining Duct Size

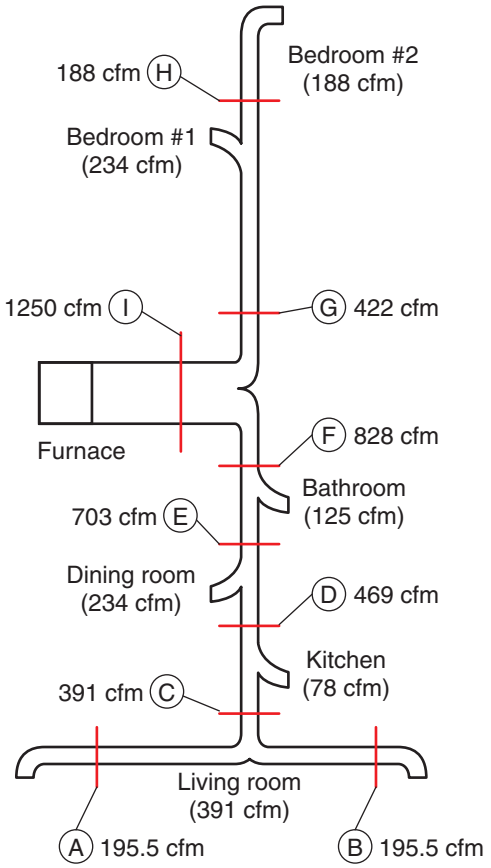
After calculating the airflow requirements for each room, the airflow through each duct section can be determined. See **Figure 29-48**. With the airflow rate and friction rate known, the required duct size can be determined using an airflow friction chart like the one shown in **Figure 29-49**.

Airflow friction charts are a graph of duct diameters, airflow rates, pressure drops from friction, and air velocities. Lines parallel to the vertical red dashed line in the figure represent airflow rates in cfm. Lines parallel to the blue line represent airflow velocities in fpm. Lines parallel to the horizontal yellow line represent pressure losses due to friction, and the lines parallel to the green line represent diameters of round duct. Reading an airflow friction chart is very similar to reading a standard psychrometric chart. If you know any two variables plotted on the chart, you can find their intersection. You can then determine the value of the other two variables.

Sizing Ducts Using the Friction Chart

Given the friction rate and air quantity through a section of duct, use the following procedure to determine the correct duct size.

1. Find the point where the friction rate (left side of chart) intersects the air quantity (bottom of chart).
2. Select either the closer or larger of the duct diameter lines the point falls between. The larger size will result in less friction and more airflow; the smaller size will result in more friction and less airflow.
3. Check the velocity based on the location of the point. Duct air velocities above 700 fpm can cause excessive noise. Air velocities at supply registers greater than 500 fpm may produce drafts. If the velocity is too high, follow the air quantity line down to the next higher duct diameter. If this point is at an acceptable velocity, use the larger duct diameter.
4. For rectangular sections of duct, convert the duct diameter to an equivalent rectangular size using the chart illustrated in **Figure 29-9**.



Goodheart-Willcox Publisher

Figure 29-48. Simple duct sketch with design air quantities noted for each duct section.

Example:

Determine the size of duct diameter to use for the duct cross sections labeled A through H in **Figure 29-48**. The system has a friction rate of 0.06 in. WC/100′.

Solution:

The table in **Figure 29-50** lists the air quantity at each duct section, and the chart shows a point plotted

for each quantity at the design friction rate. The selected duct diameters are listed in the table.

Pro Tip

Duct Calculators

Mobile device apps and programs may be used in place of duct calculators and airflow friction charts. These may be used to determine duct sizes. These tools provide the same basic information.

29.5.3 ACCA Manual D

The Air Conditioning Contractors of America (ACCA) is a non-profit organization of HVAC contractors and professionals. ACCA writes standards and procedures for the design, testing, performance, and installation of HVAC systems. ACCA's ***Manual D*** was developed to be used to design both the supply and return ducts of a building.

The Manual D spreadsheet has worksheet tabs for effective losses, friction rate, and duct sizing. The effective losses for various supply and return fittings are located in group tabs. Each supply and return fitting is assigned an effective length, which is input into the appropriate group line, **Figure 29-51**. The output of the worksheet yields a design total effective length for both the supply and return ducts, **Figure 29-52**.

The total effective length of the supply and return duct systems is input into the Friction Rate Worksheet. Blower cfm and component pressure losses are input by the user to generate a Friction Rate Design Value, **Figure 29-53**.

The duct sizing worksheet requires the input of the heating and cooling load for each supply run. The program will automatically generate duct sizes for

round metal ducts. If rectangular ducts are used, enter the height in the column, and the duct size will be calculated. The last column will show the equivalent size for a flexible duct, **Figure 29-54**.

There are several other alternatives to manual calculation of duct sizing, including duct sizing services, smart phone apps, and tablet calculators. Apps often allow the user to take a screen shot of the final design numbers and save it for future reference. Physical and online duct calculators are popular and easy to use. These allow the user to input basic information to determine duct sizes, **Figure 29-55**.

Smart phone and tablet apps provide the service technician with the mobility to quickly generate duct sizing while on the jobsite. They are also useful to determine if the existing ductwork in a building is sized correctly. **Figure 29-56** illustrates one type of smart phone app.

More detailed duct sizing can be accomplished by using sophisticated software programs. There are several ACCA-approved software programs that utilize Manual D standards. These programs allow the HVAC duct designer to input building configurations, heating and cooling loads, and generate a floor plan that includes duct routing and sizing. Programs are also available that generate a final bill of material and cost estimate for project. The user can customize the duct routing based on the layout of the building. Supply and return trunks can be added or deleted as the program automatically balances the system overall cfm and duct size. **Figure 29-57** shows the duct layout generated by one type of program.

9

29.6 Fans

Air movement is generally produced by some type of fan. Usually, fans are located in the inlet of the air handler. Air can be moved by creating positive pressure. It can also be moved by creating negative pressure. All fans produce both conditions. Negative pressure is generated at a fan's air inlet, and positive pressure is created on the exhaust side of the fan. See **Figure 29-58**. The air flowing into a fan is called ***induced draft*** and the exhaust from a fan is called ***forced draft***.

Fans are constructed of metal and plastic. There are several types of fans, but the two most popular types are the ***axial flow fan*** (propeller fan) and the ***radial flow fan*** (centrifugal fan). If air leaves the fan along the direction the axle is pointing, it is called axial flow. If air leaves the fan at right angles to the axle, it is called radial flow. This is shown in **Figure 29-59**.

ACCA – The Indoor Environment & Energy Efficiency Association

Figure 29-53. Manual D Friction Rate Worksheet.

An axial flow fan is usually direct-driven by mounting fan blades on the motor shaft. These fan blades should be handled carefully. If they are bent or twisted, the fan should be replaced. A four-blade axial flow fan is shown in **Figure 29-60**.

Radial flow fans are commonly referred to as squirrel cage fans. Radial flow fans can be directly driven by a fan motor or can be driven by a belt and pulley system. In direct-drive radial flow fans, the motor shaft is connected directly to the hub of the fan. Belt-driven fans use a pulley on the motor shaft and a pulley on the fan shaft. The ratio of the fan pulley to the motor pulley can be adjusted to multiply torque or to multiply fan speed. A belt-driven radial flow fan assembly is shown in **Figure 29-61**.

The Air Movement and Control Association, Inc. (AMCA) has developed four classifications of fan. These are based on fan air pressure output. Total fan pressure is the pressure differential between the inlet and the outlet of a fan. A chart listing the four classes of fans and their pressure levels is shown in **Figure 29-62**.

Radial flow fans have either backward-inclined blades or forward-inclined blades. Large fans typically have backward-inclined blades. If the blades were forward-inclined, they would not be able to handle the weight of the load. Smaller fans typically have forward-inclined blades. See **Figure 29-63**.

Static pressure increases by the square of the factor of increase in the airflow rate. To determine the increase in static pressure when airflow has increased, first determine the factor by which airflow rate has increased. For example, if a fan's output is doubled from 1000 cfm to 2000 cfm, the factor of increase is 2. This is calculated by dividing 2000 cfm by 1000 cfm.

$$2000 \text{ cfm} \div 1000 \text{ cfm} = 2$$

Next, calculate the square of the factor of airflow rate increase. Since 2 was the factor determined, square the number 2.

$$2^2 = 2 \times 2$$
$$2^2 = 4$$

Lastly, multiply the static air pressure for the original airflow rate of 1000 by the square of the airflow

rate increase (4). In this example, airflow rate doubled, so the square of the increase factor was 4 ($2^2 = 2 \times 2$). If the increase factor was 3, then the square of the factor would be 9 ($3^2 = 3 \times 3$).

Since airflow rate is directly proportional to the speed at which the fan is turning, an increase in the fan's speed also results in an exponential increase in the static pressure produced by the fan. Increasing the static pressure against which a fan must operate reduces the amount of airflow delivered by the fan. **Figure 29-64** shows how to measure the pressure of a fan.

To determine the fan capacity for an air handler, use the following formula:

Output of air handler = 1.08 × temperature rise

The air temperature rise in °F is determined by subtracting the temperature of the air in the return ducts from the temperature of the air in the supply plenum. The 1.08 factor (the density of standard dry air of 0.075 lb/ft^3 × the specific heat of air 0.24 Btu/lb/F × 60 sec/min) is the total external static pressure.

For cooling, blowers are often sized to produce 400 cfm/ton of cooling capacity. For most residential

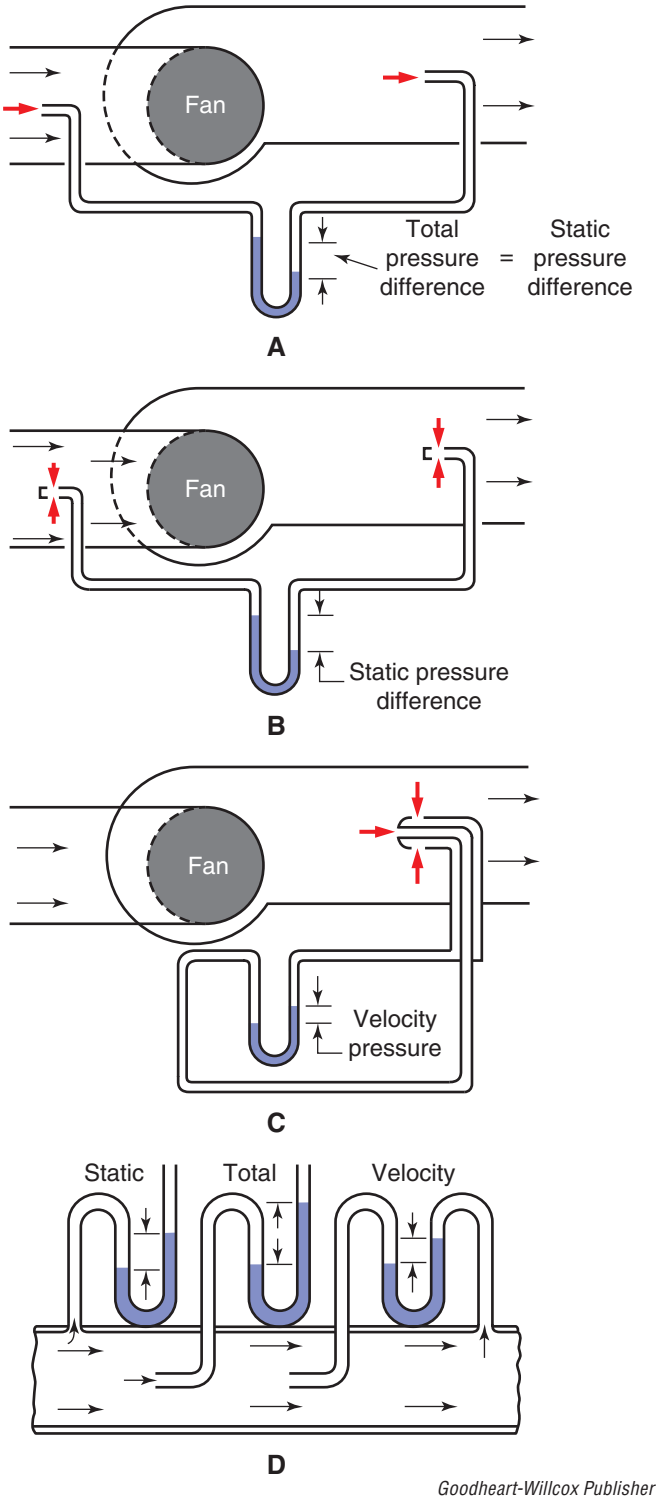
systems, the ***total pressure drop*** (the difference between the supply air duct static pressure and the return air duct static pressure) must not exceed 0.5 in. WC.

29.7 Air Curtains

Certain buildings have garage doors, delivery docks, and similar boundaries that must be opened on a regular basis. These openings make it difficult to maintain the indoor climate. One method of reducing heat loss or gain is to install an air curtain across these openings.

An ***air curtain*** is a powerful stream of air blown across a building opening that reduces heat loss or gain. A powerful blower directs airflow across an opening, such as an open garage door. An air curtain may have a recirculation path so the same air continuously blows across the opening. It stops any natural flow of air from the building to the outside or any natural airflow from the outside air into the building. The purpose of an air curtain is to maintain inside air conditions by blocking the infiltration of outside air through an opening.

In commercial refrigeration, open display cases with refrigerated contents at supermarkets often use an air curtain to keep cool air from escaping.



Goodheart-Willcox Publisher

Figure 29-64. Measurements of static, velocity, and total pressures are used to assess fan performance. A—The pitot tubes measure total pressure on both sides of the fan. The inlet velocity pressure equals outlet velocity pressure because the same airflow rate is produced on both sides of the fan. Therefore, the difference shown on the manometer is an increase in static pressure. B—This setup measures the static pressure difference between the inlet and outlet sides of the fan. C—This setup measures the velocity pressure. D—Some technicians measure pressure relative to room air pressure.

Chapter Review

Summary

- Before designing or installing an air distribution system, the weight of air, the manner in which air absorbs heat, and the way air separates into layers (stratification) should be considered.
- Two types of heat can be added or removed from air: latent heat and sensible heat. Devices such as humidifiers, dehumidifiers, and evaporative cooling systems can be used to modify air comfort by changing humidity levels. This can affect latent heat of an indoor climate.
- In warm air heating, the three basic systems used to circulate air are gravity, intermittent forced-air, and continuous forced-air. The gravity system is rarely used. Intermittent is common, and continuous is becoming more common.
- Air delivered to a room from a supply duct is called primary air. The distance the air travels from the duct outlet before it slows down to 50 fpm is called the throw.
- More return air leaving a room than supply air entering a room results in a negative pressure in the room. Return duct inlets should be located at the farthest distance from the supply duct outlets.
- Living spaces must have air with sufficient oxygen content. Bringing in replacement air through an air-conditioning system ensures that a definite amount of fresh air (makeup air) is brought in to provide a healthy oxygen level. This can be done using HRVs/ERVs or a damper-controlled fresh air inlet.
- Positive pressure (higher than atmospheric pressure) can be maintained in a building to help keep out airborne dirt, dust, and pollen. Negative pressure (below atmospheric pressure) should be avoided in most cases because it brings in outside contaminants and can reduce the efficiency of exhaust fans and of fuel-fired appliances.
- Ventilation is usually based on air changes per hour for a conditioned space. Air changes can be calculated according to the number of people in a building or by calculating building volume. The process that produces the greater number of changes per hour should be used.
- Attics can be vented or unvented. An unvented attic is closed off and essentially made into part of the conditioned space. A vented attic can achieve adequate airflow using louvers, various vents, ventilators, or a whole house fan. Basements often requir ventilation to reduce dampness and prevent mold growth. How this is accomplished is based on outdoor air conditions, building construction, the HVAC system, and other considerations.
- Ducts can have round, square, or rectangular cross sections. Round ducts are more efficient, but square or rectangular ducts conform better to building construction. Tables are available that compare the airflow capacities of rectangular and round ducts.
- Duct systems may be installed in basements, crawl spaces, attics, concrete slabs, and within false ceilings.
- Ducts are commonly made of galvanized sheet metal, because it is durable, inexpensive, and corrosion-resistant. Sheet metal joints must be airtight and strong. Ducts should be sealed using metal tape or mastic sealant. Never use duct tape to seal ductwork.
- Some ducts are made of nonmetal, such as fiberglass, textile, urethane, plastic, or sheetrock.
- The ratio of a duct's wide side to its narrow side is called the aspect ratio. An aspect ratio of 1:1 provides the smallest perimeter for any given cross-sectional area.
- Registers, grilles, and diffusers control airflow into and out of ducts and prevent large objects from entering the ducts.
- Duct dampers can be adjusted to balance airflow. Three common types are multiple-blade, butterfly, and split dampers.
- Fire dampers are designed to close automatically on detection of heat. Automatic fire dampers should be installed in all vertical ducts, as well as ducts passing through a firewall, in commercial and industrial buildings.
- When designing a duct system, install the air handler in a central location, keep duct runs as short as practical, and always install branches from the sides of a plenum, never the end.

Copyright Goodheart-Willcox Co., Inc. 2017

- The effective length of a duct run is determined by adding the physical length of the ductwork to effective length values for each fitting in the duct run. Total effective length (TEL) is the greatest effective length for a supply duct run in a system added to the greatest effective length for a return duct run.
- With the airflow rate and airflow velocity known, a required duct size can be looked up on an airflow friction chart. Airflow friction charts are a graph of duct diameters, airflow rates, pressure drops from friction, and air velocities.
- ACCA's Manual D is used to design a building's supply and return air ducts. It includes spreadsheets for effective losses, friction rate, duct sizing, and other considerations. Other tools and apps are also available for sizing ductwork.
- Two common fan types are axial flow (propeller) fans and radial flow (centrifugal, squirrel cage) fans. If air leaves the fan along the direction the axle is pointing, it is called axial flow. If air leaves the fan at right angles to the axle, it is called radial flow. An air curtain is a stream of air blown across a building opening to reduce heat loss or gain.

Review Questions

Answer the following questions using the information in this chapter.

1. Air expands to fill a greater space as _____.
   A. relative humidity increases
   B. pressure drops
   C. temperature rises
   D. All of the above.
2. To bring fresh air into a building's conditioned space and minimize how much it might affect indoor temperature, use a(n) _____.
   A. barometric damper
   B. HRV or ERV
   C. motorized damper
   D. soffit vent and ridge vent
3. Return air inlets should be placed _____.
   A. always near the ceiling
   B. always along the floor
   C. the minimum distance from the supply duct outlets
   D. the maximum distance from the supply duct outlets
4. Negative pressure in a building _____.
   A. enhances the efficiency of exhaust fans
   B. helps keep out airborne pollen
   C. makes a fuel-fired furnace more efficient
   D. tends to bring in outside contaminants
5. A system in cooling mode should provide at least _____ cfm of air per person.
   A. 5
   B. 15
   C. 50
   D. 100
6. Which shape of ducts provides the least resistance to airflow?
   A. Hexagonal.
   B. Square.
   C. Rectangular.
   D. Round.
7. Which of the following is true of sheet metal ducts?
   A. They are used for warm air distribution.
   B. They are usually coated with zinc.
   C. They expand and contract as they heat and cool.
   D. All of the above.
8. The ratio of a duct's wide side to its narrow side is called the _____.
   A. effective length
   B. aspect ratio
   C. throw
   D. length ratio
9. A rectangular duct with a _____ aspect ratio can hold the maximum amount of air using the minimum amount of material.
   A. 1:2
   B. 2:1
   C. 1:1
   D. 3:1
10. To prevent oil canning when a blower starts and stops, _____ any large panels of sheet metal ductwork.
    A. cross-break
    B. doubly insulate
    C. perforate with vent holes
    D. Use a reveted steel band to reinforce

Copyright Goodheart-Willcox Co., Inc. 2017

11. _____ are usually used as covers for return air ducts and have no adjustments.
    A. Diffusers
    B. Grilles
    C. Registers
    D. Dampers
12. A _____ damper is used in round ducts.
    A. butterfly
    B. globe
    C. multiple-blade
    D. split
13. A fire damper rated for a 2-hour to 4-hour hold is classified as Class _____.
    A. A
    B. B
    C. C
    D. D
14. Installing long-radius elbows in ducts _____.
    A. maximizes airflow turbulence
    B. minimizes airflow turbulence
    C. minimizes airflow velocity
    D. All of the above.
15. Which of the following is a general guideline for duct design?
    A. Make duct runs as long as possible.
    B. Whenever possible, install a duct in the end of a plenum.
    C. Install the blower in a central location.
    D. All of the above.
16. Which of the following are *not* found on airflow friction charts?
    A. Duct diameters.
    B. Pressure drops from friction.
    C. Air velocities.
    D. Heat load.
17. To determine the _____ of a duct run, add the physical length of the ductwork to the effective length values for each fitting in the duct run.
    A. effective length
    B. friction rate
    C. heat load
    D. total pressure drop
18. Duct air velocities above _____ fpm can cause excessive noise.
    A. 50
    B. 150
    C. 500
    D. 700
19. The air flowing into a fan is called the _____ draft.
    A. forced
    B. induced
    C. axial
    D. radial
20. The ACCA developed Manual _____ to be used to design both the supply and return ducts of a building.
    A. A
    B. D
    C. J
    D. N

CHAPTER 30 Ventilation System Service

Chapter Outline

30.1 Airflow Measurement
- 30.1.1 Visible Airflow Indicators
- 30.1.2 Flow Hoods
- 30.1.3 Air Handler Flowmeter
- 30.1.4 Blower Door Testing
- 30.1.5 Duct Testing

30.2 Special Duct Problems and Duct Maintenance
- 30.2.1 Noise Problems
- 30.2.2 Drafts
- 30.2.3 HVAC System Cleaning
- 30.2.4 Balancing the System
- 30.2.5 Dirt on Walls and Drapes
- 30.2.6 Removing Odors

30.3 Fan Service

30.4 Filter Service
- 30.4.1 Service of Disposable Filters
- 30.4.2 Service of Electrostatic Filters
- 30.4.3 Service of Electronic Air Cleaners

Learning Objectives

Information in this chapter will enable you to:

- Recall the various methods for checking airflow and air leakage.
- Explain how to identify, isolate, and correct duct noise problems.
- Use proper equipment and techniques to clean a duct system.
- Apply knowledge of airflow to balance a duct system.
- Recall methods of removing odors from the air.
- Summarize periodic maintenance tasks that must be performed on fans.
- Explain procedures for inspecting and servicing various types of air filters.

Review of Key Concepts

Reviewing these concepts from earlier chapters will help you understand new concepts presented in this chapter:

- Air circulation depends on the number and size of the duct supply outlets and return inlets. It also depends on the velocity of the air moving through the supply outlets. (Chapter 29)
- Air that flows from a supply register at more than 500 fpm causes occupants of the space to feel a draft. (Chapter 29)
- Blower fans can be directly driven by the fan motor or can be driven by a belt and pulley system. (Chapter 29)

Introduction

Air distribution systems are designed to circulate clean air without causing discomfort to the occupants. Two common air circulation issues are drafts and noise. Monitors are available to determine sources of noise or drafts.

The airtightness of a building envelope can be tested using blower door testing, which creates a pressure differential between the indoor and outdoor air. Ducts can be tested by pressurizing the ducts themselves. A system must be balanced to avoid inconsistencies in room temperatures and humidity.

Air ducts present a potential indoor air quality (IAQ) issue. They must be monitored for contaminants. The technician should take care to check air filters for cleaning and replacement.

9

30.1 Airflow Measurement

Special instruments are needed to measure the flow and pressure of air. Many of these air-measuring instruments were explained in Chapter 27, *Air Movement and Measurement*, along with suggested positions for placing air-measuring instruments over grilles. In addition to thermometers and pressure gauges, the following instruments are useful for airflow study:

- Manometer, **Figure 30-1**.
- Barometer.
- Pitot tube.
- Anemometer.
- Smoke (as a velocity or leak indicator).
- Hot-wire anemometer.

Dwyer Instruments, Inc.

Figure 30-1. This digital manometer measures, records, and stores differential pressure and air velocity readings electronically. The two upper parts of the high and low pressure inputs for measurement.

To determine airflow rate, both the air velocity and the size of the opening must be determined. The grille opening size is the area of the opening, **Figure 30-2**. The grille mesh or bars are not considered when determining the opening size.

30.1.1 Visible Airflow Indicators

Drafts of 15 fpm to 25 fpm are allowable within a room. If air movement is less than 15 fpm (4.6 m/min), air stagnation results. Air movement more than 500 fpm at a supply register can cause occupants to feel a draft.

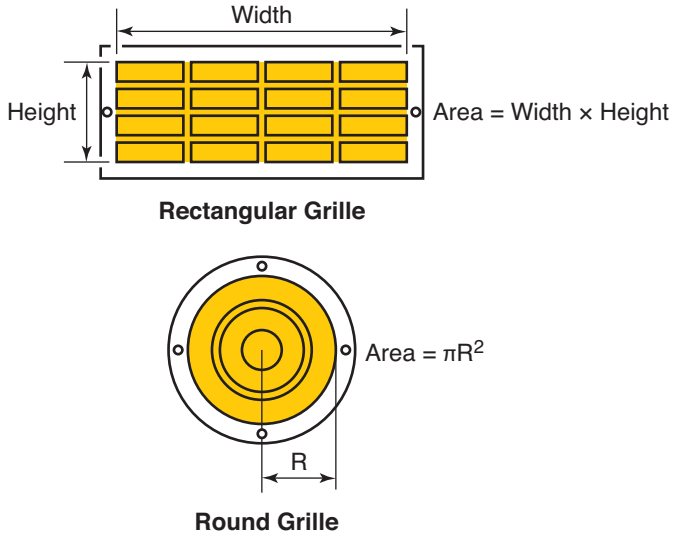
Smoke is used to determine the amount and direction of a draft, to check air movement, and to locate air leaks. Smoke generators release small puffs of smoke into the space being tested. The distance the puffs move in a given time is then observed. Because this is an imprecise measurement, several readings are taken and averaged.

Safety Note

Smoke Generators

Some chemicals used to generate smoke present health hazards if precautions are not taken. Carefully read and follow all safety warnings provided in the manufacturer's information. Always wear goggles, rubber gloves, and a respirator when handling these materials.

Nontoxic smoke sticks, smoke guns, and smoke candles are used for testing. Sticks and candles are ignited and placed in the air distribution system intake



Goodheart-Willcox Publisher

Figure 30-2. Area to be measured when calculating the volume of air leaving a grille. The area does not include the rim of the grille, but does include strips of metal inside.

Copyright Goodheart-Willcox Co., Inc. 2017

with the filter removed. The distribution of air and air balance can then be observed in the system. The smoke can also be used to check for window and door leaks, as well as refrigerator door seals. Although the smoke is nontoxic and harmless to clothing and the building's contents, long exposure to it is not recommended. Avoid using too much smoke.

30.1.2 Flow Hoods

Airflow can be measured using various instruments. A ***flow hood*** is an instrument used to direct and calculate all of the airflow through a duct at a given supply or return. These devices have sensors that are primarily used to determine air velocity and air volume. Many can also measure temperature, relative humidity, and other variables. These often have remote control devices or connectivity to mobile devices, **Figure 30-3**.

30.1.3 Air Handler Flowmeter

Airflow through a central HVAC system's air handler can be measured using an ***air handler flowmeter***. These devices are placed in the air stream of an air handler to measure the total airflow of a central system. Air handler flowmeters are typically sized to fit over a large return grille or in the space normally occupied by the system's air filter, **Figure 30-4**.

30.1.4 Blower Door Testing

To measure air leakage, a technician must first create a pressure difference. This may be a difference between the outdoors air pressure and that of the conditioned space, or a difference between the pressure inside a duct system and that of a conditioned space. The initials ***WRT*** stand for the phrase *with respect to* and are used to indicate the reference to which a pressure reading is being compared.

Blower door testing is used to determine the airtightness of the building envelope. When conducting a blower door test, a technician uses a powerful fan to create a pressure difference between the interior of the structure and the outdoors. The negative pressure created indoors causes the higher-pressure outside air to flow in through cracks and openings. The technician then measures the amount of air flowing through the structure at a specified pressure. This amount of air is a measure of the airtightness of the building envelope.

The building envelope consists of the components of the structure, such as walls or floors, separating conditioned space from unconditioned space. Two key components of the building envelope are the insulating value of the structure and its air barrier. A "tight" building envelope minimizes the amount of unconditioned air passing through into conditioned space. A tight building envelope has no gaps in its insulation and air barrier.

TSI Incorporated

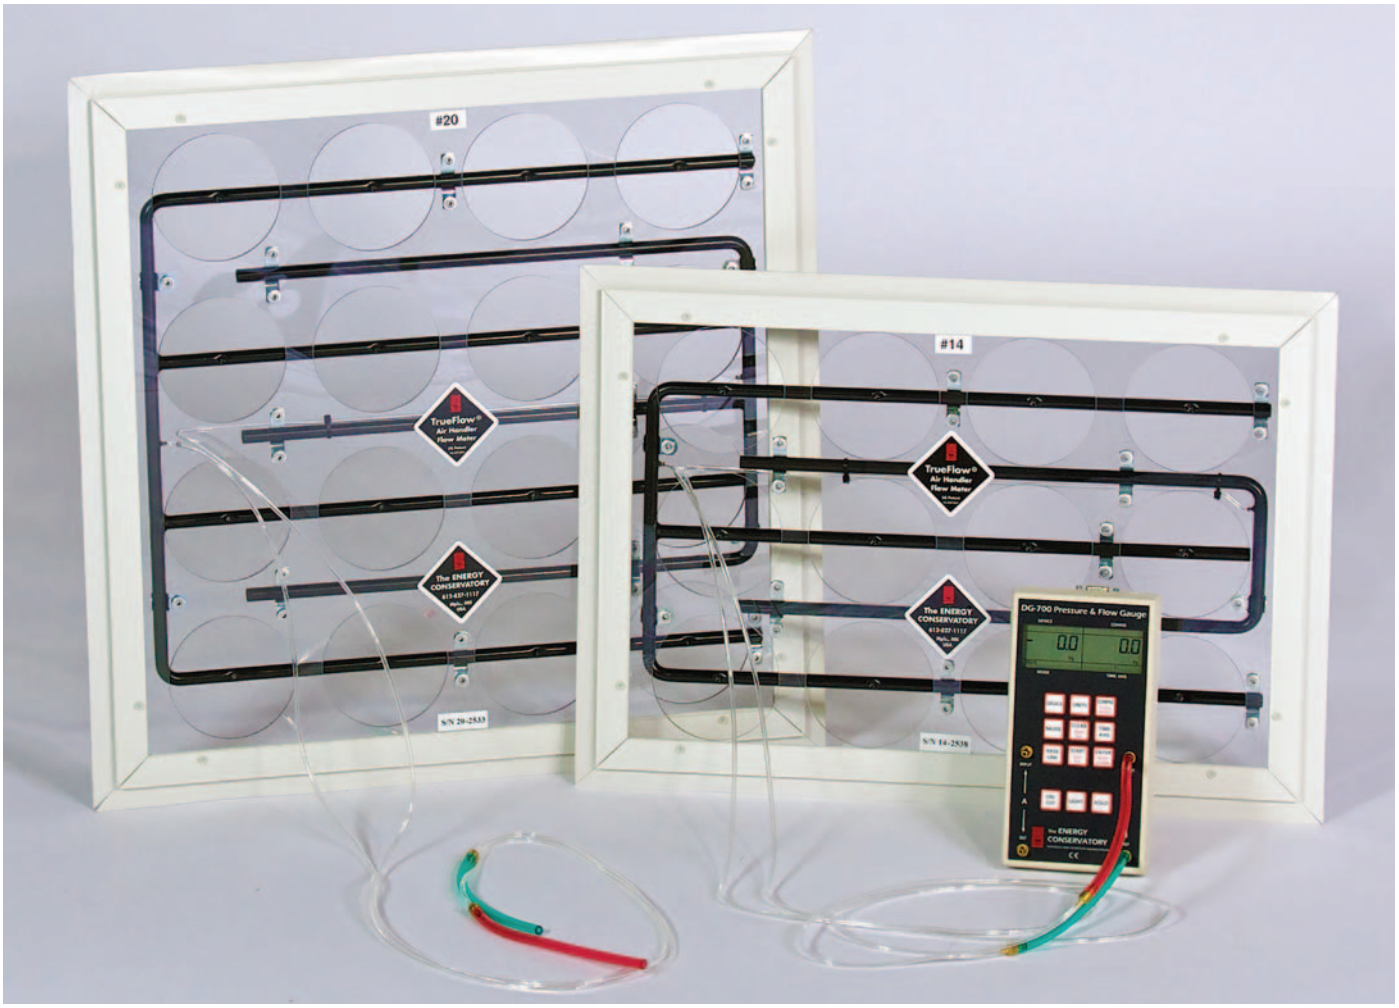
Figure 30-3. An airflow hood raised to a ceiling supply register being monitored using a mobile device.

Code Alert

Building Envelope

Local building codes specify the requirements for the building envelope. These specifications can be very detailed, describing the minimum standards for selecting and installing insulation and air barriers in the various areas of a building. These regulations take into consideration the requirements of the space and the local climate.

Copyright Goodheart-Willcox Co., Inc. 2017



TSI Incorporated

Figure 30-4. Two common sizes of air handler flowmeters used to measure total airflow through a central HVAC system.

A blower door test shows how effectively the building envelope prevents unconditioned air from infiltrating conditioned space. Blower doors can be used to find air leakage sites in the building envelope, to test the air leakage rate of the building as a whole, and to test the airtightness of the duct system.

A blower door system has several components:

- An adjustable door frame fitted with a hard or fabric panel.
- A variable-speed fan attached to the blower door frame.
- A manometer to measure the pressure difference between the interior of the building and the outdoors.
- Airflow sensors to measure the airflow through the fan.
- Inserts of various size used to adjust the fan's capacity (available with some blower door systems).

Pro Tip

Preparing for a Blower Door Test

When you are preparing a house for a blower door test, keep a list of adjustments you make, such as closing dampers and opening registers. After performing the test, use your list to ensure that you return the house to its pretest condition.

Performing a Blower Door Test

Blower door test procedures are specific for each model of blower door. Always follow the blower door manufacturer's procedure when performing a blower door test. The following procedure is typical of blower door tests.

1. Prepare the house for testing:
   - Exterior windows and doors are closed.
   - Interior doors are open.

Copyright Goodheart-Willcox Co., Inc. 2017

The Energy Conservatory

Figure 30-5. A blower door system being used to test building airtightness with measured readouts on a mobile device.

- Dampers (exhaust, intake, makeup air, backdraft, and flue) are closed.
- Exterior dampers for fresh air, continuous ventilation systems, and HRVs/ERVs are closed and sealed.
- Heating and cooling systems are turned off.
- Combustion appliances are turned off.
- Exhaust appliances are turned off.
- Fireplaces and wood stoves are extinguished, and ashes are cleaned.
- All supply air registers are fully opened.

2. Install the blower door assembly with the fan blowing out of the house, **Figure 30-5**.
3. Block the fan opening in the blower door and measure the "baseline" pressure difference between the interior and exterior: _____. For the outdoor measurement, place the end of the manometer tube away from the buildings wall in a location protected from any wind.
4. After the baseline pressure difference is recorded, remove the fan cover and attach a fan insert (if provided).
5. Activate the fan and adjust the speed until an interior pressure of –25 Pa with respect to (WRT) outdoors is achieved.
6. While the pressure is at –25 Pa, perform a walk-through of the house to make sure that no damage is occurring.
7. Increase the fan speed until an interior pressure of –50 Pa WRT outdoors is achieved.
8. Record or measure the airflow through the fan at the –50 Pa pressure. This airflow value is called cfm_{50}: _____.
9. Turn off the blower door fan.
10. Return all equipment in the house to its original conditions.

An ***air change*** occurs when the volume of air within a building is replaced with an equal volume of air. When performing a blower door test, an air change occurs when the volume of air that has passed through the blower door fan equals the volume of air within the building envelope. As described in the earlier procedure, cfm_{50} is the measured airflow through a blower door fan when indoor pressure is held at –50 Pa WRT outdoors. This cfm_{50} measurement is used to calculate the number of air changes per hour (ACH). This number of air changes when indoor pressure is held at –50 Pa WRT outdoors is referred to as ACH_{50} (number of air changes at a 50 Pa pressure difference). The formula for calculating ACH_{50} is as follows:

$$ACH_{50} = \frac{cfm_{50} \times 60 \text{ min/hr}}{\text{Volume of conditioned space (ft}^3\text{)}}$$

Code Alert

Allowable ACH

The *International Residential Code* (*IRC*) and the *International Energy Conservation Code* (*IECC*) specify a maximum ACH_{50} of three for most of the United States and Canada. The codes allow an ACH_{50} of five in some warmer regions. Refer to the codes for the requirement that pertains to the specific building location.

During a blower door test, the air infiltration into a house is greater than normal due to the depressurization of the house. Therefore, infiltration sites can be

Copyright Goodheart-Willcox Co., Inc. 2017

more effectively located while conducting the blower door test. Thermal imaging or smoke generators, such as smoke sticks or smoke candles, can be used to pinpoint air leaks, **Figure 30-6**. Thermal imaging is discussed in Chapter 46, *Energy Conservation*.

Blower door testing is sometimes used together with duct blasters (air duct blowers). Duct blasters are part of an airflow measurement system designed to determine the airtightness of duct systems.

Code Alert

Third-Party Blower Door Testing

The *International Energy Conservation Code* (*IECC*) states that testing must be conducted by an approved third party where required by the code official. Certification may be achieved through agencies such as the US EPA Energy Star program and the Building Performance Institute.

30.1.5 Duct Testing

To be efficient, ductwork must be properly sealed. Ducts are tested to locate leaks or damage so that problem areas can be repaired.

Code Alert

Duct Testing Requirement

When the air handler and ductwork are contained within the building envelope, duct testing is not required.

Duct testing is performed by pressurizing the ducts themselves. Duct airflow is then measured to determine leakage. A ***duct blaster*** is an instrument that uses a variable-speed fan and gauges to pressure test the ductwork of a central HVAC system. A fan connected to the duct system forces air through all the cracks and openings in the ductwork. Precise leakage measurements are then made using pressure gauges connected to the system, **Figure 30-7**.

After all registers and grilles have been sealed, a fan with calibrated pressure gauges supplies a gentle flow of air into the sealed duct system. The ducts are pressurized to +25 Pa WRT the conditioned space. The airflow needed to obtain –25 Pa in the conditioned space is referred to as cfm_{25}. The pressure gauges then indicate how much pressure is escaping from the system.

The following equation is used to calculate the allowable cfm:

$$\text{cfm}_{25} = \frac{\text{Conditioned space (ft}^2\text{)}}{100\ \text{ft}^2} \times \text{Maximum leakage (cfm)}$$

DiversiTech Corporation

Figure 30-6. Smoke-emitting devices are available in a variety of packages and styles.

The Energy Conservatory

Figure 30-7. A duct blaster pressure testing a central HVAC system's ductwork.

Copyright Goodheart-Willcox Co., Inc. 2017

Code Alert

Maximum Duct Leakage

The *International Energy Conservation Code (IECC)* specifies a maximum duct leakage of 4 cfm per 100 ft² of conditioned space when the ducts are pressurized to 25 Pa. If the ductwork is tested before the air handler is installed, the maximum duct leakage is 3 cfm per 100 ft² of conditioned space.

Pro Tip

Duct Pressure Testing

Duct pressure testing treats all duct leaks as being equal. However, all duct leaks are not equal with regard to system efficiency. A duct leak in an unconditioned space is a much greater concern than a duct leak in a conditioned space. When installing and inspecting duct systems, make sure that ducts passing through unconditioned spaces are completely sealed.

30.2 Special Duct Problems and Duct Maintenance

Visible ducts may need to be painted for good appearance. Paint will not stick very well on galvanized (zinc-coated) steel. Wiping down the duct with vinegar or other weak acid before painting will etch the surface, allowing the paint to stick. If any ducts are outdoors, the weather will etch the surface. The duct can then be painted. Some contractors store ducts outside until they are needed, making use of the natural weathering.

The outdoor intake end of a fresh air duct should be fitted with a strong screen and bar combination. The fresh air intake must be guarded and filtered to keep out debris, birds, animals, and insects.

Aluminum-to-steel joints are especially prone to corrosion. This is due to electrochemical action between the two different metals. Joints between different metals should be avoided. However, if one must be made, slip a thin strip of zinc or magnesium into the gap between the two different metals. The zinc or magnesium will corrode before the aluminum or steel duct can be damaged.

City and state codes require smoke detectors in residential and commercial structures. These detectors must be properly located to be effective. High-velocity air from ducts can keep smoke detectors from working. When a long horizontal run of duct ending in an outlet grille is not concealed, the smoke detector should be hung on the underside of the duct. It should be located just behind the outlet grille. With other duct designs, such as residential wall, floor, or ceiling grilles, the duct is concealed. In these systems, smoke detectors should be as far away from the grilles as possible. Detectors should never be put in corners where there is almost no airflow.

Air distribution systems should be designed to circulate clean air while ensuring that the movement of the air does not cause discomfort to the occupants. Two common problems that must be prevented are objectionable noise and drafts.

30.2.1 Noise Problems

Noise problems can be divided into three components:

- Noise source.
- Noise carrier.
- Noise amplification or reflection.

The ***noise source*** is an audible vibration. This vibration may start in the heating unit, cooling unit, fan mechanism, duct panels, duct hangers, or grilles. Noise caused by air traveling through the ducts at high speed, causing air turbulence, is a common complaint. This is often the result of a blower that has been sped up in an attempt to compensate for an undersized heating or cooling system or duct.

A noise source is a vibration that is loud enough to be heard. This vibration may originate in the heating system, cooling system, or fan mechanism. Noise is produced by movement of an object or air movement against an object.

Sources include the following:

- Fans and motors.
- High-velocity air traveling through ducts and causing turbulence. This type of noise is often the result of an undersized unit or duct. Noise problems develop when the blower has been sped up to compensate for a lack of capacity.
- Vibrating duct panel. Alternate waves of low-pressure and high-pressure air are created, producing a sound similar to the hum of a mosquito. Duct noise can be very disturbing.
- Sucking and throbbing noises produced by compressors.
- High-velocity refrigerant flow, especially at sharp bends in piping.

Types of noise associated with air distribution systems include the following:

- A high-pitch sound. This is usually caused by an air velocity that is too high. It may be due to air hitting sharp metal edges.
- A low-pitch rumble. This is usually caused by fan and motor sounds traveling along the duct system.

Copyright Goodheart-Willcox Co., Inc. 2017

- A popping sound when the unit starts or stops. This may be caused by expansion or contraction of the duct as it warms up or cools.

Noise carriers, or vibration carriers, are rigid structures that carry vibrations to places where the sound may be annoying. Floors, ceilings, ducts, doors, and pipes can all act as noise carriers.

Noise amplifiers, or reflectors, are usually hard, smooth surfaces like walls, ceilings, floors, and furnishings. Noise amplifiers can pick up a small vibration and reflect it at a frequency and direction that effectively increases the noise. Soft fabrics, such as drapes and curtains and fabric-covered furniture, are ***noise absorbers***, which are materials that mute noises. Felt-lined or soft-insulation-lined ducts also absorb noise.

Solving Noise Problems

To locate the source of a high-pitched sound, remove the grille or diffuser. If the noise stops, it is caused by sharp edges in the grille. If it continues, the air velocity is too high (use an anemometer to measure), or there is a sharp edge in the duct system. Locate the problem and correct it.

Where noise is a factor, the velocity should be kept to a minimum. If the velocity cannot be decreased, noise can be reduced by other means. An acoustical discharge chamber may be used. The ducts can be lined or wrapped with sound-absorbing material, such as felt.

30.2.2 Drafts

If a duct system is not balanced, air may enter a room at an excessive rate. Drafts are the result of air that flows past people at too high a velocity. Air velocity greater than 500 fpm at a register may result in a draft. Different methods can be tried to alleviate drafts from registers:

- If a register has adjustable louvers, adjust the louvers to direct airflow to a generally unoccupied space.
- Replace the register with one that diffuses the air more broadly.
- Adjust the damper in the duct run to reduce airflow to the register. However, this may upset the system balance, result in uneven heating or cooling from room to room.

30.2.3 HVAC System Cleaning

The benefits of a clean HVAC system include fewer health and comfort complaints by occupants, more effective system performance, reduced energy costs, and longer unit life. A program of regular maintenance and IAQ evaluation together with HVAC cleaning will reduce indoor air pollution.

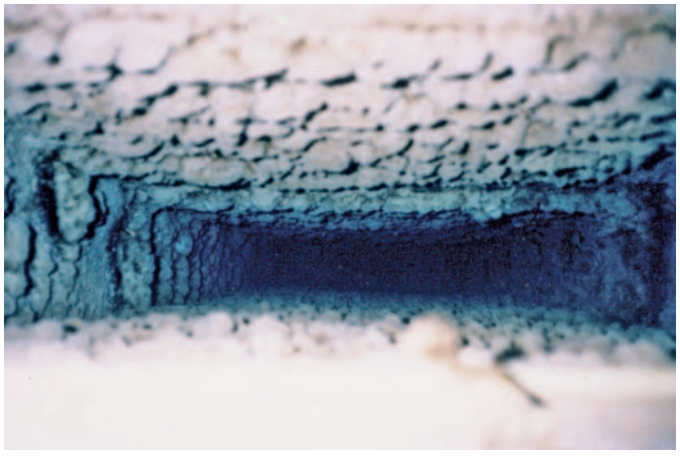
A cleanliness inspection can reveal a variety of conditions that indicate a need for HVAC system cleaning. These conditions include a significant accumulation of contaminants, debris, or evidence of microbial growth. A discharge of visible particulates into the occupied space may be noted. Other signs that cleaning is required are restrictions or deposits of contaminants on heat exchange coils, cooling coils, airflow control devices, filtration devices, or air-handling devices, **Figure 30-8**.

For effective results, all portions of an HVAC system must be cleaned. HVAC systems are good breeding grounds for contaminants due to enclosed spaces, constant temperature, humidity, and dirt. Areas that often contain microbial contamination include the condensate drain pan, areas downstream of cooling coils, and areas around humidifiers.

The air handler should be inspected, including air filter, air bypass line, heat and cooling coils, condensate pans, condensate drain lines, humidification systems, acoustic insulation, fan and fan compartment, dampers, door gaskets, supply duct and components, and return duct and components. The inspection should not disrupt any settled dust or debris in order to prevent them from entering other spaces in the building. In sensitive environments, or if HVAC system contamination is suspected, environmental engineering controls should be implemented. Engineering controls include source control, isolation barriers, HEPA vacuuming, and filtration.

Duct Cleaning

Air ducts can be a breeding surface for bacteria, mold, mildew, and fungi. Duct systems should have



National Air Duct Cleaners Association (NADCA)

Figure 30-8. Accumulation of debris in ductwork.

Copyright Goodheart-Willcox Co., Inc. 2017

no "dead ends" where dust and stagnant air can collect. If a duct must have dead space, a duct door for cleaning may be needed. Any section of duct, straight or not, will collect some dust. Reversing the direction of airflow can loosen some of the dust. The dust can then be caught in a filter. Periodic duct cleaning should be done to maintain proper airflow through the duct system.

Preparation for Duct Cleaning

The site must be prepared before ducts are cleaned. Occupant safety should be ensured by determining a containment strategy plan for removal of debris, particularly if occupants have respiratory sensitivities or other health concerns. Flooring, carpet, and tile should be protected. Computers or other office equipment, as well as furniture, should be covered, **Figure 30-9**.

Safety Note

Duct Cleaning

Use caution and wear protective gear to avoid inhalation or exposure to debris during the duct cleaning process. See **Figure 30-10**.

Tools for HVAC Cleaning

Tools for HVAC system cleaning include hand tools and power tools. Hand tools are divided into three categories: access tools, inspection tools, and cleaning tools.

Access tools allow the technician to create a point in the HVAC system from which to inspect and clean. Any openings made in the ductwork must be closed again when the inspection and cleaning is complete, **Figure 30-11**.

Inspection tools allow the technician to see inside the system in order to identify debris and contamination, monitor the cleaning process, and evaluate the success of the cleaning procedure. Such tools may include a telescoping handheld mirror, optical borescope, closed circuit television camera system, and a camera.

Handheld ***cleaning tools*** include brushes, scrapers, and agitation and vacuum devices. See **Figure 30-12**. A variety of brush heads may be required depending on the surface to be cleaned, **Figure 30-13**. Handheld HEPA vacuums can be used for removal of debris.

Caution

Cleaning Fiberglass-Lined Ductwork

Fiberglass-lined metal ductwork, flexduct, and ductboard can be damaged by aggressive cleaning techniques. Always clean carefully to avoid causing damage.

National Air Duct Cleaners Association (NADCA)

National Air Duct Cleaners Association (NADCA)

Figure 30-12. An agitation device being installed.

National Air Duct Cleaners Association (NADCA)

Figure 30-13. An agitation tool, such as this brush, is effective at removing dust from walls of ductwork.

Heavy cleaning equipment includes vacuum collection devices, compressed air sources, handheld HEPA vacuums, and wet vacuums. Vacuum devices create a negative pressure in the HVAC system and trap airborne particles of debris. See **Figure 30-14**.

Vacuum devices may be mounted on trucks or trailers or may be portable units. Truck/trailer equipment is more powerful, but lacks the flexibility of portable equipment. Some tools for cleaning use compressed air to supply pressure. If a gasoline-powered compressor is used, it must be located outside the facility. Do not allow fumes to enter the building. Wet vacs (vacuums) are frequently used to remove microbial contaminants and sludge. If a wet vac exhausts inside the facility, it must be HEPA filtered.

Cleaning Ductwork

A three-step process is used to clean ductwork:

1. A ***duct sweeper*** is rotated through the sides of the ducts to release dust, mold, and mildew.
2. A high-velocity vacuum removes loose particles from the ductwork.
3. A microbial biocide is sprayed into the cleaned duct system to prevent mold and mildew buildup.

National Air Duct Cleaners Association (NADCA)

Figure 30-14. A technician placing a vacuum into ductwork.

Copyright Goodheart-Willcox Co., Inc. 2017

Filters should be checked, cleaned, or replaced if necessary to reduce future contamination. The final product should be a clean, debris-free system. See **Figure 30-15**.

30.2.4 Balancing the System

Balancing means sizing the ducts and adjusting the dampers to be sure that each room receives the correct amount of air. Conditioned air must be fed in the proper amounts to each room. Also, the correct amount of air must be returned. If the system is not balanced, rooms will maintain different temperatures, have incorrect relative humidity, or have stale air. Some ducts will be noisy.

In order to achieve balance, the air velocity leaving each grille must be measured. Then, the "free" area of the grille or diffuser is determined. The "free" area is the actual size of the air openings.

Balancing a System—Long Method

To balance a system, perform the following steps:

1. Inspect the complete system; locate all ducts, openings, and dampers.
2. Open all dampers in the ducts and at the grilles.
3. Check the velocities at each outlet.
4. Measure the "free" grille area.
5. Calculate the airflow rate at each outlet.

$$\text{airflow rate (cfm)} = \frac{\text{velocity (fpm)} \times \text{area (in}^2\text{)}}{144 \text{ in}^2/\text{ft}^2}$$

6. Add together the airflow rates from all outlets.
7. Determine the floor areas of each room. Add the square footage of all rooms together to determine the total square footage of the conditioned spaces.
8. Determine the portion of total airflow each room should have:

$$\text{cfm for room} = \frac{\text{area of room}}{\text{total floor area}} \times \text{total cfm}$$

9. Adjust duct dampers and grille dampers to obtain these values.
10. Recheck all outlet grilles.

In some cases, it may be necessary to overcome excess duct resistance. To do this, install a duct booster. A ***duct booster*** is a fan that increases airflow when a duct is too small or too long. They may also be used where a duct has too many elbows. **Figure 30-16** shows various air duct boosters.

Balancing a System—Short Method

An effective but simpler technique can be used to balance airflow to different rooms:

1. Place thermometers in each room. Locate the thermometers on tables away from sunlight, lamps, or any extra heat source. Make sure the temperature sensing element is not in contact with any surfaces or objects.
2. Adjust dampers until each room has the temperature desired. Allow several hours for the system to adjust to any damper change.

Remember, if one room is too warm, one or more others should be too cool. If the heating system is operating, close the dampers slightly in rooms that are too warm and open the dampers slightly in the cool rooms. If the cooling system is running, open the dampers slightly in rooms that are too warm and close the dampers in rooms that are too cool.

National Air Duct Cleaners Association (NADCA)

Figure 30-15. View of a clean duct system.

Thinking Green

Airflow Balance

To operate efficiently, an air conditioning system's airflow must be balanced. If a room has a supply duct but no return duct, then conditioned air must pass through part of a hallway or from one room to another on its way back to the air handler. In such rooms with no return air inlet, a small gap at the bottom of the door or another opening should be present to allow return airflow. System balance should be checked with the doors open and also with the doors closed.

Copyright Goodheart-Willcox Co., Inc. 2017

Tjernlund Products, Inc.

Figure 30-16. A duct booster is selected for a specific duct size and volumetric flow rate.

30.2.5 Dirt on Walls and Drapes

Dirt can collect on walls, ceilings, and drapes in a conditioned space. In most cases, this dirt does not come from the ducts, but is already in the room. Room air movement (convection air current) is responsible for carrying dirt to the room surfaces.

The collection of dirt around warm-air grilles is called ***thermal precipitation***. Warm air exiting the grille picks up dirt from the room air. As this air hits cooler surfaces, the dirt settles (precipitates) on the surfaces. This precipitation takes place on windows also. The cooler the surface, the more dirt it collects. Therefore, insulation and storm sashes reduce the amount of dirt settling out of the air.

Studies have noted a relationship between the incidence of infection and the level of air contamination. Therefore, clean rooms are used for surgery and research. ***Clean rooms*** maintain an environment that limits the concentration of airborne particles. The temperature, humidity, and air quality are tightly controlled. Clean rooms are also used for the manufacture, repair, and service of critical items, such as instruments and computer components. Four methods of maintaining climate control are used in a clean room:

- Extremely high–efficiency filters.
- Laminar airflow (introducing supply air into the operating room at low uniform airflow, resulting in a stable downward flow of air).
- Anticontamination devices.
- Higher pressure in the clean room than outside the room.

30.2.6 Removing Odors

Vapors and odors frequently make up a large percentage of atmospheric air contaminants. Since most odors are gases, filters (even electronic ones) will not remove them. Some odors can be removed by cooling the gases to their condensation or freezing temperature. Some are removed by oxidation and by ultraviolet

Copyright Goodheart-Willcox Co., Inc. 2017

light treatment. Others can be removed by combining them with other chemicals. The contaminants may be diluted with air or absorbed into a liquid. They may also be adsorbed into a solid. Both vapors and odors can be removed with activated charcoal or activated alumina with potassium permanganate.

30.3 Fan Service

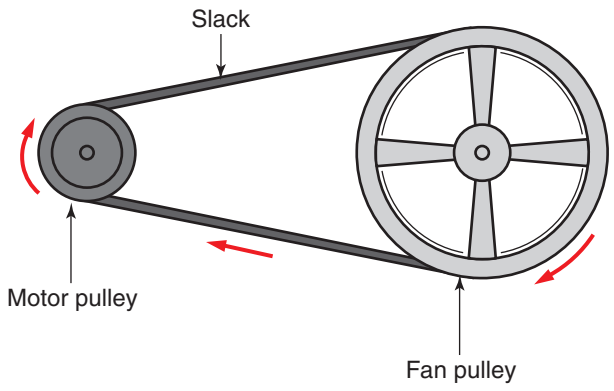
If possible, belt tension should be on the lower belt section in order to provide more efficient belt drive. Belt tension is good when the belt can be pushed out of line a distance equal to belt width, **Figure 30-17**. Fan speed can be varied by using adjustable (variable pitch) pulleys, **Figure 30-18**.

All fans collect lint and dirt, which reduces the efficiency of the fan. Dirt should be removed every six months. Remove the fan and scrape, rub, or vacuum the dirt off the blades. Blades will collect dirt even more quickly if the fan bearings are oiled too much. The extra oil coats the fan blades and traps any dust that lands on the blades. Each bearing requires only one or two drops of oil each year. The bearings on direct-drive fans should also be checked and lubricated. See Chapter 17, *Servicing Electric Motors and Controls*, for more fan motor service information.

Thinking Green

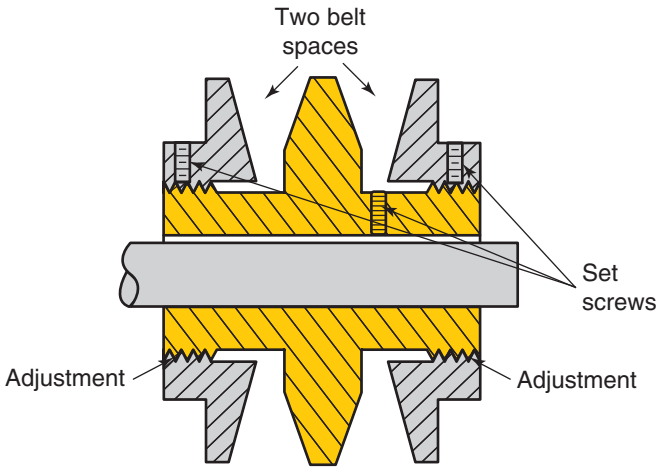
Clean Fans

Most technicians recognize the need to keep heat transfer coils clean, but fans and fan motors should also be kept clean to maximize efficiency. Dirt buildup on a fan can reduce its ability to move air efficiently. Motors with dirt buildup operate at higher temperatures, which can lead to motor failure.



Goodheart-Willcox Publisher

Figure 30-17. Motor pulley and fan pulley. Note tension on lower part of belt and slack at upper. This is how a tensioned belt should look in operation.



Goodheart-Willcox Publisher

Figure 30-18. Variable pitch pulley. Note the location of the setscrews. A pulley is used on a dual belt system and can provide fan variation of about 100 rpm through adjustment.

30.4 Filter Service

In order for heating and cooling systems to work efficiently, the correct rate of airflow must be produced by the ventilation system. Clogged air filters put excessive strain on the blower motor and can decrease airflow below acceptable levels. The following sections describe how to inspect and service various types of air filters.

30.4.1 Service of Disposable Filters

The most commonly used filters are disposable filters. See Chapter 28, *Air Quality*, for a description of the various types of disposable filters. Disposable filters should be replaced at least every three months or whenever they become inefficient or clogged. Clogged air filters produce too much pressure drop across the filter. Visual inspection is one way to determine if a filter needs replacement. Measuring pressure on both sides of the filter can also reveal whether the filter needs to be changed. The following are some guidelines for inspecting filters:

- Inspect the air filter for tears, holes, and excessive dirt. To determine how dirty the filter is, place a strong light on one side of the filter. Then, look through the filter from the other side. Replace any filter that is excessively dirty, punctured, or has damaged or deteriorating filter material.
- Use a manometer to check the pressure drop. Measure the pressure on each side of the filter. Subtract the smaller value from the larger. The difference represents the pressure drop through the filter. If the pressure drop across the filter is more than 25% of the pressure drop across the fan, the filter should be changed.

Copyright Goodheart-Willcox Co., Inc. 2017

- Check the housing for signs of corrosion. If corrosion is present, clean the housing by sandblasting and repaint it.

Many air filters are unidirectional, which means they are effective only when air passes through them in the correct direction. Always replace filters so the arrows printed on the filter frame point in the direction of airflow. If this is not done, the filter will quickly load with dirt and clog.

30.4.2 Service of Electrostatic Filters

Electrostatic filters are often permanent, washable filters. These filters carry an electronic charge that attracts dust particles. However, many newer units combine the use of electronically charged plates as well as a replaceable media filter. The electronic cells on these units do not need to be cleaned. Only the media filter needs to be replaced. Review manufacturer literature for specific instructions.

30.4.3 Service of Electronic Air Cleaners

Electronic air cleaners (EACs) need service in the following situations:

- Trouble lights remain on.
- Strong ozone odor is detected.
- Rooms are dusty and dirty.
- Unit arcs constantly.

Before beginning service, ask the owner when the filter was last cleaned. Be sure the power doors or panels are closed and the power switch is on. Check the fuses. Check the meter readings or operating indicator.

Refer to the service manual for information about interpreting the meter readings or trouble light codes. Meters or trouble lights, when correctly interpreted, typically indicate whether the filter is dirty or wet or if an electrical problem is indicated.

If a problem is suspected, but the indicator lights or meters indicate that conditions are normal, follow the instructions in the manual to troubleshoot the unit.

If the filter is dirty, the building and air-handling system should be inspected. New carpeting, for example, may temporarily cause an overload on the filter. Leaking duct systems and untreated concrete floors all cause unusual high-load conditions. Dusty construction work in the vicinity may also overload the unit.

Electronic air cleaners should be cleaned on a planned schedule. Many companies now offer a free e-mail reminder system to remind homeowners to clean filters. Frequent washing of a unit is not harmful. However, a neglected unit will not clean air effectively.

Washing an Electronic Air Cleaner Filter

Refer to the owner's manual for specific cleaning instructions. The following is a general cleaning procedure.

1. Turn the electronic air cleaner, furnace, and blower power off.
2. Remove lint screens and ionizing collecting cells.
3. Clean the screens and cells using hot soapy water, and rinse thoroughly.
4. Replace lint screens and collecting cells after they have dried thoroughly.

Caution

Washing and Drying Collecting Cells

Do not run an electronic air cleaner without replacing the screens and cells. Some manufacturers recommend washing the collecting cells in a dishwasher. Do *not* allow the unit to run through the drying cycle. If the cells are not thoroughly dried, electrical arcing may occur when system is turned on. Also, running the cells through the dishwasher drying cycle may bake on any particles not removed during the wash. Air dry the collecting cells after any washing.

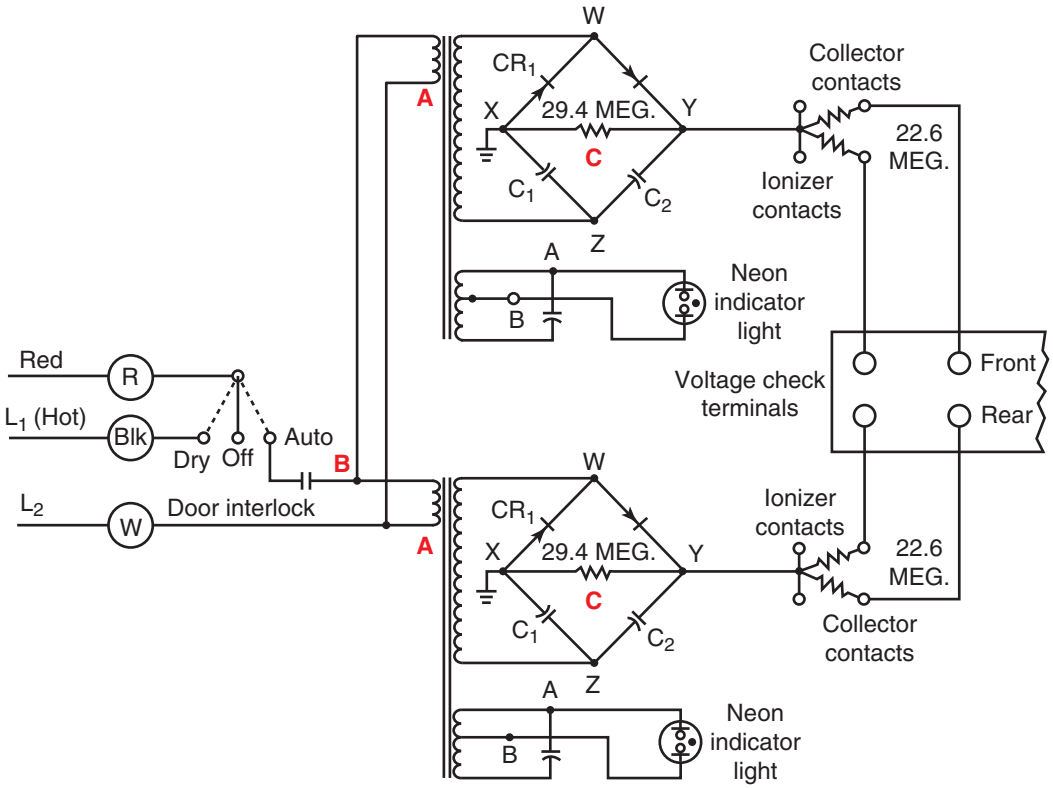
If the water used to wash collecting cells becomes black, you know the cleaner is removing contaminants from the air. A unit that is operating correctly allows only fine white dust to leave the ducts. The effectiveness of an electronic air cleaner can be checked by placing cheesecloth over a supply grille. If the cheesecloth becomes discolored after the cleaner has been in operation for two or three days, the electronic air cleaner is not working properly.

If a wet filter is indicated, check the electronic air cleaner for a "dry" switch. Some units are equipped with a switch that will automatically operate the blower to dry the filter. If the cleaner does not have a "dry" switch, use the thermostat to run the blower continuously or periodically to keep the filter dry. Inspect the system to determine why the filter is getting wet, and correct the problem if possible.

Electrical Service

Electronic air cleaners have an electrical circuit that converts 120 Vac to about 9000 Vdc. This circuit also has safety devices, such as door interlocks, and service devices, such as diagnostic circuits. Note the two step-up transformers, the door interlock, the rectifiers, and the neon light circuit in this electronic air cleaner's electrical circuit, **Figure 30-19**.

Copyright Goodheart-Willcox Co., Inc. 2017



Honeywell Inc.

Figure 30-19. Wiring schematic for an electronic air cleaner.

Service to electronic air cleaners includes checking rectifiers and high dc voltage. Electrical troubles can occur in the power source circuit or in the high-voltage circuit. If the trouble is in the high-voltage circuit, the "power pack" capacitors and collecting cell ionizing wires should be inspected and electrically tested.

Safety Note

Servicing Electronic Air Cleaners

Electronic air cleaners should be serviced only by someone with special training on the model being serviced. Standard multimeters and leads are not designed to read the high voltages used in these air cleaners. A high-voltage probe must be used with a standard multimeter to read the voltage.

Recent developments in air cleaners allow technicians to check the status of an electronic air cleaner through the use of a performance indicator. The performance indicator informs the homeowner and technician of the status of the electronic air cleaner. The indicator should be located near the thermostat. The *On* reading confirms the electronic air cleaner is operating. The *Battery* reading prompts replacement of the performance indicator's battery, and *Service* indicates the prefilter and cells need cleaning. A *Fault* reading confirms there is extreme dirt loading, electronic malfunction, or other problems.

The collector section should be inspected visually for bent plates, plates out of position, dirt bridging the gap between ionizing wires and the plates, broken insulators, and broken wires. Plates must be straight. Broken insulators and ionizing wires should be removed and replaced. Cleaning the plates is essential.

Chapter Review

Summary

- Special instruments are needed to precisely measure the flow and pressure of air. The rate and pattern of airflow can be estimated by observing the movement of smoke from smoke generators, aspirators, smoke sticks, smoke guns, or smoke candles. Special instruments include flow hoods and air handler flowmeters.
- Blower door testing is used to determine the airtightness of a building's envelope and to locate air leaks. A blower door assembly consists of an adjustable door frame, a variable-speed fan, a manometer, airflow sensors, and related accessories.
- An air change occurs when the volume of air within a building is replaced with an equal volume of air. A blower door test determines the number of air changes per hour (ACH_{50}) when indoor pressure is held at –50 Pa WRT outdoors. This value is calculated based on the measured airflow through a blower door fan when indoor pressure is held at –50 Pa WRT outdoors (cfm_{50}). Building codes limit the maximum allowable number of ACH.
- Duct testing is performed by pressurizing a central HVAC system's ductwork with a duct blaster to a pressure of +25 Pa WRT the conditioned space. Duct airflow is then measured to determine leakage and locate the leaks. Building codes limit the maximum amount of duct leakage.
- Common problems encountered when working with duct systems include corrosion caused by dissimilar metals at joints, noise problems, drafts, dirty ductwork, and systems out of balance. If steel and aluminum ducts are joined, corrosion can be reduced by inserting a thin strip of zinc or magnesium between duct sections made of dissimilar metals.
- Noise problems are caused by something that is vibrating. The sound can travel a far distance from the source through the ductwork. In order to eliminate the problem, the source of the noise must be identified and conditions causing the unwanted vibration must be corrected.
- To alleviate drafts from registers, the louvers can be adjusted to direct airflow to an unoccupied space, a register can be replaced with one that diffuses air more broadly, or dampers in the duct run can be adjusted.
- A clean duct system increases the efficiency of the heating and cooling systems and reduces IAQ complaints. A variety of equipment is available for duct cleaning. Any duct vacuum that exhausts indoors must be HEPA filtered.
- An out-of-balance duct system can cause differences in temperature, humidity, and airflow from room to room. A duct system can be balanced by adjusting the dampers and registers so the proper airflow is provided to each room. If the problem is caused by excess friction in the ducts, a booster fan can be used to increase airflow.
- Fan belt tension must be properly adjusted and the fan blades must be clean in order for a fan to function efficiently. One or two drops of oil should be applied to the fan shaft every year.
- Excessively dirty or clogged air filters decrease the efficiency of the ventilation system and put an excessive strain on the blower motor. Disposable air filters can be visually inspected and should be replaced if they are damaged or dirty. The condition of an air filter can also be determined by measuring the pressure drop across the air filter.
- Most electronic air cleaners have self diagnostics that inform the technician if the filter is working properly, if the filter is dirty or wet, or if there is an electrical problem with the system.

Review Questions

Answer the following questions using the information in this chapter.

1. An instrument used to direct and calculate all of the airflow through a duct at a given supply or return is a(n) _____.
   A. air handler flowmeter
   B. barometer
   C. duct blaster
   D. flow hood
2. An instrument used to measure all airflow through a central HVAC system is a(n) _____.
   A. air handler flowmeter
   B. barometer
   C. duct blaster
   D. flow hood

Copyright Goodheart-Willcox Co., Inc. 2017

3. Duct blasting involves _____.
   A. pressurizing the ducts
   B. measuring duct airflow
   C. sandblasting ductwork
   D. Both A and B.

4. When blower door testing, initials used to indicate the reference to which a pressure reading is being compared are _____.
   A. ACH
   B. cfm
   C. IAQ
   D. WRT

5. Aluminum-to-steel joints are _____.
   A. commonly used because they resist corrosion
   B. more enduring with a strip of zinc or magnesium between the metals
   C. the ideal ductwork joints
   D. *not* affected by electrochemical action between the metals

6. Rigid structures that transmit vibrations to places where the sound may be annoying are called noise _____.
   A. amplifiers
   B. carriers
   C. sources
   D. strengtheners

7. A high-pitched sound in an air distribution system is usually caused by _____.
   A. air velocity that is too high
   B. air velocity that is too low
   C. expansion of the duct as it warms up
   D. fan and motor sounds traveling along the duct system

8. If a high-pitched noise stops when a grille or diffuser is removed, the noise is caused by _____.
   A. air velocity that is too low
   B. sharp edges in the grille
   C. expansion of the duct as it warms up
   D. fan and motor sounds traveling along the duct system

9. A handheld HEPA vacuum is an example of a(n) _____ tool.
   A. access
   B. inspection
   C. cleaning
   D. None of the above.

10. A simple method of balancing airflow is to adjust the _____ until all rooms have the desired temperature.
    A. air filter
    B. blower fan speed
    C. dampers
    D. duct booster

11. Odors can be removed from indoor air by _____.
    A. combining them with other chemicals
    B. using activated charcoal to adsorb them
    C. oxidation and ultraviolet ray treatment
    D. All of the above.

12. Dirt on blower fan blades should be removed _____.
    A. every day
    B. every week
    C. every six months
    D. once a decade

13. The pressure drop across an air filter can be measured with a(n) _____.
    A. access tool
    B. barometer
    C. borescope
    D. manometer

14. When washing an electronic air cleaner filter, you should *not* _____.
    A. leave everything energized
    B. remove the lint screens and ionizing collecting cells
    C. turn the blower power off
    D. use hot soapy water

15. Electronic air cleaners need service when _____.
    A. trouble lights remain on
    B. rooms are dusty and dirty
    C. the unit arcs constantly
    D. All of the above.

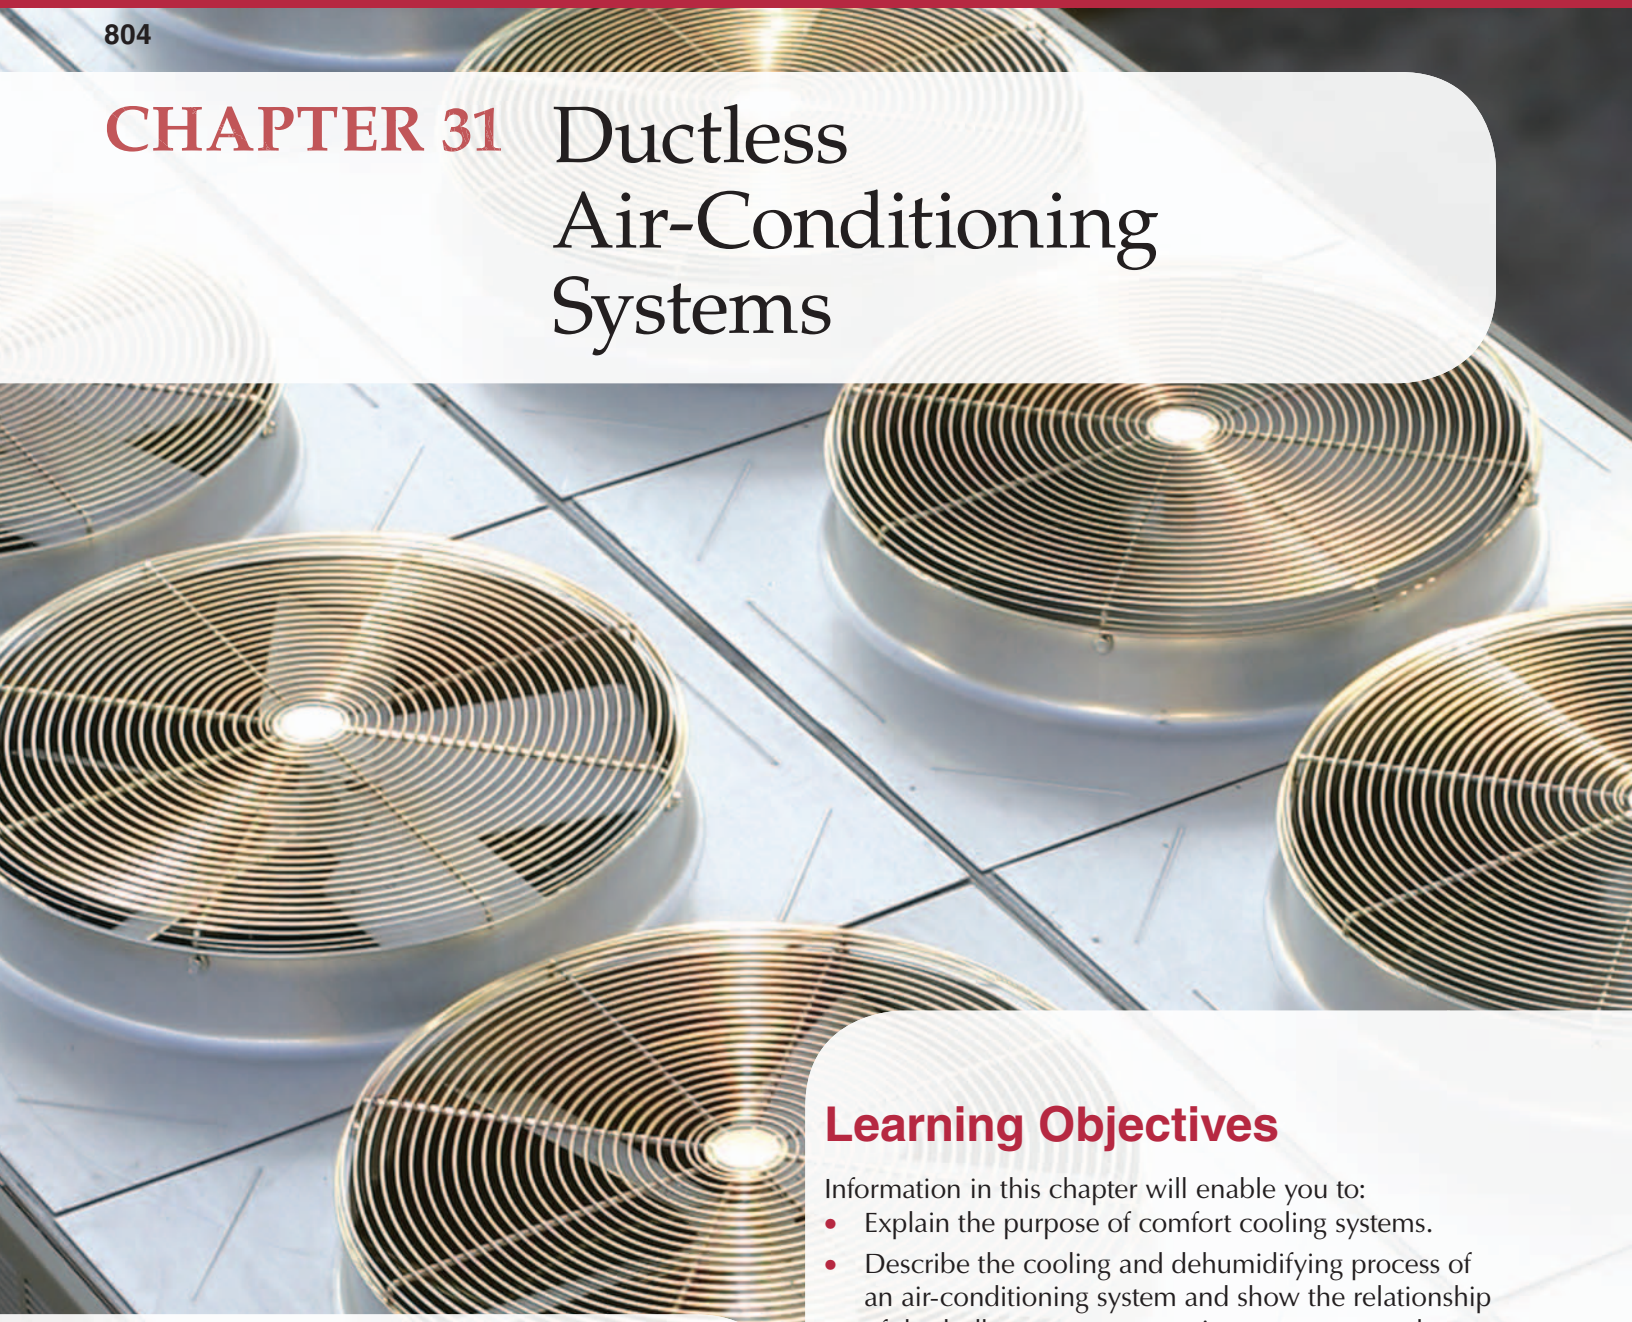
CHAPTER 31 Ductless Air-Conditioning Systems



Chapter Outline

31.1 Principles of Cooling and Humidity Control
31.2 Room Air Conditioners
- 31.2.1 Room Air Conditioner Features
- 31.2.2 Installing Room Air Conditioners
- 31.2.3 Servicing Room Air Conditioners

31.3 Packaged Terminal Air Conditioners
31.4 Console Air Conditioners
- 31.4.1 Installing Console Air Conditioners
- 31.4.2 Servicing Console Air Conditioners

31.5 Portable Air Conditioners
31.6 Multizone Ductless Split Systems
- 31.6.1 Ductless Split System Installation
- 31.6.2 Ductless Split System Service

Learning Objectives

Information in this chapter will enable you to:

- Explain the purpose of comfort cooling systems.
- Describe the cooling and dehumidifying process of an air-conditioning system and show the relationship of dry-bulb temperature, moisture content, and relative humidity on a psychrometric chart.
- Summarize the characteristics of window and wall-mounted room air conditioners.
- Install and service window and wall-mounted room air conditioners.
- Discuss the operation and application of packaged terminal air conditioners and console air conditioners.
- Identify the characteristics and uses of portable air conditioners.
- Explain the operation, components, and arrangement of ductless split systems.
- Identify the features of multizone ductless split systems.
- Install and service ductless split systems.

Review of Key Concepts

Reviewing these concepts from earlier chapters will help you understand new concepts presented in this chapter:

- Relative humidity (rh) is a term used to express the amount of moisture in an air sample compared to the total amount of moisture the same sample would hold if it were completely saturated at the same temperature. (Chapter 27)
- The amount of moisture that air can hold depends on dry-bulb temperature. Warm air can hold more moisture than cold air. (Chapter 27)
- Only certain temperature and humidity ranges are comfortable to humans. Effective temperature is the combined effect of dry-bulb temperature, wet-bulb temperature, and air movement that provides an equal sensation of warmth or cold. (Chapter 27)

Introduction

Comfort cooling systems are systems that reduce the temperature and humidity in living and work spaces to a level comfortable for the occupants. Comfort cooling systems often use a mechanical refrigeration system to maintain the high-temperature refrigeration range (between 55°F to 90°F). The refrigerant evaporating temperature of most comfort cooling systems is 40°F to 50°F (4°C to 10°C). The information in this chapter is applicable to the most popular designs of ductless systems using mechanical refrigeration for cooling and dehumidifying.

10

31.1 Principles of Cooling and Humidity Control

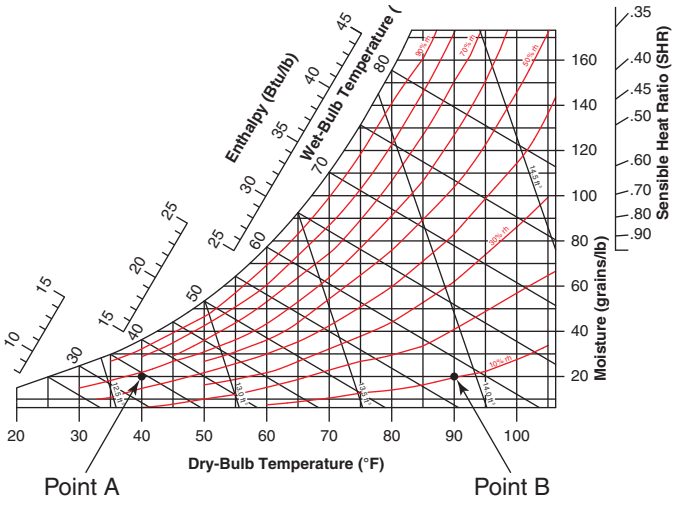
As explained in Chapter 27, *Air Movement and Measurement*, only certain combinations of temperature and relative humidity are comfortable to humans. Certain industrial operations also rely on controlled temperature and humidity. For example, large industrial computer installations must operate in cool and dry conditions. Also, very specific conditions must be maintained where medicines and biological products are being produced. Industrial operations dealing with hygroscopic (water-absorbing) materials require strictly controlled humidity.

Figure 31-1 shows the operation of a typical cooling system. Return air is mixed with some fresh air. Then, this air mixture is filtered and passed over the evaporator, where it cools. As the air cools, some of the moisture in the air condenses on the evaporator coil and is drained away.

Cool air leaving the evaporator is at 100% relative humidity. However, remember the psychrometric charts from Chapter 27, *Air Movement and Measurement*. The lower the temperature of air, the less moisture it can hold. This explains the 100% relative humidity of the cool air. A set amount of moisture in a set volume of air can have high relative humidity at a low temperature and low relative humidity at a higher temperature, even though the amount of moisture the air contains has not changed at all, **Figure 31-2**.

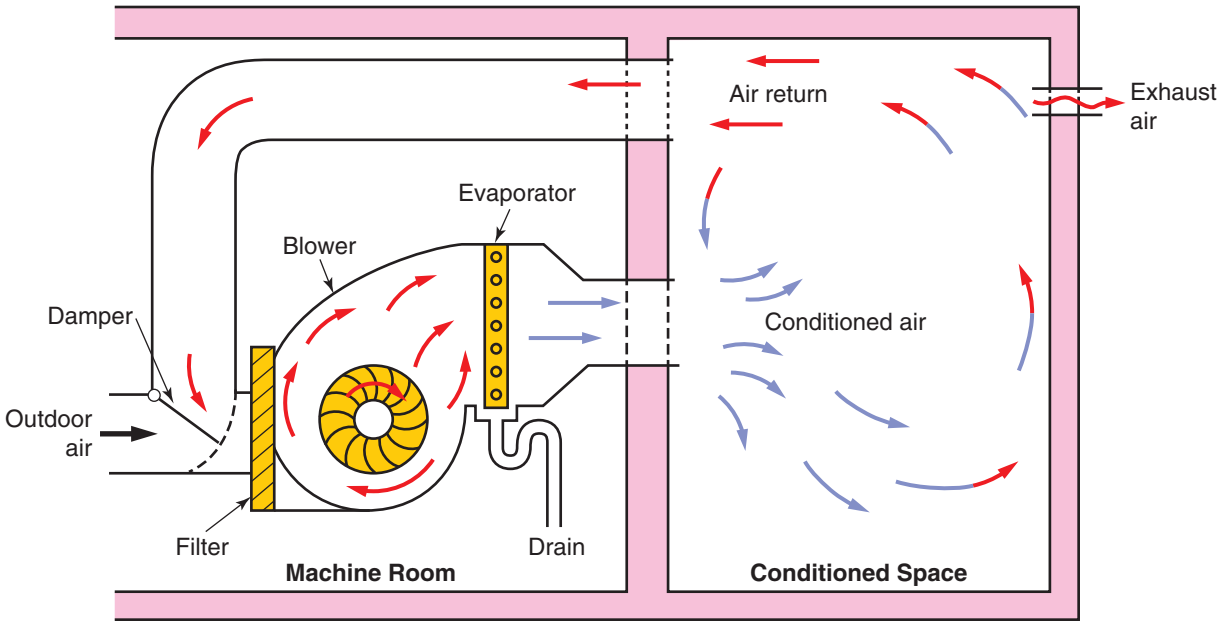
As this cool, saturated air moves away from the evaporator and mixes with air in the conditioned space, it warms up and mixes with room air, lowering its relative humidity. With this influx of drier air, relative humidity in the space is brought down to a comfortable level.

In some cases, controlling relative humidity may be more important than temperature control. In these



Goodheart-Willcox Publisher

Figure 31-2. In this example, a set volume of air has 20 grains/lb of moisture. At 40°F dry-bulb temperature, it is at 60% relative humidity. When dry-bulb temperature rises to 90°F, it is at 10% relative humidity, even though this air still contains the same amount of moisture (20 grains/lb).



Goodheart-Willcox Publisher

Figure 31-1. Basic operation of an air conditioner that cools, recirculates, and removes moisture from outdoor air. The air is moved with a centrifugal blower.

Copyright Goodheart-Willcox Co., Inc. 2017

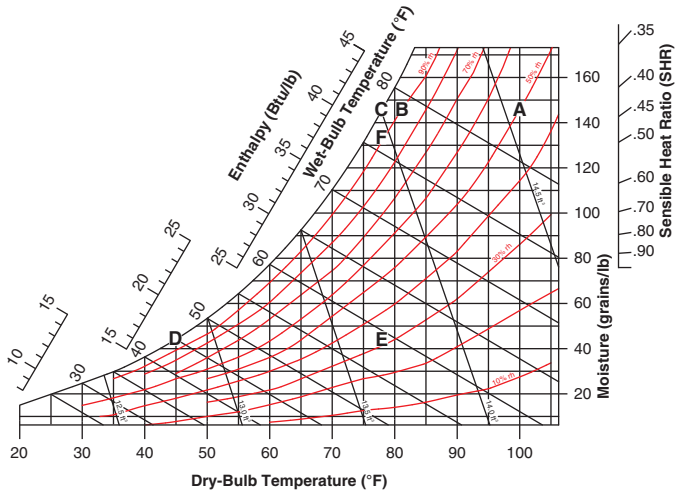
designs, some of the return air bypasses the evaporator and is fed into the air conditioner outlet. The bypass warms the cooled air before it leaves the duct system. This allows the system to provide dehumidification without overcooling the conditioned space. The amount of return air bypassed around the evaporator is controlled by a damper. This type of system is shown in **Figure 31-3**.

In a cooling cycle, the dry-bulb (db) temperature of the air is lowered. When this happens, like the shift from Point A to B in **Figure 31-4**, the level of relative humidity increases. This is due to colder air being able to contain less moisture than warmer air. The air contains the same amount of moisture, but the amount it can hold is reduced. When air's dry-bulb temperature reaches dew point (100% relative humidity), some moisture can condense and be removed. In comfort cooling, reducing humidity makes the air more comfortable. Moisture can be removed by either of two methods:

- Dehydrate the air with chemicals.
- Cooling air until moisture condenses.

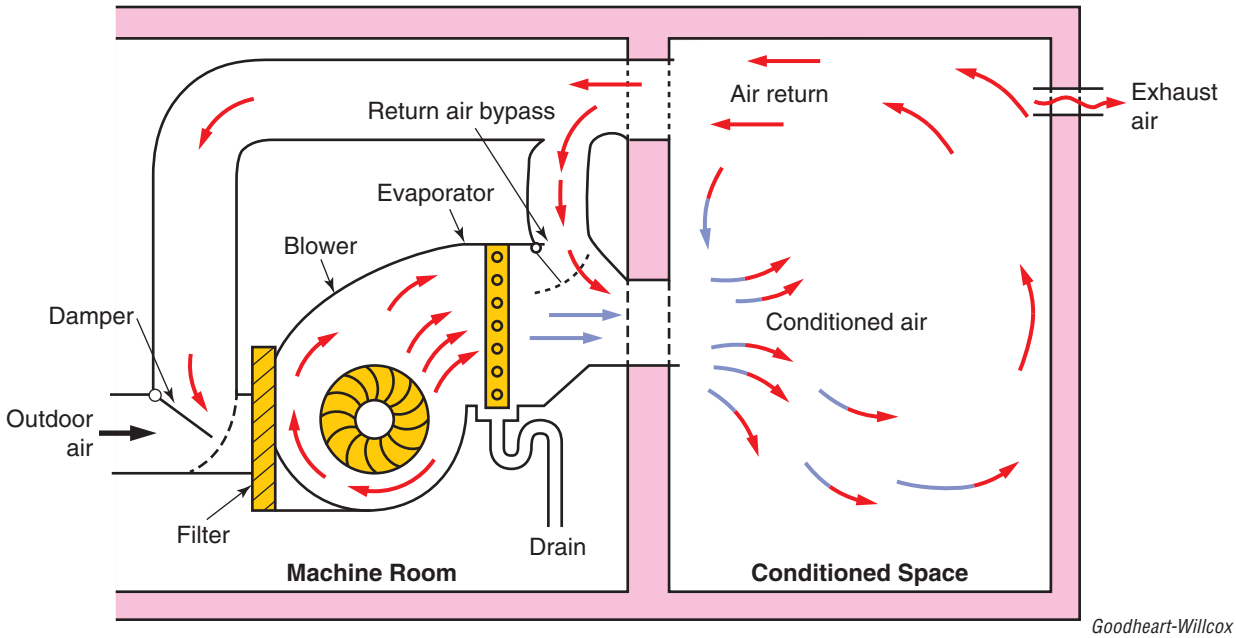
When the dry-bulb temperature in **Figure 31-4** is reduced to about 77°F, its relative humidity is at 100% (Point C). Moisture is effectively removed from air by condensing on a cool surface. This is represented by the curve from Point C to Point D. Look along the right side of the chart to see the vertical distance from C to D along the Moisture scale. This shows the drop in moisture content in grains per pound. The psychrometric chart shows an approximate reduction from 143 grains/lb down to 42 grains/lb of moisture.

Reheating the air (horizontal line from Point D to Point E) decreases the air's relative humidity. However, in most systems the cooled air leaving at Point D is mixed with the room air. Since the return air is at



Goodheart-Willcox Publisher

Figure 31-4. Cooling cycle on a psychrometric chart. A—Condition of room air. B—Partly cooled air. C—Air cooled to saturation (100% relative humidity). D—Air cooled to remove some moisture. E—Rise in temperature of cooled air mixed with room air. F—Rise in relative humidity of cooled air mixed with room air.



Goodheart-Willcox Publisher

Figure 31-3. Comfort cooling system with a return air bypass for relative humidity control. The air passing through the evaporator is cooled and dehumidified. However, because the air leaving the evaporator is mixed with relatively warm, dry return air, the cooling capacity of the system is reduced. This allows the system to continue running to dehumidify the air without overcooling the conditioned space.

10

Copyright Goodheart-Willcox Co., Inc. 2017

45°F (Point D) and the room air is 100°F (Point A), the dry-bulb temperature of this mixture will increase to about 78°F. Not only will temperature change, but relative humidity will change. The result of the mixture of return air and room air will result in a relative humidity of 90%. This is reduction of temperature by 12°F and of moisture content by about 10 grains/lb of moisture. Relative humidity is higher, but moisture content and temperature are lower.

Several types of comfort cooling systems can be used to provide cooling and humidity control. Of ductless systems, these systems may be self-contained (packaged) or split. A ***self-contained air-conditioning system*** is a comfort cooling system with all parts and controls in a single cabinet. An example is a room air conditioner. Within its cabinet is the metering device, compressor, condenser, evaporator, controls, and necessary accessories. A packaged terminal air conditioner (PTAC) is another example of a self-contained air-conditioning system.

All self-contained air-conditioning units provide cooling during the hot season. Some models can also provide heating during the cold season. Both types have a complete refrigeration system, including compressor, condenser, refrigerant controls, evaporator, filters, and related parts. Individual room thermostats provide temperature control.

Unlike self-contained air-conditioning systems, a ***split air-conditioning system*** divides its components into two or more separate locations. A split system's condensing unit may be placed outdoors and its evaporating unit may be placed indoors. In comfort cooling, both central air-conditioning systems and ductless systems may be either packaged or split.

31.2 Room Air Conditioners

A ***room air conditioner*** is an inexpensive and simple self-contained air-conditioning system that provides cooling to a portion of a building or residence. Most room air conditioners are installed in a window opening, and installation is relatively easy. Window units are available that fit double-hung or casement windows. Other room air conditioners, called *through-the-wall room air conditioners*, are designed to be installed in a standard size wall opening. See **Figure 31-5**.

A basic room air conditioner cools, filters, and recirculates air through a replaceable filter. High-pressure vapor refrigerant condenses in the condenser. It flows from the liquid line, through the metering device, and into the evaporator. Most room air conditioners use a capillary tube, a bypass AXV, or a TXV as its metering device. When the air conditioner is in operation, the evaporator is under low pressure. The liquid refrigerant rapidly boils and picks up heat from the evaporator surface. A motor-driven evaporator fan draws air from inside the room and pulls it through a filter. The fan forces the air over the evaporator. Air flowing over the evaporator is cooled. The cooled air is blown back into the room. The arrows in **Figure 31-6** show the airflow pattern.

As room air is blown across the evaporator coil, moisture from the air condenses on the evaporator's surface. This moisture then drains to a drip pan. In some units, the drip pan is drained to the outside. In other units, moisture from the evaporator flows into a pan in the compressor compartment. As the moisture evaporates, it helps to cool the compressor and condenser.

Goodheart-Willcox Publisher

Figure 31-6. This diagram shows airflow, refrigerant flow, and pressure conditions in a basic window or through-the-wall room air conditioner. Note that the conditioned airflow and the condenser airflow are completely separated from each other.

Low-pressure refrigerant vapor is drawn from the evaporator through the suction line back into the compressor. Compressed to high-side pressure, the vapor is then forced into the condenser. The compressor and condenser are in the part of the unit outside the building. The compressor compartment fan draws in outdoor air, circulates it over the condenser, and discharges it outside. The refrigerant in the condenser is cooled and condensed to a liquid, and the cycle begins again.

Pro Tip

Evaporator and Compressor Compartment Fans

The evaporator and compressor compartment fans may be driven by the same motor, or each may have its own motor. Check manufacturer literature for fan and motor arrangements.

Room air condtioners contain a built-in thermostat to operate the unit. A thermostat's sensing bulb is usually mounted at the inlet of the evaporator. A temperature differential of 5°F (3°C) between the evaporator inlet and duct exhaust is normal. If the part of the bulb farthest from the evaporator is insulated, the bulb will respond better to evaporator temperatures. It will cool sooner and stop the unit before it overcools. It will also stop the unit if the evaporator ices up. The unit will be prevented from starting again until the ice melts.

Caution

Restarting a Room Air Conditioner

As with all capillary tube refrigeration systems, if the unit is shut off and then immediately restarted, it may stall or fail to cycle on. The compressors in systems that use a capillary tube as a metering device are designed to cycle on under a certain high-side pressure. Immediately restarting such a system does not allow high-side pressure enough time to equalize with the low-side pressure. Allow enough time for the system to equalize after shut down to prevent compressor damage.

Copyright Goodheart-Willcox Co., Inc. 2017

As noted in the preceding section, a room air conditioner usually consists of a compressor, condenser, evaporator, refrigerant control, and motor controls. In some models, electric heating elements are included for cold weather use. During cold weather, the refrigeration system is turned off and the electric heating elements are activated. The evaporator fan is turned on. The same fan is used to circulate warm air in cold weather and cooled air in warm weather. The user can select the desired temperature to maintain using the control panel on the front of the unit, **Figure 31-7**.

31.2.1 Room Air Conditioner Features

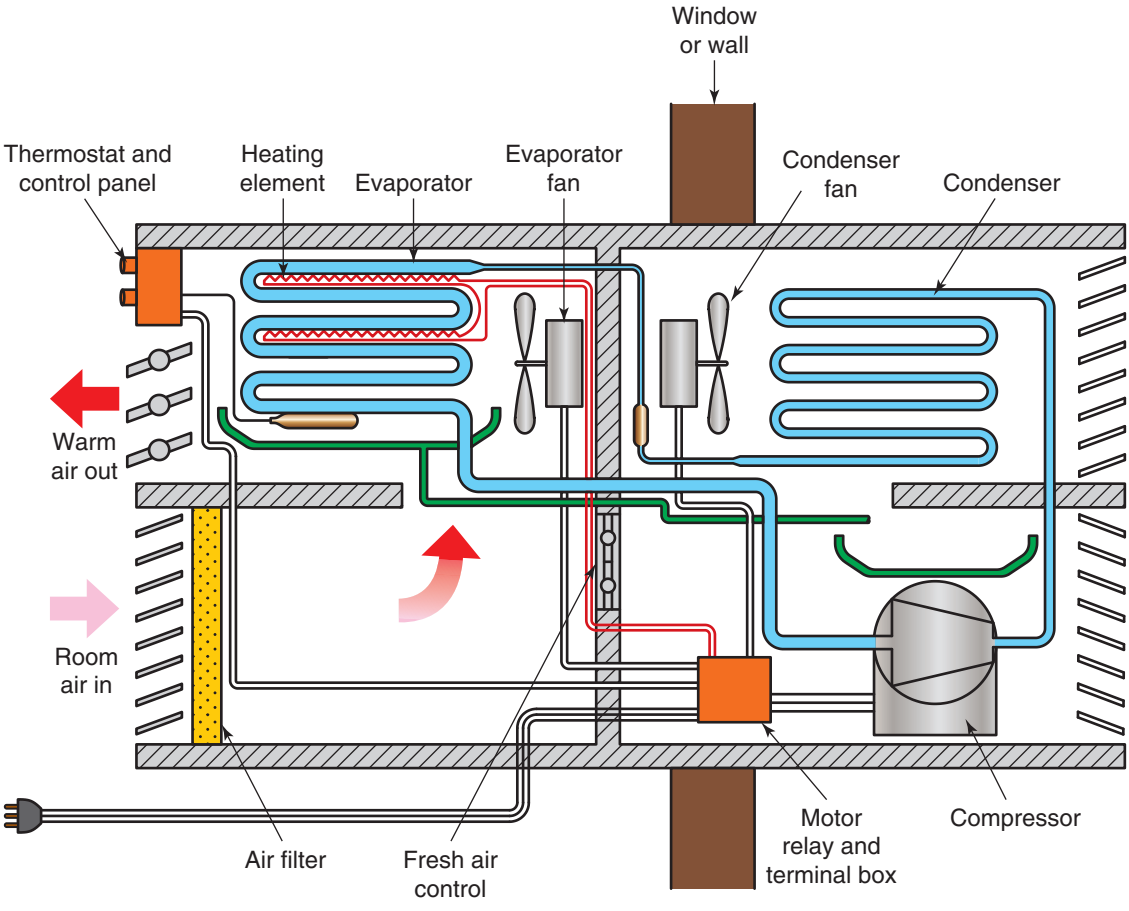
Some room air conditioners are equipped with handheld, infrared, remote controls. On some remote controls, indicator lights identify the operating mode and temperature setting currently selected. The user can use the handheld remote control to operate the system from any place that has a clear line of sight to the air conditioner. Most remote controls allow the user to program the clock, select the operating mode, change the fan speed, adjust the temperature setting, and set start and stop times.

Some basic room air conditioners are equipped with a fresh air intake to bring in outside air to mix with the recirculated indoor air. Another variation has an auxiliary electrical resistance heating unit to furnish heat. Another variation is self-contained heat pump, which is capable of providing both comfort cooling and heating simply by reversing the flow of refrigerant through the refrigeration system.

Some room air conditioners are designed so the conditioned air stream oscillates side-to-side as the unit runs. This helps distribute the conditioned air throughout the room. The oscillation is created by rotating angled deflector plates inside the conditioned air passage. The plates are mounted on a shaft. The shaft is turned by a turbine in the air passage, **Figure 31-8**.

31.2.2 Installing Room Air Conditioners

Window air conditioners are installed into a window opening using metal plates, rubber gaskets,



Goodheart-Willcox Publisher

Figure 31-7. Some room air conditioners have electric heating elements that provide heat during cold weather. Notice that the refrigeration system is shut down and high-side and low-side pressures equalize when the heating elements are energized.

Goodheart-Willcox Publisher

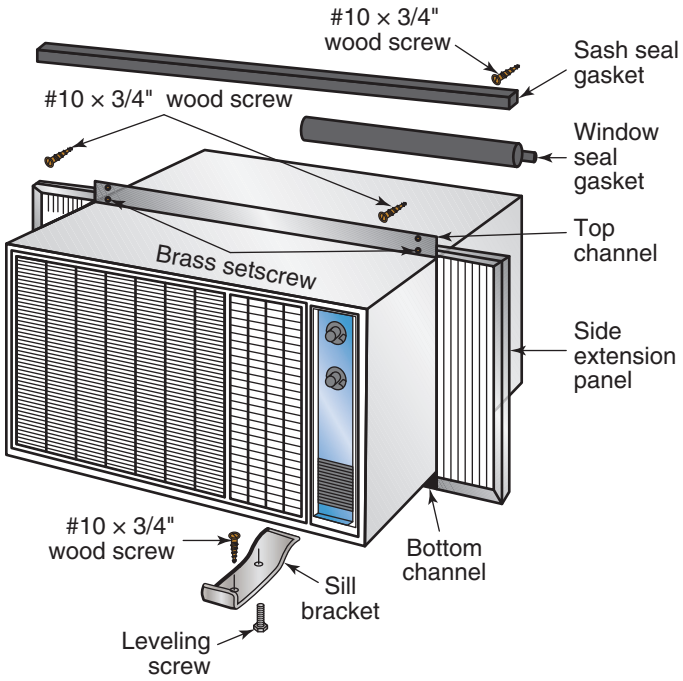
Figure 31-8. The operation of an oscillating grille deflector is shown here. A shaft connects a turbine in the exhaust passage to a series of angled deflector plates in the conditioned air passage. As the turbine spins, the deflector plates wobble around their centers. The wobbling deflector plates cause the conditioned air stream to oscillate left and right as it exits. One half of a rotation is shown here.

and sealing compounds. The condensing side of the unit must be tilted down slightly so the condensate can drain outside the building. A window air conditioner and the parts needed to install it are shown in **Figure 31-9**.

The unit must be securely fastened in place to prevent it from falling out of the window. The window itself must be secured in the proper position. A bracket on the outside of the building can provide support for the condensing side of a window air conditioner, **Figure 31-10**.

Room air conditioner manufacturers provide different methods of mounting. **Figure 31-11** shows a windowsill with a leveling bracket and security bracket mounted. Another method of bracing and leveling a window air conditioner is shown in **Figure 31-12**.

Manufacturers each have slightly different methods for mounting window units, however, most are similar. The first step in installing a window air



Goodheart-Willcox Publisher

Figure 31-9. Drawing showing a window air conditioner and the parts needed to mount it safely and seal the gaps in the window opening.

conditioner is to install the sleeve provided with the air conditioner into the window opening. The air conditioner chassis will slide right into the sleeve after it is installed. The sleeve is the outer shell of the air conditioner, and the chassis consists of a frame to which all of the functional parts of the air conditioner are mounted.

The air-conditioner sleeve should be adjusted to tilt downward about 1/4″ on the outside. This will tilt

RectorSeal

Figure 31-10. A mounting bracket supporting a window air conditioner.

Figure 31-11. Bracing is used to hold a window air conditioner on the windowsill.

the air conditioner enough to provide proper condensate drainage. A sponge rubber or plastic strip is usually placed between the air conditioner housing and the windowsill to help make a leakproof joint. The sill brackets and housing are screwed into the windowsill. Then, the rubber seal strips and the filler boards are put in place, **Figure 31-13**.

When the lower sash is raised to make room for the air conditioner, an air gap is created between the two sashes. This opening can be sealed with a sponge rubber or foam strip. The strips can be notched to fit the space. Sealing the air gap this way prevents heat leakage into the conditioned space, improving the efficiency and effectiveness of the air conditioner, **Figure 31-14**.

The air-conditioner chassis is heavy. It should be moved on a dolly or special carrier. Avoid using the tubing or coils as hand grips for moving or lifting the chassis. Carry the unit by holding onto the bottom pan.

Do not force the air-conditioner chassis into the sleeve. As the chassis slides into the sleeve, make sure the refrigerant lines and wiring are free and clear. When the chassis is in place inside the housing, install the front grille, filter, and control knobs. As a final step, check the installation for tightness. Check all seams to see if light is showing through and seal any that are found using foam strips or, where appropriate, caulk. All edges around the window and air conditioner should be sealed to minimize air infiltration.

A room air conditioner should be equipped with a grounded (three-prong) electrical cord. Plug the air conditioner into a separate, dedicated electrical circuit. Check the unit nameplate for appropriate electrical information. A suitable electrical circuit is necessary.

Air conditioners that mount through the wall are popular in apartments. They can be left in place year round and do not prevent the windows from being opened and closed. Typically, an insulated cover is placed over this type of air conditioner during the heating season. **Figure 31-15** shows a typical through-the-wall air conditioner installation.

31.2.3 Servicing Room Air Conditioners

Servicing room air conditioners (window, through-the-wall, and packaged terminal) is similar to servicing small domestic refrigeration systems, like refrigerators and freezers. The diagnosis and service of domestic refrigeration systems were explained in Chapter 25, *Installation and Troubleshooting of Domestic Refrigerators and Freezers*, and Chapter 26, *Service and Repair of Domestic Refrigerators and Freezers*. Some of the

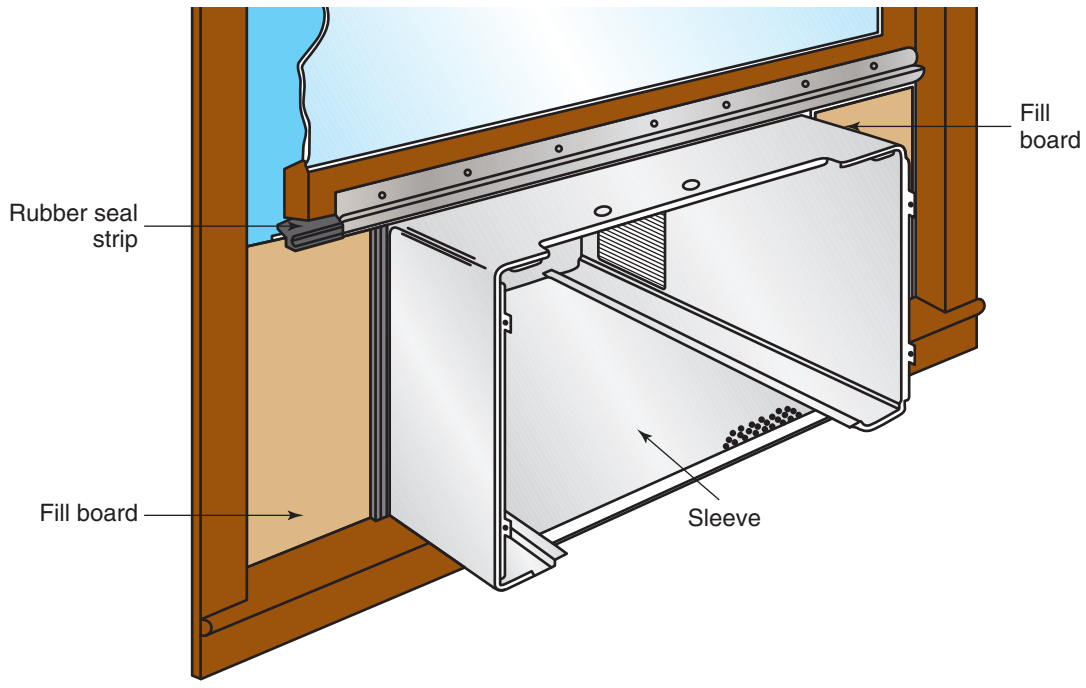
external service operations specifically intended for room air conditioners are described in the following paragraphs.

On a semiannual basis, the air filter should be inspected and either cleaned or replaced. This task is usually performed by the owner. **Figure 31-16** shows a typical filter design for a room air conditioner.

Every year, thoroughly clean the evaporator, condenser, fan blades, fan motor, compressor, and housing. To prepare the unit for service, the chassis should be removed from its housing or sleeve.



Goodheart-Willcox Publisher

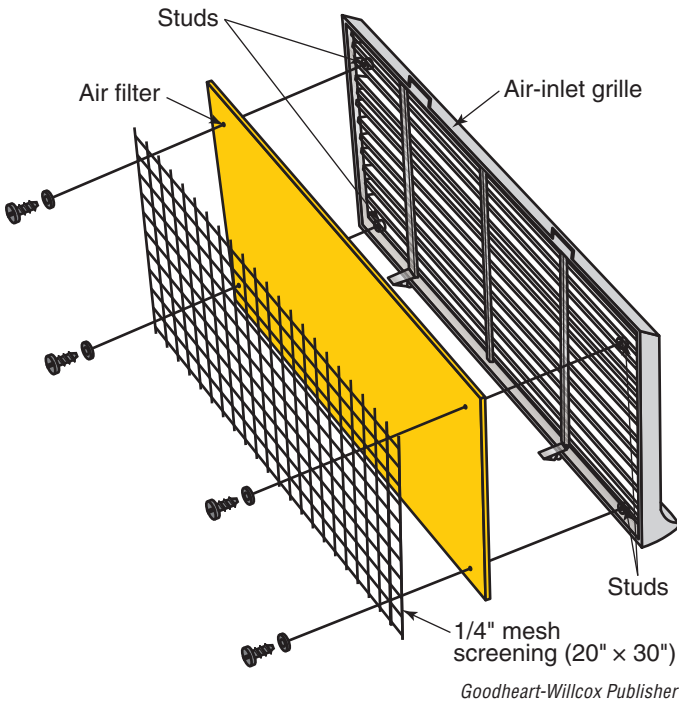
Goodheart-Willcox Publisher

Figure 31-15. Typical through-the-wall room air conditioner installation.



Goodheart-Willcox Publisher

Figure 31-16. Typical air filter installation for room air conditioner.

Before removing the air-conditioner chassis from its housing, place a tarp or newspapers on the floor to catch any dust or dirt that falls. Remove the chassis carefully, and carry it to a designated area for service. If possible, clean the air conditioner outdoors. This reduces the chance of creating a mess and increases the number of cleaning methods that can be used.

Remove or tie back curtains or drapes, and then use a commercial vacuum cleaner with a brush nozzle to clean the inside of the air-conditioner housing. After the housing is clean, move on to the chassis. Finned evaporators and condensers are difficult to clean. The fin spacing prevents the vacuum brush from reaching the lint and dirt. In such cases, use plastic blades and a powerful vacuum to remove most of the dirt. Any dirt on the evaporator or condenser reduces their ability to transfer heat, reducing the effectiveness of the unit. Never use metal blades for cleaning; they can poke through the coil tubing, causing leaks. If the air conditioner is being cleaned outdoors, a powerful water and detergent spray can be used to clean the coils. Clean the coils as thoroughly as possible and straighten any bent fins on the coils.

Copyright Goodheart-Willcox Co., Inc. 2017

While the air-conditioner chassis is out of its housing for cleaning, inspect the fan motor or motors and lubricate them (unless they have sealed bearings). Always wipe away excess oil. Oil residue on the fan blades will collect lint and reduce the fan's ability to move air. When servicing fan motors, make certain that fans are tight on the shaft. They should be carefully positioned in the shroud for efficient air movement. Avoid bending or twisting the fan blades. An off-balance fan will be noisy because of vibration and will quickly wear out the motor bearings. Replace damaged fans.

Inspect the condensate drain. It must be clean and free of any blockage. Remove lint from the drain hole and tube using a soft wire. Check all bolts, nuts, and screws for tightness. Before reinstalling the air-conditioner chassis into the housing, run the air conditioner to check for noise. If an unusual noise is heard, find its source and correct the problem. Always put a cloth over the air conditioner's conditioned air outlet when it is first started after cleaning. Any loosened dirt not removed by the vacuum cleaner will be blown out of the adjustable grille when the air conditioner starts up for the first time.

The wiring of a window air conditioner is very similar to the wiring of other refrigeration units. See **Figure 31-17**. External electrical service procedures are

Copyright Goodheart-Willcox Co., Inc. 2017

usually the same as those for domestic refrigeration systems, with the following exceptions:

- Fan motors usually have two or three speeds.
- Some systems have three capacitors: a start capacitor, a run capacitor, and a fan motor capacitor.

A unit with a start capacitor and a run capacitor is shown in **Figure 31-18**. An arrangement with three capacitors is shown in **Figure 31-19**. In this example, the run capacitor and the fan motor capacitor are located together in a single case.

Figure 31-20 shows a wiring diagram for a window air conditioner equipped with a three-speed fan motor. The system operates on a 240 V circuit and has a 21,000 Btu/hr (6.15 kW) capacity.

The procedures for testing electrical components is similar to those for servicing small domestic refrigeration systems. Fan and compressor motor testing is described in Chapter 17, *Servicing Electric Motors and Controls*. Before doing internal service work, make sure the malfunction is not in the external circuit. Test for power. Check the thermostat, the relay, the capacitors, and the overload protectors (both electrical and temperature).

Most window air conditioners are equipped with a thermostat. These thermostats are typically adjustable to cut out between 56°F (13°C) and 60°F (16°C).

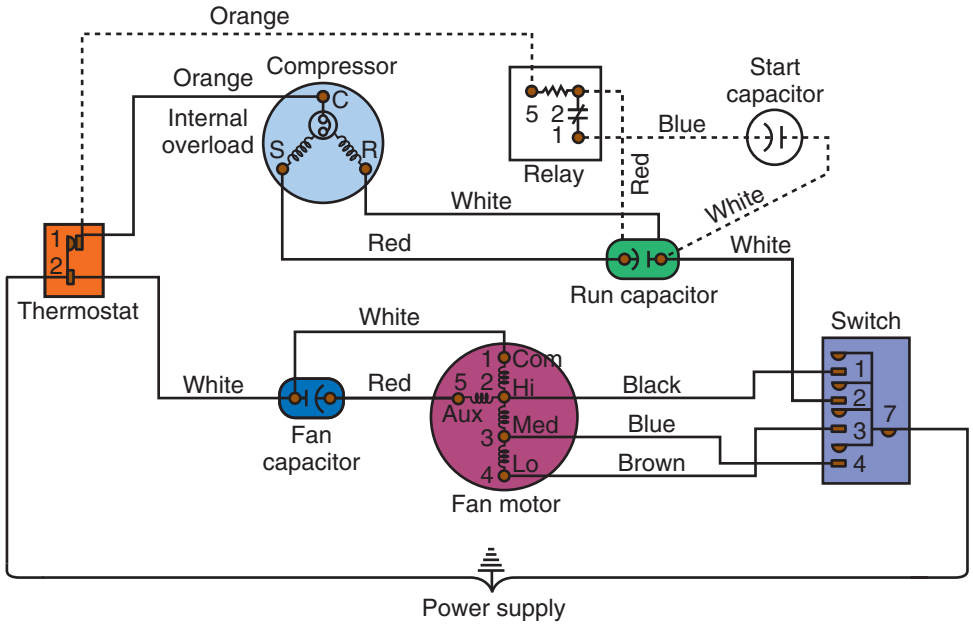
Super cool	C	C	O	O
C = closed O = open				



Fedders North America, Inc.

Figure 31-20. Wiring diagram of three-speed fan system.

The cut-in adjustment is typically between 77°F (25°C) and 80°F (27°C). Their differentials vary between 3°F (2°C) and 8°F (4°C). If a thermostat fails, the unit will not start. To test the operation of a thermostat, cover the air outlet and air inlet with a cloth. This will cause the air inside the unit to recirculate, which will quickly drop the air temperature to the cut-out temperature. Use a thermometer to monitor the air temperature so it can be compared to the desired cut-out temperature.

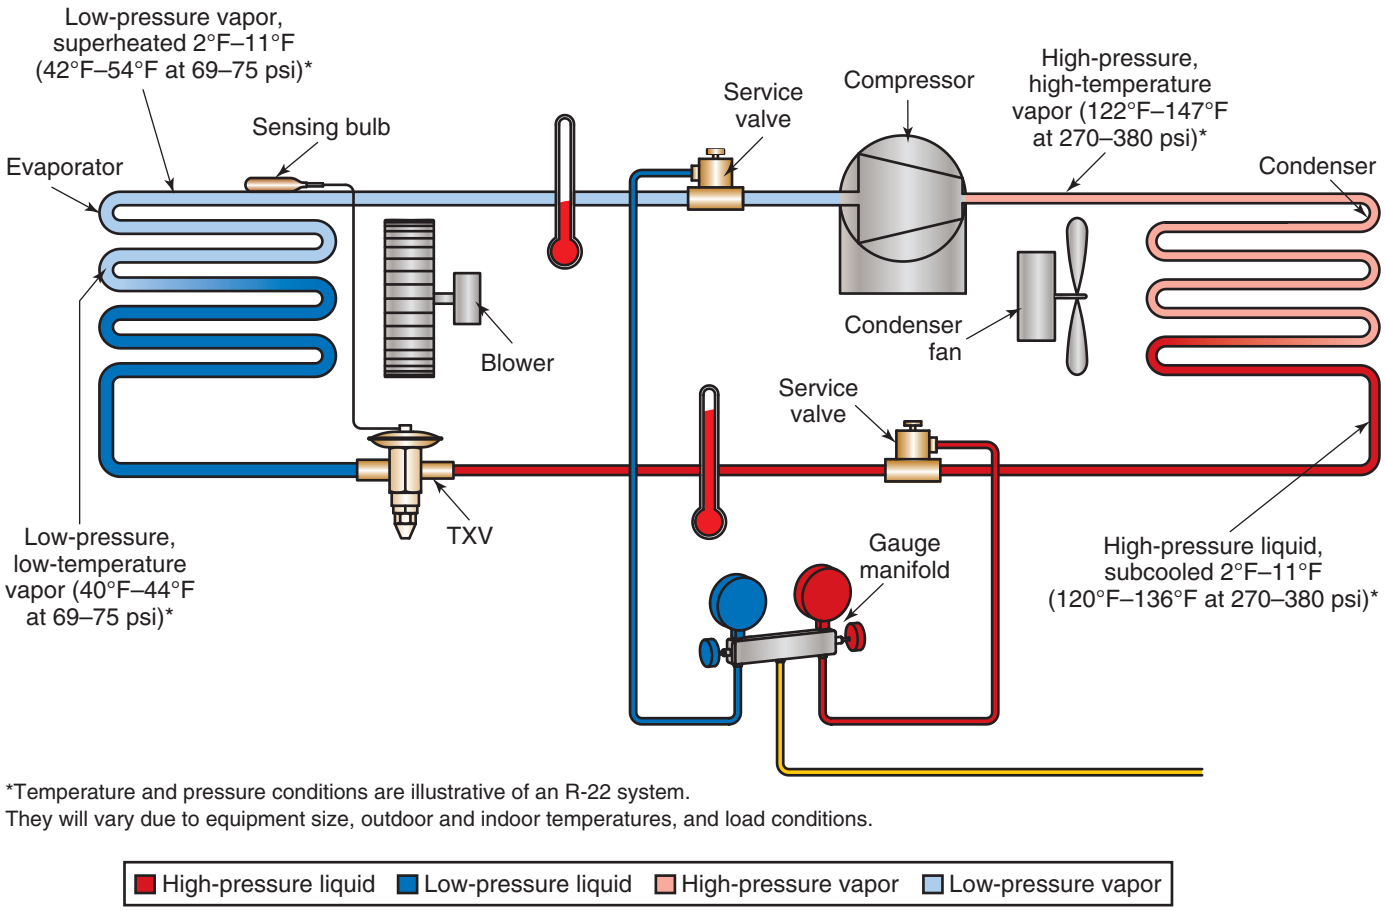
Other troubles inside a room air conditioner can include the following:

- Lack of refrigerant.
- Stuck compressor.
- Inefficient compressor.
- Clogged refrigerant circuit.
- Short circuit, open circuit, or grounded motor windings.

The motor condition can be checked with a test light or ohmmeter. To check for lack of refrigerant or clogged refrigerant lines, install a gauge manifold. If the system is not equipped with service valves, it may be necessary to install piercing valves on the suction line and discharge or liquid line before attaching a gauge manifold, **Figure 31-21**.

If the system lacks refrigerant, locate the leak and repair it before recharging the system. If the compressor is bad, it can be replaced on the owner's premises, or the unit can be taken to a shop for repair.

Copyright Goodheart-Willcox Co., Inc. 2017



Goodman Manufacturing Company

Figure 31-21. Air conditioning unit cycle diagram showing gauge manifold installed.

Many window air conditioners use PSC (permanent split capacitor) compressor motors. These motors do not use a relay for starting and will have difficulty starting if the supplied voltage is low (10% or more). Many service technicians install a start capacitor and a relay to overcome this problem. The capacitor and the relay must be the correct size for the motor. The best way to determine the correct size is to follow the manufacturer's recommendation. If this is not available, the table in **Figure 31-22** will help in selecting the correct start capacitor.

A start capacitor circuit must include a relay that opens the circuit when the compressor reaches a satisfactory speed. Special start capacitors are available for compressors with PSC motors. See **Figure 31-23**.

Replacement capillary tubes for room air conditioners are selected by size. **Figure 31-24** gives the correct sizes for replacement capillary tubes in systems charged with R-22 and those systems charged with R-410A refrigerants.

Window air conditioners are often removed during the winter season. However, if this is inconvenient,

the unit can be winterized. The air inlet and the outlet grilles can be blocked with cardboard or flexible plastic sheeting. A storm sash can be custom built to fit around the air conditioner. Plywood held in place with caulking or rubber grommets can also be used. Check the manufacturer's service manual for proper winterization of the unit.

If the window unit drips water into the room, it is not correctly installed. Check the slope of the unit from inside to outside with a level. It must slope to the outside (condenser edge) about 1/4″. Condensate water will then run to a depression in the housing under the condenser fan and condenser. Make sure the drain hole is open, and then level the unit along its other dimension. Finally, recheck the unit installation for airtight sealing in the window opening.

31.3 Packaged Terminal Air Conditioners (PTACs)

A ***packaged terminal air conditioner (PTAC)*** is the type of self-contained, ductless air-conditioning system commonly used in hotels and apartment buildings. PTACs are installed in an exterior wall of a building. When a PTAC is installed, the condensing side of the unit is positioned outside the building wall, and the evaporator side of the unit is positioned inside. Often, PTACs provide heating and cooling, though some may only be designed for cooling. PTACs are designed to condition air in an individual room or zoned part of a building. They are frequently used in hotel rooms, apartments, dormitories, shops, offices, banks, and restaurants. See **Figure 31-25**.

Many PTACs are designed to fit through a standard 42″ × 16″ wall space. While they provide cooling using standard mechanical refrigeration, they provide heat using one of the following methods:

- Electric resistance heater.
- Operating as a heat pump.
- Operating as a heat pump with electric resistance heater.
- Gas-fired heater.

Electric resistance heat PTACs use electric resistance heaters mounted in the air distribution section of the unit. Usually, these units require 240-volt wiring to efficiently operate the electric resistance heaters. More information about electric resistance heating is presented in Chapter 43, *Electric Heating Systems*. **Figure 31-26** shows an exploded view of a packaged terminal air conditioner with an electrical resistance heater.

A ***packaged terminal heat pump (PTHP)*** can reverse its refrigeration cycle in order to produce heat.

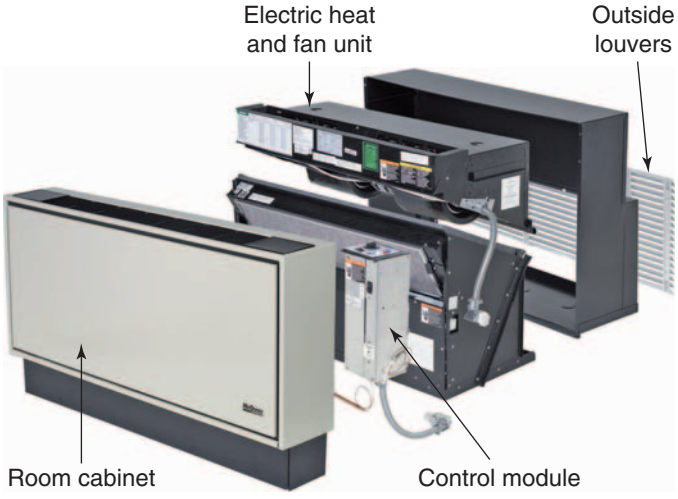
McQuay International

Figure 31-25. Packaged terminal air conditioners (PTACs) usually contain both heating and cooling systems. PTACs are frequently used to provide year-round comfort in offices and apartments.



McQuay International

Figure 31-26. This PTAC uses electrical resistance heaters to provide heat.

In the heating mode, a four-way reversing valve changes the pathways to the suction line and liquid line, reversing the flow of refrigerant through the system. While the compressor still operates as it does during the cooling cycle, the reversing valve causes the compressor to draw in low-pressure vapor from the outdoor refrigerant coil, and it causes the compressor to send high-pressure refrigerant into the indoor refrigerant coil. More information about heat pump operation is presented in Chapter 40, *Heat Pumps*.

Thinking Green

Heat Pump vs. Electric Heat

Heat pumps produce heat up to three times more efficiently than electric resistance heating. In all but the coldest of regions, a packaged terminal heat pump will significantly reduce energy consumption compared to a packaged terminal air conditioner equipped with electric resistance heat.

Packaged terminal heat pumps are generally suitable for geographical regions where temperatures do not typically drop below freezing. The control can be set for the desired temperature, and the unit automatically selects heating or cooling mode based on measured air temperature.

In cold climates, a packaged terminal heat pump may not be able to provide sufficient heat while running a reverse cycle. The packaged terminal heat pump is then assisted by electric resistance heaters. Packaged terminal heat pumps with auxiliary resistance heaters can provide heat in any climate conditions, but they operate more efficiently when the temperature is above 35°F (2°C).

Another type of PTAC is equipped with gas-fired heater that uses electronic ignition and either LP or natural gas supplied to the system. The heater section of the PTAC is completely sealed off from the inside living space. It draws in outside air for combustion and exhausts the products of combustion to the outside as well. The heat of combustion is transferred indoors through a heat exchanger, which keeps the indoor air completely separate from the combustion air. One drawback of a gas-fired heater is that it requires a gas line to be run to the unit. More information about gas-fired heating is presented in Chapter 41, *Gas-Fired Heating Systems*.

Return air enters a PTAC through a lower grille. Conditioned air is discharged through the upper grilles, **Figure 31-27**. Some PTACs simply recirculate indoor air while others have adjustable fresh air intakes and evaporator bypass controls. PTACs often must have drains to remove the condensate flowing from the evaporator.

All types of packaged terminal air conditioners use hermetic compressors, which can be rotary, scroll, or reciprocating. Their refrigerant controls are typically capillary tubes or thermostatic expansion valves. PTACs are normally charged with R-134a or R-410A.

Copyright Goodheart-Willcox Co., Inc. 2017

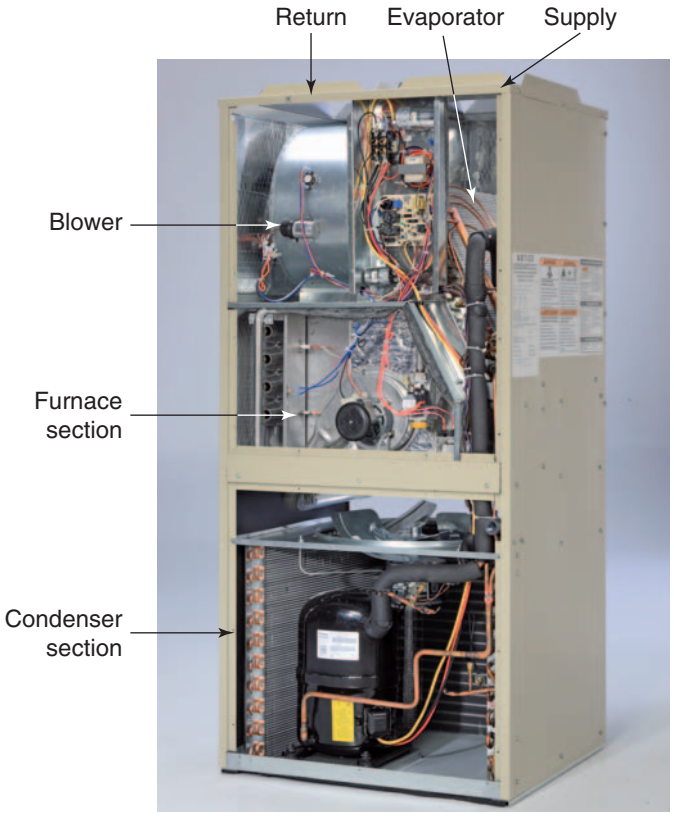
A PTAC's airflow system includes a blower fan for the evaporator and another fan for the condenser. Typically, the entire PTAC will slide out of its wall cabinet for easy service. Basic user controls include a heating and cooling thermostat and rotary switches for selecting heating or cooling operations and fan settings.

31.4 Console Air Conditioners

A ***console air conditioner*** is an entire air-conditioning system mounted in a stand-up cabinet. These systems are also commonly referred to as *vertical packaged terminal air conditioners*. They vary in capacity from 1/2 ton to 4 ton. Such units are often used in small commercial establishments such as restaurants, stores, and banks, **Figure 31-28**.

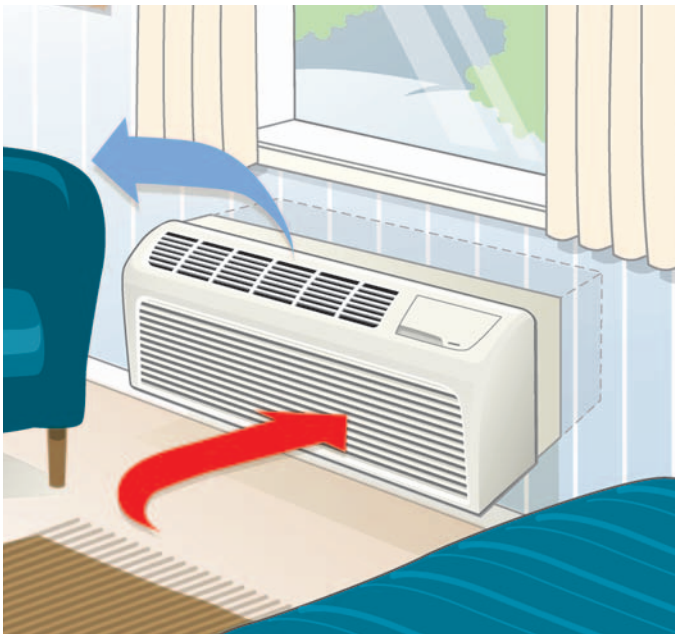
Ducts can be connected to deliver conditioned air to areas with poor air circulation, such as partitioned spaces within a room. The condensing unit is mounted in one section of the console; the air blower and evaporator are in another section of the cabinet. Some console units simply recirculate indoor air, while others have adjustable fresh air intakes and evaporator bypass controls, **Figure 31-29**.

All console units must have drains to remove the condensate flowing from the evaporator. Console units typically use a hermetic compressor. The refrigerant control is usually a thermostatic expansion valve. Most have air-cooled condensers.



Suburban Manufacturing

Figure 31-28. Console air conditioner with an air-cooled condenser and gas-fired heater. The system can be used to cool or heat a single space, or ducts can be added to provide air conditioning to multiple spaces.



Goodman Manufacturing Company

Figure 31-27. Indoor airflow through a PTAC.

31.4.1 Installing Console Air Conditioners

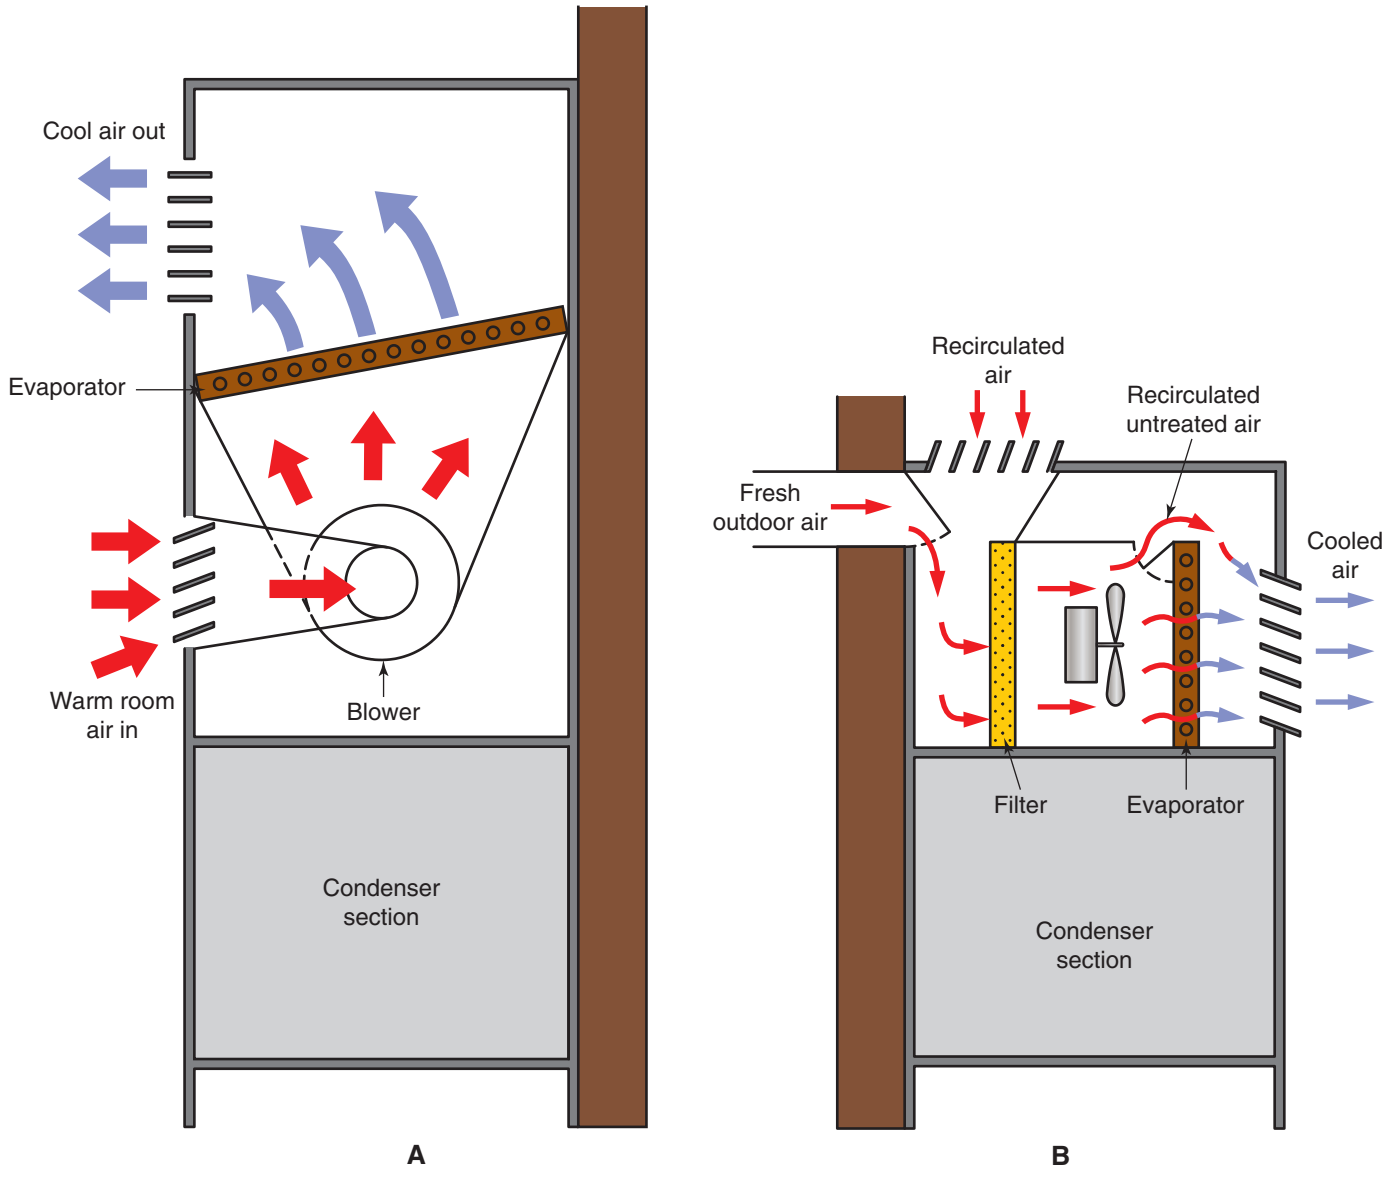
Console units are factory-assembled. After placing and leveling the unit, any necessary plumbing and electrical connections are made. Such connections must conform to local codes. Unit operation should be thoroughly checked after installation, including air temperature (both inlet and outlet), electrical load, and operating pressures. The data should be recorded for future reference and saved with the service company and also with the console owner.

31.4.2 Servicing Console Air Conditioners

When internal parts of a console air conditioner must be serviced, panels must be removed from the cabinet to gain access. Periodic maintenance that must be performed on console air conditioners includes the following:

- Replacing or cleaning the air filter.
- Cleaning the evaporator coil and fins.

Copyright Goodheart-Willcox Co., Inc. 2017



Goodheart-Willcox Publisher

Figure 31-29. Air circulation through two different console air conditioners. A—This console air conditioner can only recirculate indoor air. B—This console air conditioner has controls and corresponding dampers for mixing outdoor air with recirculated air and for allowing a portion of filtered, recirculated air to bypass the evaporator.

- Cleaning the fan motors and oiling it (unless it has sealed bearings).
- Cleaning the drain pan and drain tube.

The inner lining of the cabinet sometimes gathers lint. Any lint or other debris inside the cabinet should be vacuumed out regularly. Service of most console air conditioners is similar to service of room air conditioners, residential air-conditioning systems, and some light commercial air-conditioning systems. Check the refrigerant charge, return and supply air temperature, low-side and high-side pressure, the operation of the metering device, and the amperage draw of the compressor.

A regular maintenance schedule is necessary to ensure long and satisfactory service from any air-conditioning system. Different parts of the system must be checked more frequently than others. A record should be kept of all checks including both the data and the date it was acquired. The following are maintenance and inspection procedures that should be performed on a regular schedule.

Weekly:

- Check the condition and tension of any V belts.
- Check fans for proper operation and speeds.
- Check all remote or secondary units.

Copyright Goodheart-Willcox Co., Inc. 2017

- Check for water leaks and repair as needed.
- Check controls (pressure, temperature, and airflow).
- Lubricate the system as specified. Check the compressor oil level if sight glass is available.
- Check canvas connectors on ducts for damage and repair or replace as needed.

Monthly:

- Check the refrigeration system (check for leaks or oil spots).
- Check the air filters and clean or replace as needed.
- Check the humidifier for proper operation and scale buildup.
- Check the safety valves.
- Check the duct dampers, registers, and diffusers.
- Check the piping for proper insulation, excessive vibration, and wear.

Every six months:

- Clean fans and cabinet.
- Clean duct registers and diffusers.

Every year:

- Check the efficiency of the compressors.
- Check damper operation.
- Clean water circuits (where applicable).
- Operate all hand valves.

Every two years:

- Inspect the condenser's wet surfaces (where applicable).

31.5 Portable Air Conditioners

Portable air conditioners are used to ***spot cool*** (cool a specific, limited area) without the expense of installing a traditional cooling system. ***Portable air conditioners*** are self-contained. The evaporator, compressor, condenser, and refrigerant control are packaged together in one case, which is often equipped with wheels so the unit can be rolled where it is needed. Portable air conditioners are designed for continuous operation and can provide non-stop cooling if needed, **Figure 31-30**.

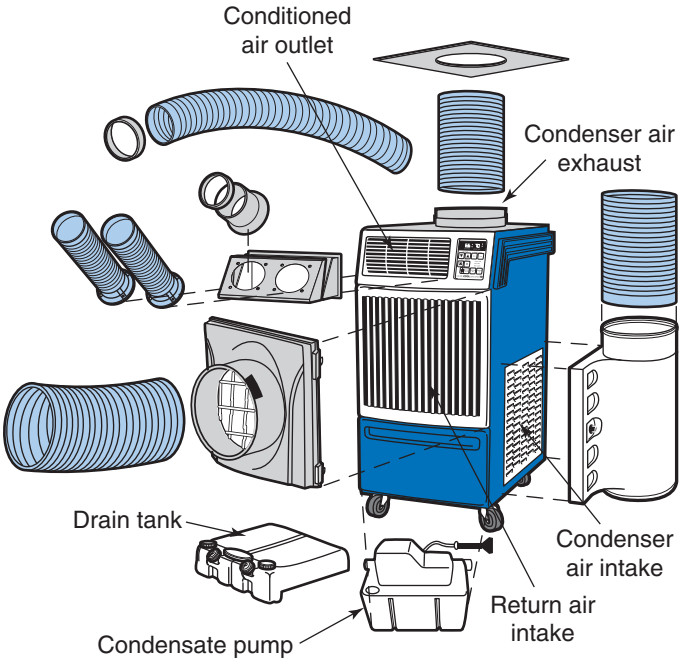
Portable air conditioners are used extensively in commercial environments, such as hospitals, office buildings, computer and server rooms, and institutional environments to cool people and equipment. Because of their compact design, they can be easily relocated to provide conditioned air wherever needed.

Units use ducts to direct warm condenser air away from the cooled area. Depending on the unit's design and the types of adapters used, the warm air can be vented out of a window, into a drop ceiling with a large common air space, or into an adjacent room. See **Figure 31-31**.

Haier America

Figure 31-30. A portable air conditioner using a window to access air for condenser cooling.

In some designs, the cooled evaporator air exits through a grille in the top front of the case. In other designs, the cooled air is directed through one or more



DENSO Sales California, Inc.

Figure 31-31. The accessory ducts and adapters available for a typical portable air conditioner.

10

Copyright Goodheart-Willcox Co., Inc. 2017

ducts or nozzles at the top front of the unit. Return air for the condenser and evaporator can be drawn through grilles in the case or can be drawn in from a remote location through ducts.

As a portable air conditioner cools the air, it also lowers the humidity of the air, **Figure 31-32**. Condensation is collected in a drain tank built into the unit. The condensation can be gravity drained or a pump can be attached to pump the condensate to a higher elevation so it can be drained out of a window or into a sink. Some advanced designs evaporate the condensate using the warm air blown over the condenser. This vaporized condensate then flows with the condenser cooling air into an unconditioned area. In these designs, since most of the condensate is removed from the unit with the hot exhaust air, the tank can be drained less often.

Uses for portable air conditioners include the following:

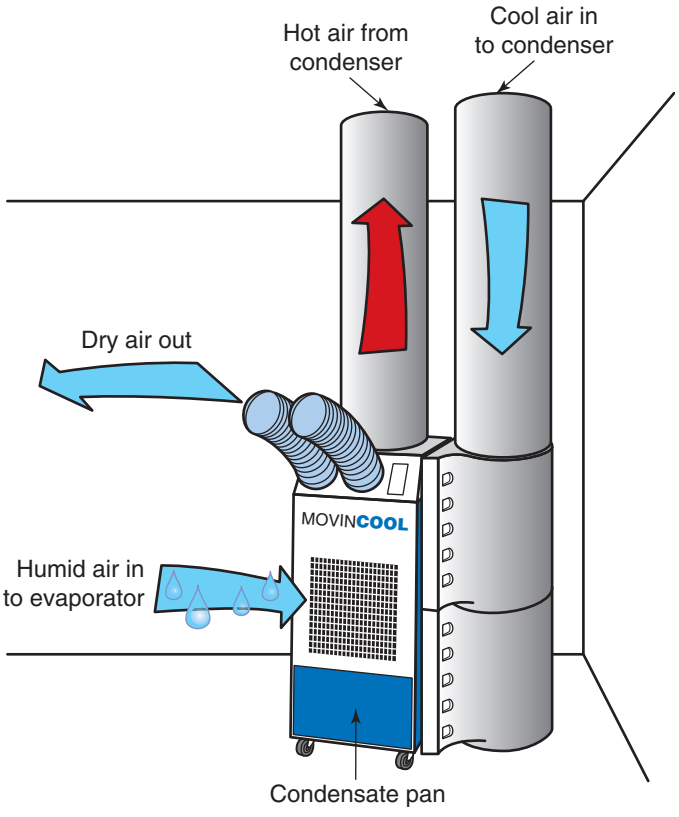
- Primary cooling. When people are exposed to hot operations such as welding, brazing, or oven curing, spot cooling improves safety and productivity. Portable air conditioning can speed up manufacturing processes by cooling materials that are too hot to handle or package.
- Supplementary cooling. When a central system is not sufficient, portable air conditioning protects electronic, computer, and telecommunications equipment against excessive heat buildup, **Figure 31-33**.
- Emergency cooling. When the central air-conditioning system fails or is down for maintenance, portable air conditioners can provide cooling in critical spaces.

Portable air conditioners have wheels and can be manually moved to the site. Most portable air conditioners have less than 5 tons of capacity.

Mobile air-conditioning units are similar to portable air conditioners but are larger and have greater cooling capacity. Mobile air-conditioning units are mounted to a trailer or skid and placed outdoors with heavy equipment. They are generally 5 tons or larger and can be used to cool an entire office building in an emergency.

Another type of spot cooling uses a ceiling-mounted air-conditioning unit. It is located between a drop ceiling and a building's roof. These installations are less involved than a traditional ductless system and more permanent than portable air conditioners. There are no refrigerant lines that need to be installed or brazed. A ceiling-mounted system requires only a little wiring and short runs of ducts. Warm air is drawn into the unit, cooled, and returned. Heat absorbed from the conditioned air is expelled into the unconditioned air above the drop ceiling or is directed outside through ducts, **Figure 31-34**.

Some companies specialize in renting portable air-conditioning equipment to meet the emergency cooling needs of their customers. For example, if the



DENSO Sales California, Inc.

Figure 31-32. Humid rooms or those damaged by flooding can be cooled and dehumidified with portable air conditioners.

DENSO Sales California, Inc.

Figure 31-33. Rooms containing a company's servers and other telecommunication devices can produce more heat than a building's HVAC equipment can handle. Portable air conditioners are a convenient solution.

Figure 31-34. Between the drop ceiling and roof, this ceiling-mounted air-conditioning unit cools the hot air in the server room and pumps out any condensate.

central air-conditioning system in a large commercial or industrial building is shut off for scheduled maintenance or because of a malfunction, the building's manager can call on one of these rental companies. The rental company will evaluate the customer's cooling needs and install portable air-conditioning equipment to meet those needs.

31.6 Multizone Ductless Split Systems

A ***ductless split system*** is a split air-conditioning system that does not use forced-air ductwork as a means of distributing cooled air. Like traditional split systems, a ductless split system has a condensing unit (compressor and condenser) outside a building that is connected by tubing to a cooling unit (evaporator) inside the building. Ductless split systems often use multiple cooling units throughout a building. These cool the air in individual rooms. The cooling units use fans to pull in warm air, absorb heat into the refrigerant in the evaporator, and blow cool air back into the room. No ductwork is used, **Figure 31-35**.

Since many ductless systems use multiple indoor cooling units through a building, they can be set up as a zoned system, if proper controls and components are available. ***Multizone ductless split systems*** are comfort cooling systems consisting of one or more outdoor units, multiple independent indoor units, and individual temperature controls for each indoor unit. This type of system is similar in design to standard split air-conditioning systems. To provide cooling, the outdoor units function as condensers and the indoor coils function as evaporators. However, multizone ductless split systems deliver conditioned air directly from the indoor unit into the room. There is no ductwork to distribute the air. See **Figure 31-36**.

Multizone ductless split systems are popular for adding air conditioning to both new construction and to older buildings that are not equipped with air duct systems. Ductless systems are frequently used in offices, motels, multifamily dwellings, and houses that use hydronic heating, electric baseboard heat, or

Mitsubishi Electric, HVAC Advanced Products Division

Figure 31-35. A ductless split system. A refrigerant line set connects the indoor and outdoor units. This room is being cooled by its cooling unit.

space heaters. Multizone ductless split systems offer a convenient solution for providing heating and cooling to room additions and small apartments, where extending or installing distribution ductwork for a central air conditioner or heating system may not be an option.

Code Alert

Code Applicability

Many factors affect a building code's applicability to a job. For example, adding air conditioning to a previously unconditioned building may fall under the purview of local building codes. If the building is part commercial and part residential, two different building codes may apply. If the building is a historic landmark, the building may be exempt from local building codes. Always check the applicability of local building codes before beginning a job.

In a multizone ductless split system, an outdoor unit is located outside. These can be installed a number of different ways, depending on the building and the space available. Common installations are on a concrete slab, pads, a wall-mounted bracket, a riser, or metal stand, **Figure 31-37**.

One or more indoor units are installed in separate rooms in the building and are connected to the outdoor unit by a line set. Each indoor unit has its own refrigerant coil, blower, metering device, and sometimes a heating unit. The line set contains the refrigerant lines. This may also be packaged with electrical wiring and a condensate drain, **Figure 31-38**.

The hookup between the outdoor and indoor units usually requires only a 3″ (8 cm) hole through a wall for the line set. Many manufacturers of multizone ductless split systems offer connecting line sets

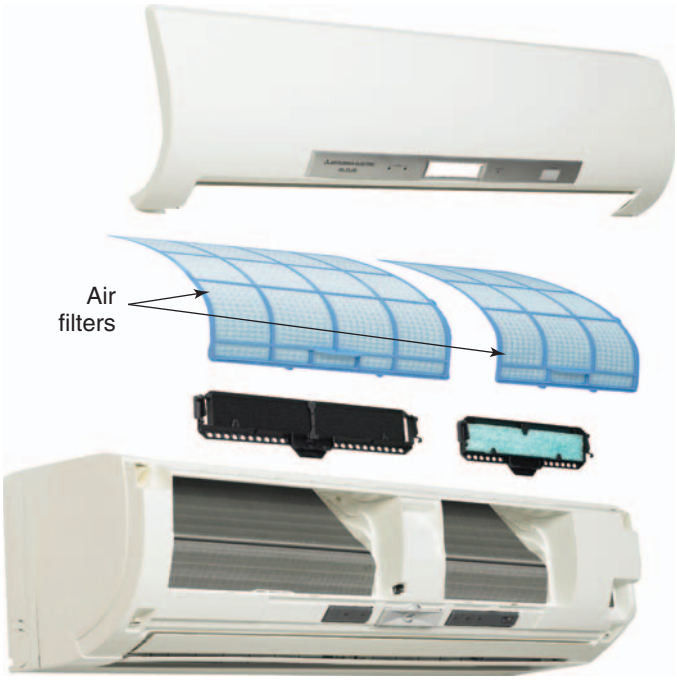
in a variety of lengths. This allows the technician to locate the outdoor unit as far away as 50′ (16 m) from the indoor unit.

An important job of a central air handler in a forced-air system is the filtering of air. Ductless split systems perform this job in each of their indoor units. Air filters are shaped to fit into the indoor units and provide filtration in individual areas, **Figure 31-39**.



Mitsubishi Electric, HVAC Advanced Products Division

Figure 31-39. This indoor unit is shown with its cover and air filters removed.

The independent temperature controls on each indoor unit determine the temperatures maintained in their corresponding spaces. Some multizone ductless split systems provide only cooling while others are heat pumps, capable of providing both heating and cooling. In a cooling-only system, the outdoor units are condensing units and the indoor units are evaporator units. In heat pump systems, the outdoor and indoor units can act as either a condenser or evaporator, depending on whether the heating or cooling mode is selected.

Some of the primary advantages of multizone ductless split systems are as follows:

- Each indoor unit temperature is set individually, enabling the system to maintain different temperatures in different spaces.
- Most units are equipped with a wireless remote control for convenient temperature control. See **Figure 31-40**.
- Because the indoor units can be mounted in a variety of ways (suspension from a ceiling, flush mounted into a drop ceiling, or hung on a wall), multizone ductless split systems provide greater flexibility for interior decorating than room or packaged terminal air conditioners. See **Figure 31-41**. Most indoor units are designed to have a thin profile.

Figure 31-41. Indoor units are available in a number of designs to meet different architectural and interior design demands. A—Wall-mounted unit. B—Slim duct unit can be concealed in a wall or soffit. C—Compact cassette-type can be flush mounted in the ceiling.

Many traditional multizone ductless split systems operate much as a standard heat pump. They use a fixed speed compressor, fixed speed indoor and outdoor fans, and a TXV as the metering device. This requires that they be correctly sized for the heating and cooling load of each zone. Newer multizone ductless units use a variable speed compressor, variable speed fans, and electronic expansion valves (EEVs) to regulate the volume of refrigerant flowing in the system. This allows the system to circulate only the amount of refrigerant needed for a specific load. These units are known as ***variable refrigerant flow (VRF) system*** or *variable refrigerant volume (VRV) system*. VRF systems are covered in more detail in Chapter 32, *Residential Central Air-Conditioning Systems*, and Chapter 33, *Commercial Air-Conditioning Systems*.

31.6.1 Ductless Split System Installation

Ductless air conditioners are installed much as standard split systems are installed. The outdoor unit is mounted outside. This can be done in a variety of manners depending on the building and the space available. Larger outdoor units are often mounted on a concrete slab or mounting pad, **Figure 31-42**. Refer back to **Figure 31-37** for other mounting options.

Many indoor units are mounted on walls, near the ceiling. It can be difficult to hold the unit in place while necessary wiring and other connections are made. Once the wall plate is secured into place, a bracket can be attached to hold the indoor unit in place, **Figure 31-43**.

Programming temperature set points and system controls depends on whether a building uses a single multizone system or more than one condensing unit to operate multiple indoor units. This will vary by each installation. It may be more convenient for a building to have one outdoor unit that works with all the indoor units on ground floor and have a second outdoor unit that works with all the indoor units upstairs.

31.6.2 Ductless Split System Service

Ductless split systems require many of the same services and maintenance procedures as other split

Fujitsu General America, Inc.

air-conditioning systems. Standard split systems with a central air handler have only one air filter. A ductless split system has at least one air filter in each of its indoor units. A common task is cleaning or replacing the air filters in the indoor units, **Figure 31-44**.

Evaporator coils in indoor units also need to be cleaned on occasion. To do this, remove outer panels, air filters, and any other accessories that could block the flow of cleaning fluid. Set up a large plastic bag or bib to catch and contain the cleaning fluid. This can be directed into a bucket for later draining, **Figure 31-45**.

Fujitsu General America, Inc.

Figure 31-44. This technician is examining an air filter from an indoor unit.

Thinking Green

Dirty Coils Decrease Efficiency

Dirt on evaporator and condenser coils decreases the coil's ability to transfer heat and, in extreme cases, increases resistance to airflow across the coil. To keep the system operating at maximum efficiency, the coils should be cleaned regularly.

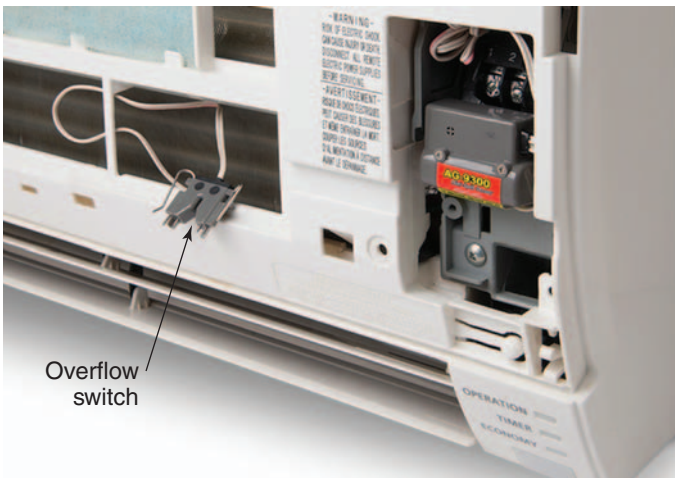
As an indoor unit operates, moisture is condensed out of the air and caught in a condensate pan. Some units are designed to drain by gravity, and other units use a condensate pump. This moisture usually drains out. However, some things can go wrong. The drain line could get blocked. The condensate pump may fail to operate. To prevent the spilling of moisture out of an indoor unit, install an overflow switch in the drain pan. When an ***overflow switch*** senses moisture, it will open a switch to shut off operation and prevent the continued accumulation of moisture, **Figure 31-46**.

SpeedClean

Figure 31-45. Use a pressurized washer with a plastic bib and bucket while cleaning an indoor unit's evaporator.

Copyright Goodheart-Willcox Co., Inc. 2017

The cool temperatures and humidity of the condensate pan in indoor units of ductless systems can unintentionally provide a breeding ground for certain microscopic organisms. Even though condensate is drained or pumped away, a small amount of moisture may still remain. To prevent microorganisms from forming in an indoor unit, regularly add ***biocide tablets*** to the condensate pan. These are designed to prevent the formation of slime, algae, mold, and other common contaminants, **Figure 31-47**.



RectorSeal

Figure 31-46. This overflow switch mounts to the condensate pan and turns off the indoor unit when an accumulation of condensate is sensed.

RectorSeal

Chapter Review

Summary

- Air-conditioning systems regulate temperature and humidity to provide the conditions needed for comfort or manufacturing operations.
- Comfort cooling systems are used to reduce temperature and relative humidity. Reduction of temperature is done by evaporators absorbing heat from a conditioned space. Once evaporators reduce air temperature down to dew point, moisture begins to condense out of the air. Removing moisture and mixing cooled air with conditioned space air reduces relative humidity levels. The relationship of relative humidity levels, moisture in the air, and temperature can be seen on a psychrometric chart.
- Comfort cooling systems can be classified as self-contained (packaged) or split. A self-contained air-conditioning system is a comfort cooling system with everything necessary for operation in a single cabinet. Examples include room air conditioners and packaged terminal air conditioners (PTACs).
- A split air-conditioning system has its components split into two or more separate locations. A split system's condensing unit may be placed outdoors and its evaporating unit may be placed indoors. Split systems can be ductless or use a central air handler.
- A packaged terminal air conditioner (PTAC) is a combined heating and cooling system in a single case. These are typically larger than room air conditioners. The heating system in a PTAC can be an electrical resistance heater, gas-fired furnace, heat pump, or a combination of a heat pump and electrical resistance heater. These are typically used in commercial applications, such as hotels, offices, and apartments.
- A console air conditioner is a complete air-conditioning system in a stand-up cabinet. These provide cooling and often can also provide heating. Like room air conditioners and PTACs, console air conditioners are installed along an outside wall of a building. Ducts can be attached to supply and return grilles to increase airflow and promote more uniform cooling. Console air conditioners are generally used in commercial applications.
- Portable air conditioners are self-contained, wheeled cooling units. They are generally used in commercial applications where traditional air conditioning cannot be installed or used. Ducts and adapters are available that can be attached to the evaporator air inlet and outlet and also to the condenser air inlet and outlet. These ducts can carry hot air away from the conditioned space, deliver cold air to a desired space, or draw air from a different space to blow over condenser or evaporator. Portable systems can be set up to control temperature, humidity, or both.
- A ductless split system is a split air-conditioning system that does not use forced-air ductwork as a means of distributing cooled air. These systems have an outdoor unit and one or more indoor units connected by refrigerant lines. Air is circulated in a given space by an indoor unit's fan and cooled by the evaporator. No air ducts are used.
- A multizone ductless split system consists of one or more outdoor units (compressor and condenser) connected to multiple independent cooling units throughout a building that operate by individual temperature controls. These system components allow great flexibility in the placement of the indoor and outdoor units, resulting in multiple temperature zones throughout a building.

Review Questions

Answer the following questions using the information in this chapter.

1. Cool air leaving the evaporator of an air conditioner has a relative humidity of 100%. This is because relative humidity level increases as _____.
   A. dry-bulb temperature decreases
   B. dry-bulb temperature increases
   C. moisture in grains per pound decreases
   D. All of the above.
2. A comfort cooling system that has its condensing unit outdoors and its evaporating unit in the center of a building is a _____ air-conditioning system.
   A. console
   B. packaged terminal
   C. room
   D. split

Copyright Goodheart-Willcox Co., Inc. 2017

3. Which of the following is a type of self-contained air-conditioning unit?
   A. A packaged terminal air conditioner.
   B. A through-the-wall room air conditioner.
   C. A console air conditioner.
   D. All of the above.
4. Which of the following window air conditioner installation steps is explained correctly?
   A. Fill the air gap between the upper and lower window sashes with a generous application of expanding foam insulation.
   B. Install the air conditioner so it slopes down toward the inside of the building.
   C. Install the sleeve first and then the chassis.
   D. Lift the chassis while gripping onto the evaporator tubing.
5. Which of the following statements regarding room air conditioner service is *not* true?
   A. It is best to remove the air-conditioner chassis from the sleeve for service.
   B. A loose fan can cause worn fan motor bearings.
   C. Use a metal putty knife to scrape dirt out from between the evaporator cooling fins.
   D. All of the above.
6. To fix hard starts in a room air conditioner with a PSC compressor motor, a technician should _____.
   A. install a larger compressor
   B. install a start capacitor and relay
   C. remove 1/4 of the refrigerant charge to reduce compressor load
   D. use a step-up transformer to double the voltage to the motor
7. Which of the following methods is *not* used to provide heat within a packaged terminal air conditioner?
   A. Electric resistance heater.
   B. Gas-fired heater.
   C. Heat pump.
   D. Wood burning stove.
8. Cooling only a specific, limited area is referred to as _____ cooling.
   A. patch
   B. split
   C. spot
   D. zoned
9. Wheels are most often found on _____.
   A. console air conditioners
   B. ductless split systems
   C. portable air conditioners
   D. PTACs
10. When installing a ductless split system indoor unit, a _____ is typically necessary.
    A. 3″ (8 cm) hole wall opening
    B. 42″ × 16″ wall opening
    C. gas supply drip leg
    D. typical window opening
11. Which of the following statements is true of multizone ductless split systems?
    A. The system can have multiple indoor units attached to a single outdoor unit.
    B. The system can have multiple outdoor units.
    C. They are a popular choice for adding air conditioning to buildings that are not equipped with ducts.
    D. All of the above.
12. Which of the following statements regarding multizone ductless split systems is *not* true?
    A. A single, central thermostat controls the temperature in all conditioned spaces.
    B. A line set connects an indoor unit and outdoor unit.
    C. A variety of different indoor unit styles is available.
    D. All of the above.
13. _____ refrigerant flow circulates only the amount of refrigerant needed for a specific load.
    A. Portable
    B. Self-contained
    C. Spot cooling
    D. Variable
14. What should be added to a ductless split system's indoor unit to prevent the growth of microorganisms?
    A. Biocide tablets.
    B. A condensate pump.
    C. High-temperature cutoff switch.
    D. An overflow switch.
15. Which device is used to prevent spilling of condensate from a ductless split system's indoor unit?
    A. Air filter.
    B. Biocide tablets.
    C. Mounting bracket.
    D. Overflow switch.

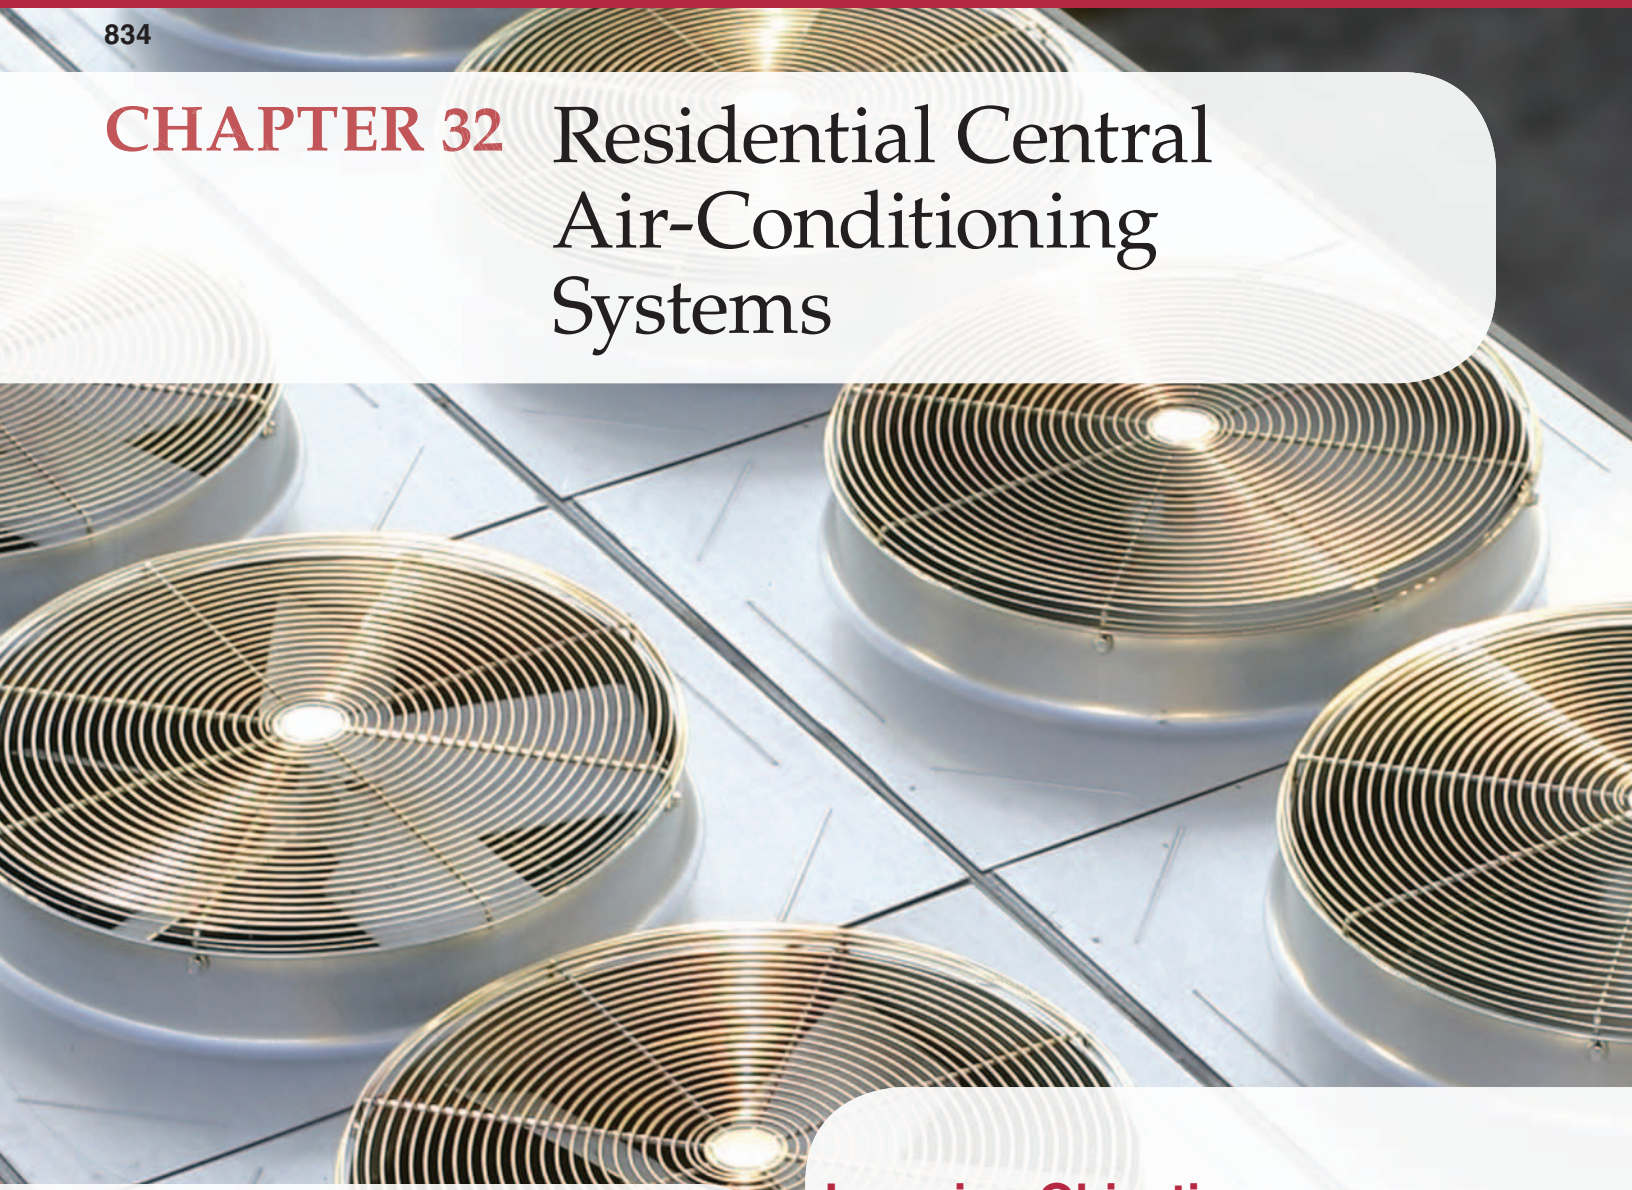
CHAPTER 32 Residential Central Air-Conditioning Systems



Chapter Outline

32.1 Central Air Conditioning
- 32.1.1 Unitary Systems
- 32.1.2 Field-Erected Systems

32.2 Split Systems
- 32.2.1 Unitary Split Systems
- 32.2.2 Field-Erected Split Systems

32.3 Comfort Cooling Controls

32.4 Installing Central Air Conditioning
- 32.4.1 Installing a Condensing Unit
- 32.4.2 Installing an Evaporator
- 32.4.3 Installing Refrigerant Lines
- 32.4.4 Installing Electrical Wiring

32.5 Inspecting Central Air-Conditioning Systems

32.6 Servicing Central Air-Conditioning Systems

32.7 Variable Refrigerant Flow (VRF) Systems
- 32.7.1 Inverter-Driven Compressors
- 32.7.2 Residential VRF Systems

Learning Objectives

Information in this chapter will enable you to:

- Identify the characteristics of a central air-conditioning system.
- Explain the differences between unitary and field-erected air-conditioning systems.
- Identify the characteristics of a split air-conditioning system.
- Identify the types of controls commonly used in central air-conditioning systems.
- Summarize the steps required to install central air-conditioning.
- Identify the areas of a central air-conditioning system that must be periodically inspected.
- Explain the tasks that must be completed as part of central air-conditioning system service.
- Understand the operation of variable refrigerant flow (VRF) as it is used in residential heating and cooling systems.

Review of Key Concepts

Reviewing these concepts from earlier chapters will help you understand new concepts presented in this chapter:

- The three major components in a control system are sensors, controllers, and controlled devices. (Chapter 16)
- There are five basic types of compressors used in refrigeration systems: reciprocating, rotary, scroll, screw, and centrifugal. (Chapter 18)
- Air-conditioning systems simultaneously control temperature, provide filtered airflow, and adjust humidity to maintain desired conditions inside a space. (Chapter 27)
- Humidity is the moisture contained in air. The quantity of humidity in the air affects evaporation rates. Drier air results in more rapid evaporation, which in turn provides more cooling effect. (Chapter 27)
- Air at a given temperature can hold only a certain amount of moisture. The warmer the air is, the more moisture it can hold. The colder the air is, the less moisture it can hold. (Chapter 27)
- To improve air quality, air can be cleaned with filters, ultraviolet lights, or a combination of these measures. (Chapter 28)
- Most refrigerant-carrying tubing used in HVACR is made of copper and is known as air conditioning and refrigeration (ACR) tubing. Steel pipe is used in refrigeration systems containing ammonia. Copper water tubing and plastic pipe are used for water lines, drains, and other nonrefrigerant applications. (Chapter 8)
- Two methods for determining a refrigeration system's charge are checking the system's subcooling and superheat. Active recovery processes use a recovery machine to remove refrigerant from a system in either vapor or liquid form. (Chapter 11)
- One method of leak detection involves pressurizing a system with an inert gas, such as nitrogen or carbon dioxide. Another method of leak detection uses the pressurized refrigerant already charged in the system. Another method requires the technician to add inert gas and a trace amount of refrigerant to an evacuated system to create a positive pressure. (Chapter 11)
- After any internal component is replaced, a refrigeration system must be evacuated and recharged. A digital scale is used to charge a system with a specific amount of refrigerant. (Chapter 11)
- A split air-conditioning system divides its components into two or more separate locations. A split system's condensing unit may be placed outdoors and its evaporating unit may be placed indoors. (Chapter 31)

Introduction

The ability to comfortably and cost effectively condition the air within multiple rooms in homes has led to an increased demand for central air conditioning. What was once considered a luxury for homeowners is now a standard feature. Therefore, it is important for the technician to be familiar with these systems.

10

32.1 Central Air Conditioning

A standard split air-conditioning system has its components in two or more separate locations. A split system's condensing unit is often located outdoors, and its evaporating unit is placed indoors. Often, the evaporator is installed in a central air handler cabinet that is connected to a network of ducts. Some of the ducts are used to deliver conditioned air, and other ducts are used to return air to the air handler. Cooled and dehumidified air is distributed to the conditioned spaces through a series of supply ducts and returned to the evaporator through return ducts. This arrangement of using forced air to cool a conditioned space describes a ***central air-conditioning system***.

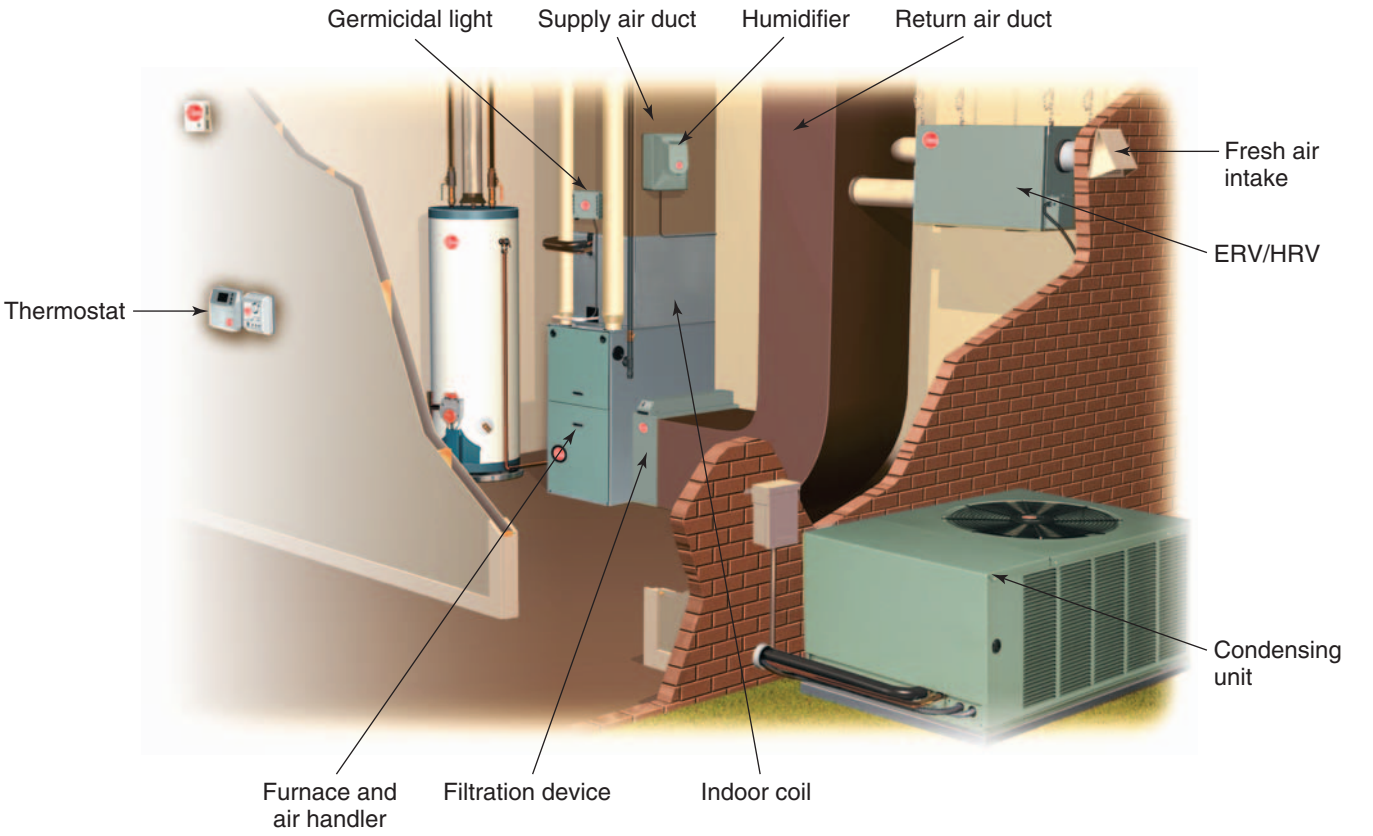
An air handler distributes conditioned air throughout a building. Such a system usually provides heating, cooling, humidity control, ventilation, and air cleaning to multiple spaces. A complete residential central air-conditioning system is shown in **Figure 32-1**.

Typically, the conditioned air is routed to the desired spaces through a network of fixed ducts. A central air-conditioning system shown in **Figure 32-2** uses a gas-fired furnace to provide heat. A compression refrigeration system provides the cooling, **Figure 32-3**. In the system shown, an A-coil evaporator is located in the furnace plenum chamber. The condensing unit (compressor, condenser, and condenser fan) is located outside the building.

Generally, an air-conditioning system uses a metering device to control refrigerant flow into its evaporator. The type of metering device used depends on system size and application. See Chapter 20, *Metering Devices*, for more information.

A single combination heating and cooling thermostat is often used in central air-conditioning systems. Conditioned air is forced throughout a building by a blower. The blower is typically positioned just after an air filter and the return air plenum. With this arrangement, the air filter in the return air plenum cleans the air before it reaches the blower. An arrangement is sometimes provided to bring in fresh outside air as needed. The fresh air inlet may be controlled thermostatically, manually, or by air pressure.

Some systems use a humidistat to control relative humidity in the conditioned space. Such systems usually have a humidifier in the plenum chamber that adds moisture to the air when the furnace is operating. During hot weather, the thermostat may call for cooling. The same air handler and ductwork is used



Rheem Manufacturing Company

Figure 32-2. A complete central air-conditioning system that provides both heating and cooling. The heating cycle is shown here, using a gas-fired furnace. A humidifier in the plenum chamber adds moisture to the warmed air. The same blower and air filter are used for both summer and winter operation.

for heating and for cooling. However, when the cooling mode is activated, the furnace's burner is off and the evaporator is cold. The evaporator lowers the temperature of the air blown through it. At the same time, any excessive humidity in the air is condensed on the evaporator's cold surface and drained away.

32.1.1 Unitary Systems

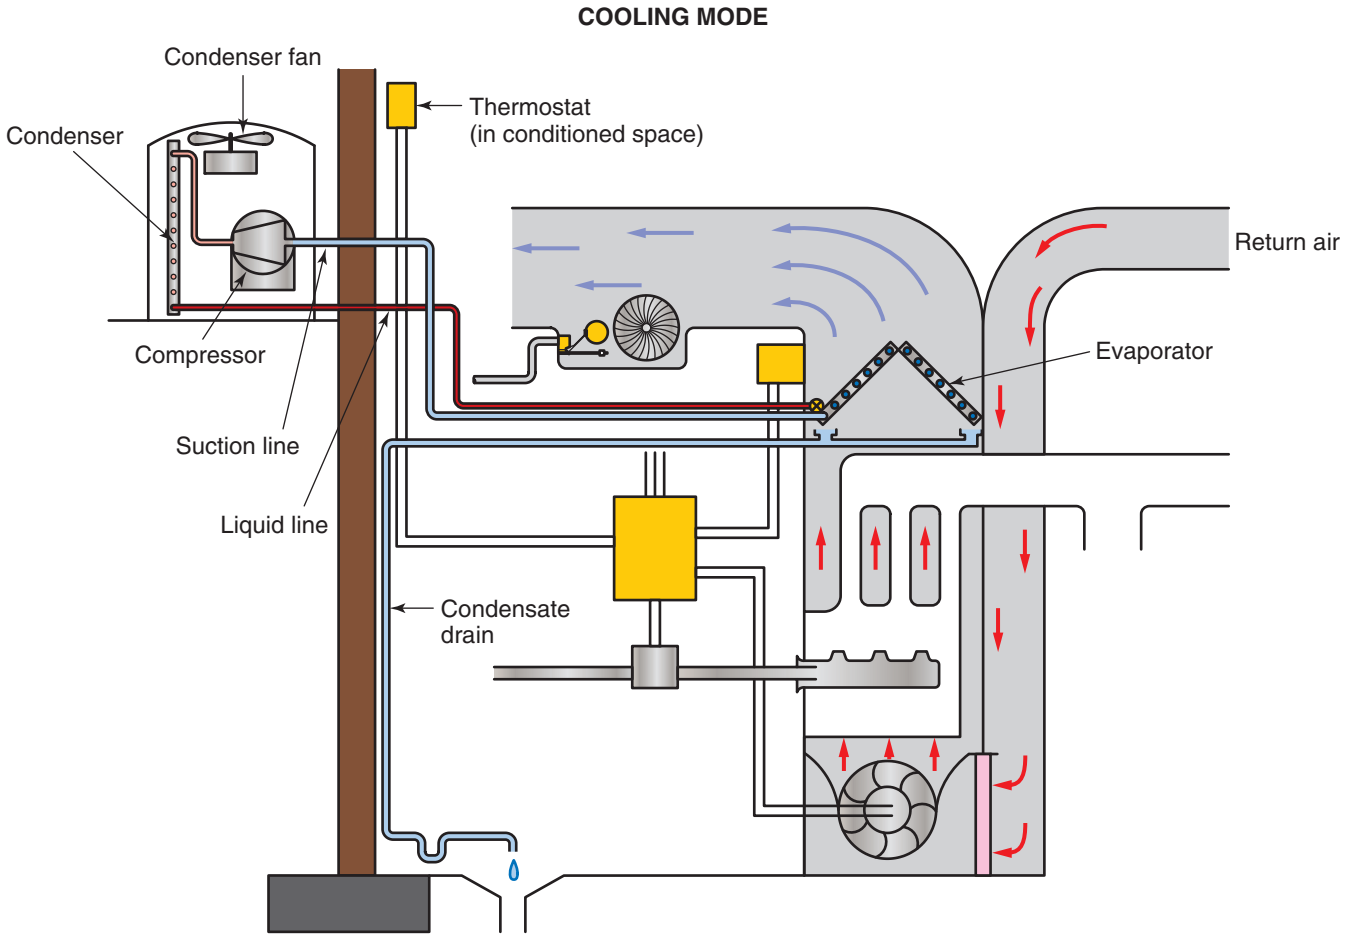
There are two basic types of central air-conditioning systems: unitary and field-erected. ***Unitary central air-conditioning systems*** are complete, with all the components needed to heat, cool, dehumidify, filter, and move air included. These units are a complete package, ready for assembly. Unitary systems are used mainly in new or retrofit home installations and small commercial installations. The main advantages of unitary systems are their low cost and the ease of installation.

Unitary equipment may be single package or a split system. Single package units consist of all components in one package. In a single package unit, all internal wiring and piping has been done. Unitary split systems consist of an indoor unit (fan and evaporator) and a matching outdoor unit (condenser and compressor), bundled together by the manufacturer.

32.1.2 Field-Erected Systems

In ***field-erected air-conditioning systems***, all major system components are purchased individually and assembled at the spot where the system is to be used. The installer is responsible for selecting the proper components to perform the required functions and to carry the estimated loads. All components must be compatible with each other. This includes the air handler, compressor, condenser, evaporator, tubing, and controls. Field-erected systems are primarily used in commercial or industrial applications. They may also be used to heat and cool various sections of a large building.

Copyright Goodheart-Willcox Co., Inc. 2017



Goodheart-Willcox Publisher

Figure 32-3. A central air-conditioning system in cooling mode. An A-coil evaporator coil in the plenum cools air forced through it by the blower. The outside condensing unit rejects the heat absorbed in the evaporator. Humidity is removed by condensing excess moisture on the evaporator surface. A drain tube carries away the condensed moisture.

32.2 Split Systems

In a split system, the condensing unit is located away from the evaporator. Many systems use evaporators with aluminum fins mechanically bonded to copper tubing. Other condensers and evaporators are built with aluminum spines fastened to aluminum tubing to reduce corrosion. Plastic grilles are often used on the condensing unit to avoid corrosion problems.

Figure 32-4 shows the internal construction of a heat pump's outdoor coil unit. The microprocessor control board controls the compressor, outdoor fan speed, and other electronic parts. It also provides information on the performance of the system. The unit also has an electronic demand defrost. This prevents ice from building up on the outdoor coil.

In heat pump–based central air conditioning, an electronic thermostat like the one shown in **Figure 32-5** monitors both indoor and outdoor temperatures. The LCD on the thermostat face shows the indoor temperature and outdoor temperature. It also shows whether the unit is in a heating or cooling mode.

32.2.1 Unitary Split Systems

Sometimes a split system is ordered completely assembled and charged. It will include the condensing unit, evaporator, controls, and tubing. The complete assembly is shipped as a single package. The tubing needed is usually carefully wrapped around the evaporator.

Work required at the point of installation includes the following steps:

1. Uncrating and carefully unwinding the tubing from the evaporator.
2. Installing the condensing unit and evaporator in their proper places.
3. Making the necessary electrical and control connections.

This type of a preassembled refrigeration system requires careful handling, since it is charged

Tempstar

Figure 32-4. Note the location of the reversing and the service valves in this cutaway view of a microprocessor-controlled heat pump. A technician can attach a manufacturer-supplied control reader to the control unit to obtain system performance data.

Rheem Manufacturing Company

Figure 32-5. A typical electronic wall thermostat with an LCD screen that displays indoor temperature, outdoor temperature, and heating or cooling mode. The thermostat can be used to raise the temperature, lower the temperature, take indoor and outdoor temperature readings, select heating or cooling mode, and select continuous or automatic fan operation.

with refrigerant. The technician must be careful while uncrating the tubing to avoid creating kinks. The kinked areas might later crack and leak.

Another type of unitary system consists of an evaporator, condensing unit, and line set that come as an unassembled but matched set, sized for the application. One or more of the components come precharged. The precharged components contain enough refrigerant for the entire system. The technician then connects the various components on-site.

Some manufacturers provide flare fittings for connecting the evaporator coil and compression or braze fittings for connecting the condensing unit. Other manufacturers provide ***quick-connect couplings*** for connecting the parts. These couplers may be connected without losing refrigerant or getting air into the system.

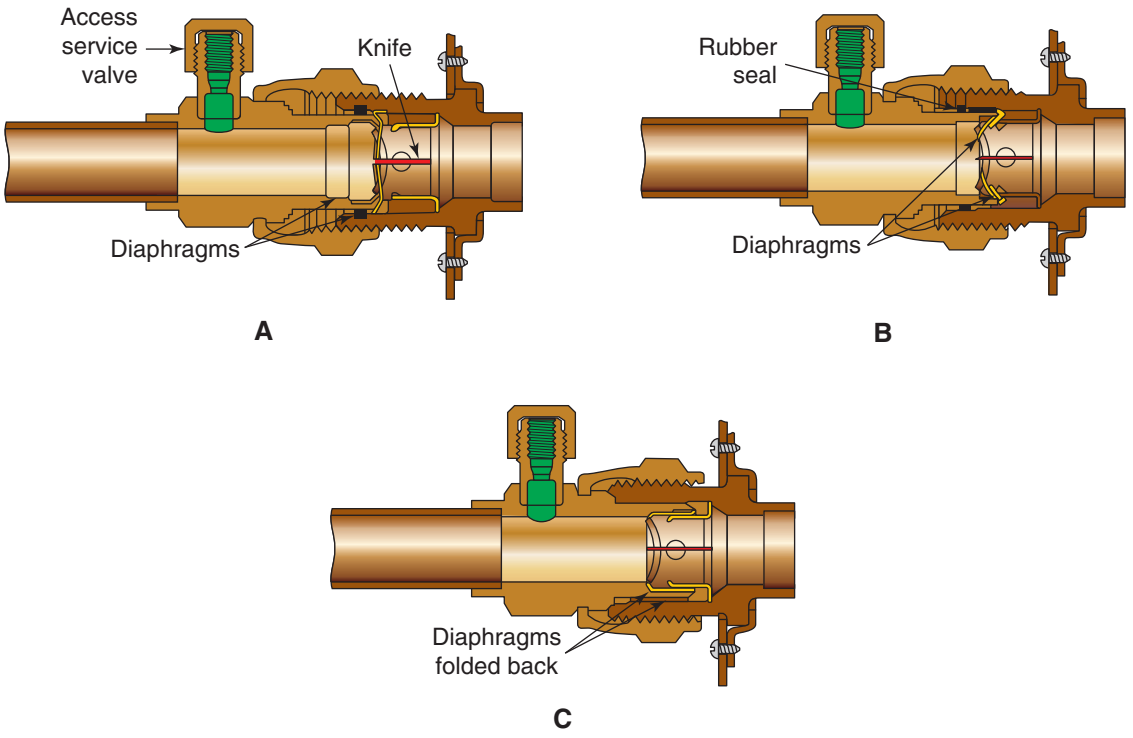
Quick-Connect Couplings

Quick-connect couplings enable manufacturers to produce precharged refrigeration and air-conditioning units. Necessary tubing is also provided in separate packages. These separate units can be assembled at the installation site. They are ready to operate without evacuating, charging, or cleaning.

Quick-connect couplings are brazed directly to the tubing. Flared joints are not needed. There are two types of quick-connect fittings:

- Those that can be connected and disconnected many times with very little loss of refrigerant. When this type of coupling separates, independent springs force valves in both halves of the coupling to close. This prevents the escape of refrigerant. This type of coupling is very seldom used.
- Those that can only be quick-connected once. The ends of these couplings are sealed off with diaphragms. When the two halves of the coupling are connected, the diaphragms are punctured. This allows refrigerant to pass through the coupling. See **Figure 32-6**. If these couplings ever need to be disconnected, the refrigerant must first be removed from the system.

Copyright Goodheart-Willcox Co., Inc. 2017



Aeroquip Corp.

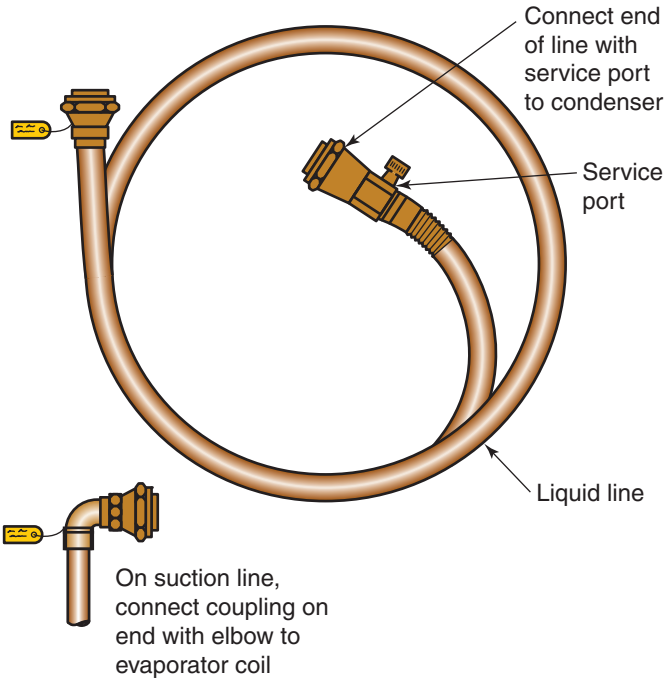
Figure 32-6. Quick-connect coupling equipped with a service valve. A—A knife edge aligns with and begins piercing the diaphragm. B—As the fitting is tightened, the diaphragm is punctured. C—When the diaphragm is punctured, refrigerant can flow through the coupling. The flow of refrigerant folds the remnants of the diaphragm out of the way.

To assemble either type of quick-connect fitting, align the couplings and tighten the coupling nut. This draws the coupling together. Quick-connect fittings are used mostly on precharged residential air-conditioning systems. They are also used on precharged transportation units. Units are usually charged at the factory. The condensing unit, refrigerant lines, and evaporator are charged separately. **Figure 32-7** shows a liquid line that has an access (service) port.

The gasket that joins the quick-connect fittings should be covered with clean, dry refrigerant lubricant just before assembly. When tightening quick-connect fittings, avoid applying excessive pressure to the wrench. Excessive pressure may distort the fitting and cause it to leak. Two wrenches should be used to tighten the fitting to prevent the tubing from twisting, **Figure 32-8**. Some quick-connect fittings can be resealed several times with the use of a special tool.

32.2.2 Field-Erected Split Systems

For a field-erected split system, the condensing unit, evaporator, controls, air handler/furnace, and tubing are purchased individually. The air-conditioning system is then assembled on the customer's premises. Most of these components are combined into a



York International Corporation, Unitary Products Group

forced-air heating and cooling system. **Figure 32-9** shows an air handler with gas furnace used to distribute conditioned air throughout a building. To add cooling to this furnace, an evaporator would be installed in the plenum above the heat exchanger, **Figure 32-10**.

Each evaporator requires a condensing unit to pressurize and circulate refrigerant through the system. The refrigerant coil of many outdoor, air-cooled condensers line the inner walls of the unit. A fan draws air into the condensing unit around the condenser coil and discharges air upward and outward, **Figure 32-11**.

A field-erected split system's evaporator coil and condensing unit must be large enough to provide adequate cooling, but they must also be sized to run long enough during each On cycle to provide adequate dehumidification.

32.3 Comfort Cooling Controls

The term *central air conditioning* implies a system that uses a distribution system (such as a network of ducts) to provide heating, cooling, humidification, and dehumidification. In many systems, electrostatic air cleaning is also provided. The components of these systems often use electrical controls.

Controls for comfort cooling include operating controls and safety controls. Operating controls regulate the normal operation of the system. Safety controls

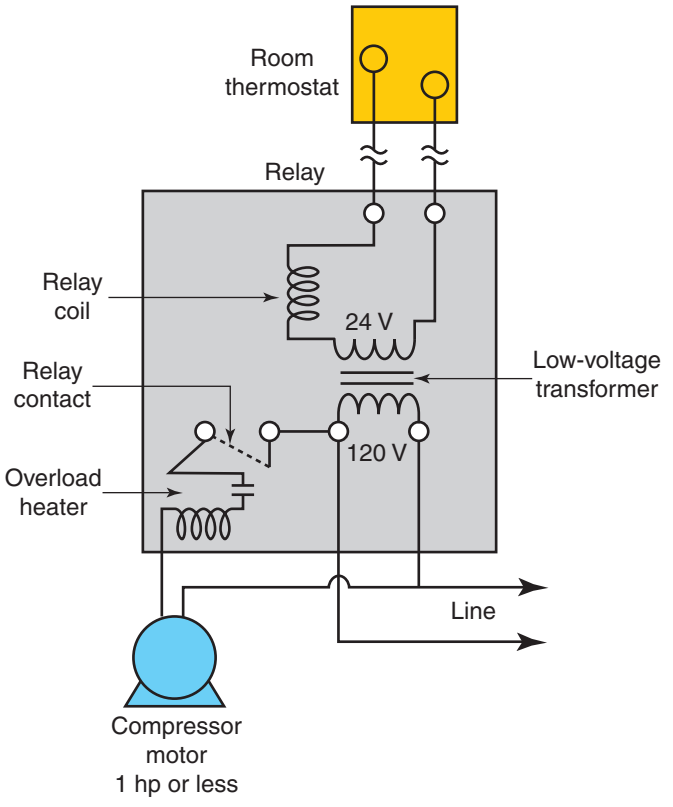
Figure 32-11. To condense and subcool the circulating high-pressure refrigerant, a central air-conditioning condenser draws in ambient air through the sides of the unit and discharges it out of the top of the unit.

regulate safe operation by turning components on or off in order to protect system components and building occupants.

Operating controls can include thermostats, pressure switches, humidistats, motor starters, and relays. Safety controls can include electrical fuses, circuit breakers, thermal overloads, internal motor overloads, refrigerant pressure limit controls, and oil pressure controls. Many of these controls are described in Chapter 16, *Electrical Control Systems*. For more information on thermostats, see Chapter 36, *Thermostats*.

The heating controls govern the operation of the heating system. A room thermostat calls for heat until the desired room temperature is reached. Then, the electrical circuit is opened and the heating device deactivated. Details concerning the arrangement, installation, and operation of heating system controls are provided in later chapters.

A room thermostat usually controls comfort cooling as well. This thermostat may be a separate instrument, or may be built in with the heating thermostat. The room thermostat turns on the comfort cooling system when the temperature of the room rises above a certain set point. It shuts off the cooling system when the temperature has been lowered to the desired level. A typical schematic diagram for a compressor with 1 hp or less is shown in **Figure 32-12**.



Goodheart-Willcox Publisher

Figure 32-12. Wiring diagram of thermostat relay combination for small cooling systems.

Copyright Goodheart-Willcox Co., Inc. 2017

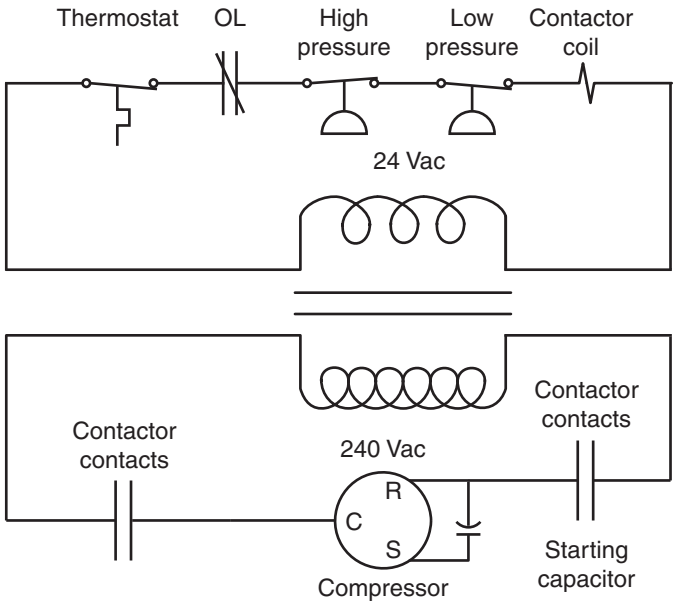
Many residential comfort cooling systems use a low-voltage thermostat. The thermostat controls a contactor that closes the compressor's motor circuit. Pressure safety devices are also installed in the circuit. A high-pressure safety switch is wired in series with the starter coil. It will open the circuit if pressures become too high, **Figure 32-13**.

Automatic controls make it possible for a central system to change from heating to cooling. If the outside air is at a certain temperature above the heating thermostat setting or a certain temperature below the cooling thermostat setting, some systems will draw in outside air to maintain a comfortable temperature inside the building. In such cases, the air-conditioning system is performing only as an air distribution and air-cleaning system. This permits the greatest economy of operation, as comfort is maintained and the minimum amount of fuel is consumed.

32.4 Installing Central Air Conditioning

Before installing an evaporator and condensing unit to an existing furnace or air handler, examine the existing system. If a furnace is old and worn or its efficiency rating is low, consider replacing the furnace with a higher efficiency model. After deciding, systems are assembled on-site in four steps:

1. Install the condensing unit.
2. Install the evaporator.
3. Install the suction and liquid lines.
4. Install the electrical wiring.



Goodheart-Willcox Publisher

Figure 32-13. Wiring diagram for a comfort cooling unit that uses pressure safety cutouts and a contactor.

Thinking Green

Replacing an HVAC System

When replacing an HVAC system, always calculate the heating and cooling loads to properly size the replacement system. Do not assume that the replacement system should have the same capacity as the system it is replacing. Changes made to the building since the previous system was installed, such as the addition or removal of windows, doors, and insulation may make a larger or smaller system more efficient. Even changes in shading due to maturing trees or new construction around the building can have a significant effect on the heating and cooling loads.

Thinking Green

Life Cycle Cost Analysis

Often, the initial cost (purchase and installation) of a system is less than 10% of the lifetime cost of the system. When comparing systems, it is often beneficial to compare the total life cycle costs of the systems rather than the initial costs. This type of evaluation takes into consideration such factors as energy efficiency and maintenance costs.

32.4.1 Installing a Condensing Unit

Most condensing units blow outdoor air over the condenser coil in order to cool the coil. However, some systems have water-cooled condensers. Condensing units can be installed in a number of different locations. Some condensing units are mounted inside the building. In this arrangement, ducts bring outdoor air to the condenser and discharge warm air outside. Some condensing units are mounted on an outside wall.

A popular practice is to mount a condensing unit on a permanent concrete slab or manufactured pad outside the building. This slab is located 12″ to 24″ (31 cm to 61 cm) away from the building. A concrete slab at least 4″ (10 cm) thick and reinforced with steel mesh is recommended. Manufactured pads are available in different size and thickness. Be mindful of local building codes to install a slab or pad having the proper thickness and the proper distance from any building or obstruction. Adequate work space is necessary. A condensing unit should be installed so that outlet air moves in the same direction as the prevailing summer winds. **Figure 32-14** shows various condensing unit arrangements.

The location of the condensing unit is important. The suction and liquid lines and electrical power lines should be as short as possible. The condensing unit should be carefully located:

Copyright Goodheart-Willcox Co., Inc. 2017

- Away from bedrooms, patios, and neighbors (to minimize noise pollution).
- At least 24" (61 cm) away from walls (for air circulation and adequate work space).
- Away from inside corners (for air circulation).
- Not under eaves (to not obstruct airflow).

Figure 32-15 shows acceptable and unacceptable locations for a condensing unit. If possible, a condensing unit should be placed along the north side of a building, where it will enjoy shade throughout the day and not endure the heat load of the sun.

A condensing unit should be mounted level, and with the proper clearances around the unit. **Figure 32-16** shows a typical condensing unit and the required clearances around the unit. Always follow the manufacturer's recommendations for locating the condensing unit.

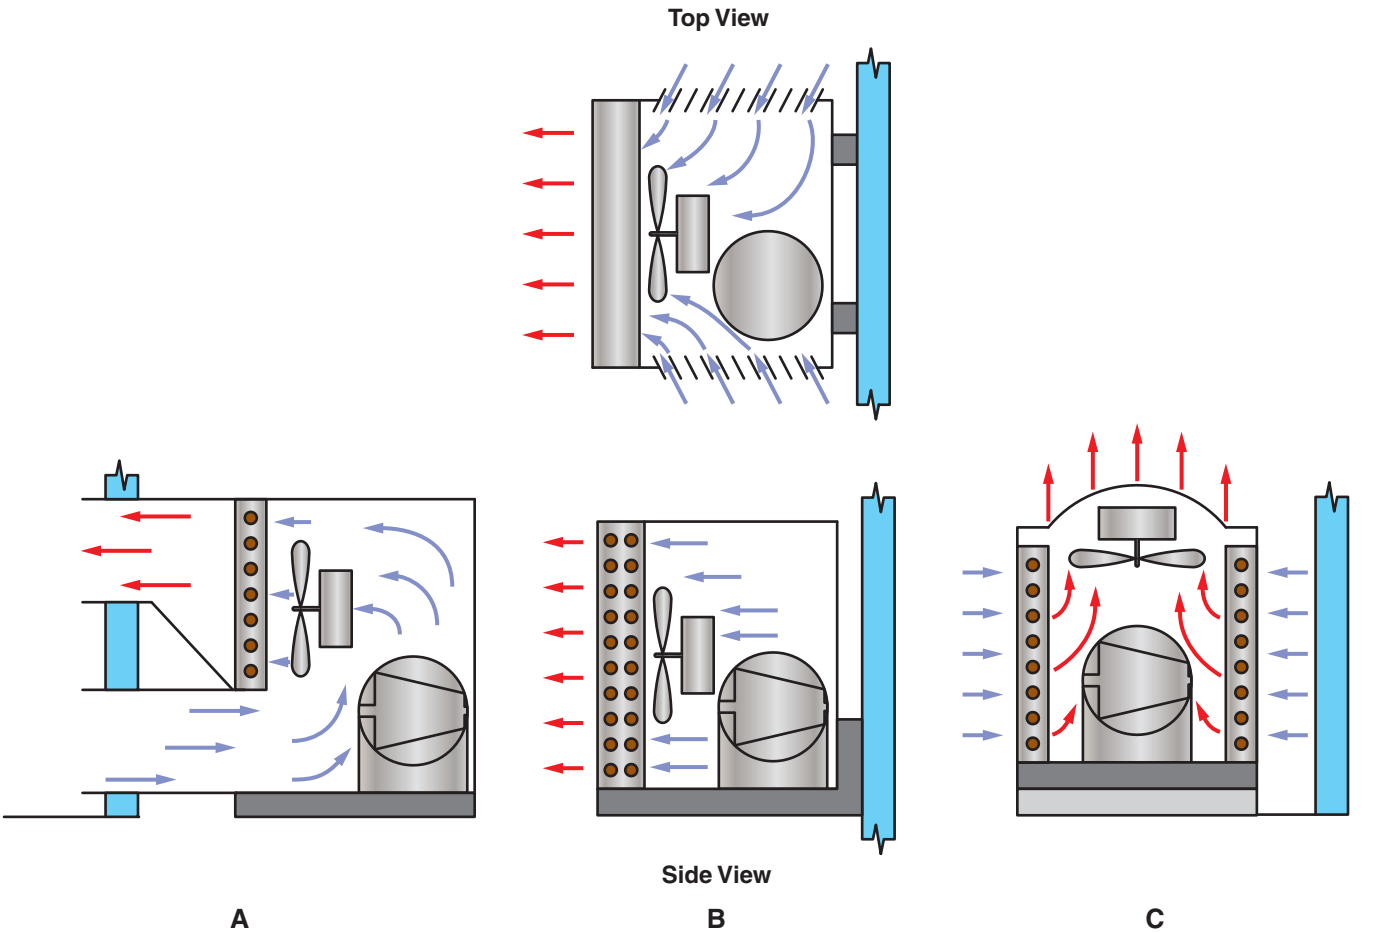
Pro Tip

Preventing Refrigerant Theft

A condensing unit that is in plain sight or monitored by security cameras can discourage refrigerant theft. Another method of prevention is the installation of ***access valve locks***. These devices are installed on the access valves of service valves. Keys and tools used to unlock these devices should only be made available to homeowners and HVACR service technicians. Many locks are color coded to indicate the type of refrigerant charge, **Figure 32-17**.

32.4.2 Installing an Evaporator

An evaporator must be mounted level and solidly in the furnace bonnet or plenum chamber. The design of the evaporator and its condensate drain depend on the type of furnace (upflow, downflow, or horizontal flow). Removable panels are installed in the plenum or



Goodheart-Willcox Publisher

Figure 32-14. Three types of air-cooled condensing units for residential air-conditioning installations. A—Condensing unit inside building. B—Unit hung on outer wall (usually through window). C—Unit mounted on concrete slab outside building.

Goodheart-Willcox Publisher

Figure 32-15. Choose a location for an outdoor air-cooled condensing unit for best airflow and least noise. Locations 1 and 2 are good locations. Location 3 is not recommended because it is in a pocket where there would be restricted airflow and is also too near a bedroom. Locations 4 and 5 are also too near bedrooms.

chamber so the evaporator can be accessed for periodic cleaning and servicing as required.

A cutout is made in the plenum and covered with a cover plate. The cover plate is slightly larger than the cutout and is secured with sheet metal screws. The bottom of the coil assembly is secured and supported by blank-off plates and rails. ***Blank-off plates*** are sheet metal plates that support the evaporator coil and block off areas of the plenum so that all the air passing through the plenum is directed through the evaporator coil. **Figure 32-18** shows a typical slant evaporator installation.

In some cases, the metering device is supplied with the evaporator coil. If the metering device is not supplied with the coil, the proper size metering device must be selected and installed at the evaporator coil inlet.

The condensate drain should be piped to an open drain. There should be an air break at the drain. Plastic drainpipe should be kept away from the warmer parts of the furnace. Some technicians install a 4″ U-trap in the drain line to stop airflow through the line. A condensate drain pan is built into the evaporator, as is the drain connection.

Code Alert

Condensate Drainage

Check the local building code for condensate drainage requirements. In some installations, a drain pump must be installed to remove the condensate to the outdoors.

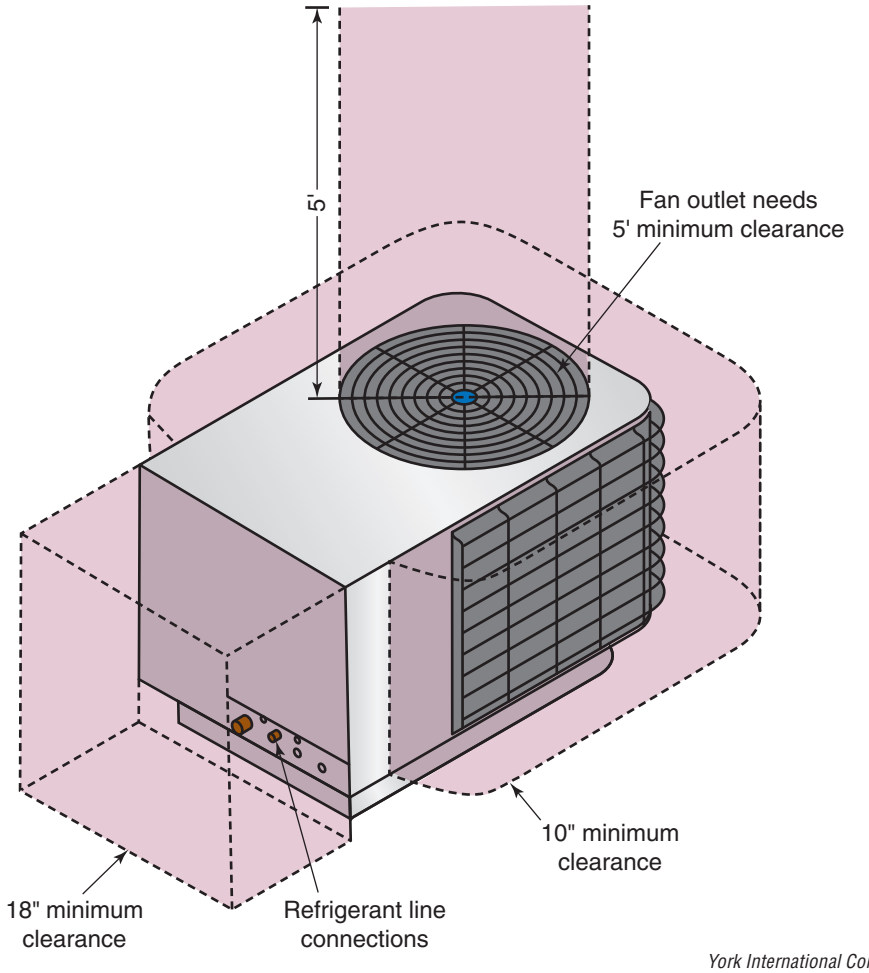
10

32.4.3 Installing Refrigerant Lines

The suction and liquid lines between the condensing unit and the evaporator coil may be connected with flared connections, brazed connections, or quick-connect couplings. The flared and brazed connections were discussed in Chapter 8, *Working with Tubing and Piping*. Quick-connect couplings were discussed earlier in this chapter.

Refrigerant lines should be kept as short as possible. The proper diameters for the refrigerant lines are determined by the size of the condensing unit and the length of the lines to connect the condensing unit to the evaporator. If the system is being installed in a hot, humid climate, the manufacturer may recommend

Copyright Goodheart-Willcox Co., Inc. 2017



York International Corporation, Unitary Products Group

Figure 32-16. A typical condensing unit installation showing the minimum acceptable clearances around such units.

RectorSeal

Figure 32-17. These access valve locks on an outdoor condensing unit restrict access to its suction and liquid lines. The color pink corresponds to the cylinder color used for R-410A.

a larger-diameter than would be recommended for a more temperate climate. Always follow the manufacturer's sizing recommendations.

Caution

Brazing Refrigerant Lines

If the refrigerant lines are to be connected by brazing, remove the Schrader valve cores from the service valves before brazing the lines to the stubs. If the valve cores are not removed, heat from the brazing process will damage the rubber and plastic parts in the valve core. Also, wrap the service valves with a wet cloth before brazing the joints. This will protect the valves from overheating.

Many condensing units are installed at a higher elevation than the evaporator. Therefore, a U-bend should be put in the suction line to assist in oil return. The suction line should slope downward slightly toward the condensing unit. It should also be insulated. If the suction line is not insulated, moisture from the air will condense on the outside of the suction line and drip.

Copyright Goodheart-Willcox Co., Inc. 2017

An uninsulated suction line would also absorb additional heat from unconditioned space, which will need to be rejected at the condenser. As a result, system efficiency will decrease, and the compressor will not be cooled as effectively.

A filter-drier and a sight glass should be put in the liquid line. The refrigerant lines should be supported and free of kinks and sharp bends. Any openings for the liquid and suction lines in the plenum and the building's wall should be sealed with weatherproof, nonhardening sealing compound and tape.

Caution

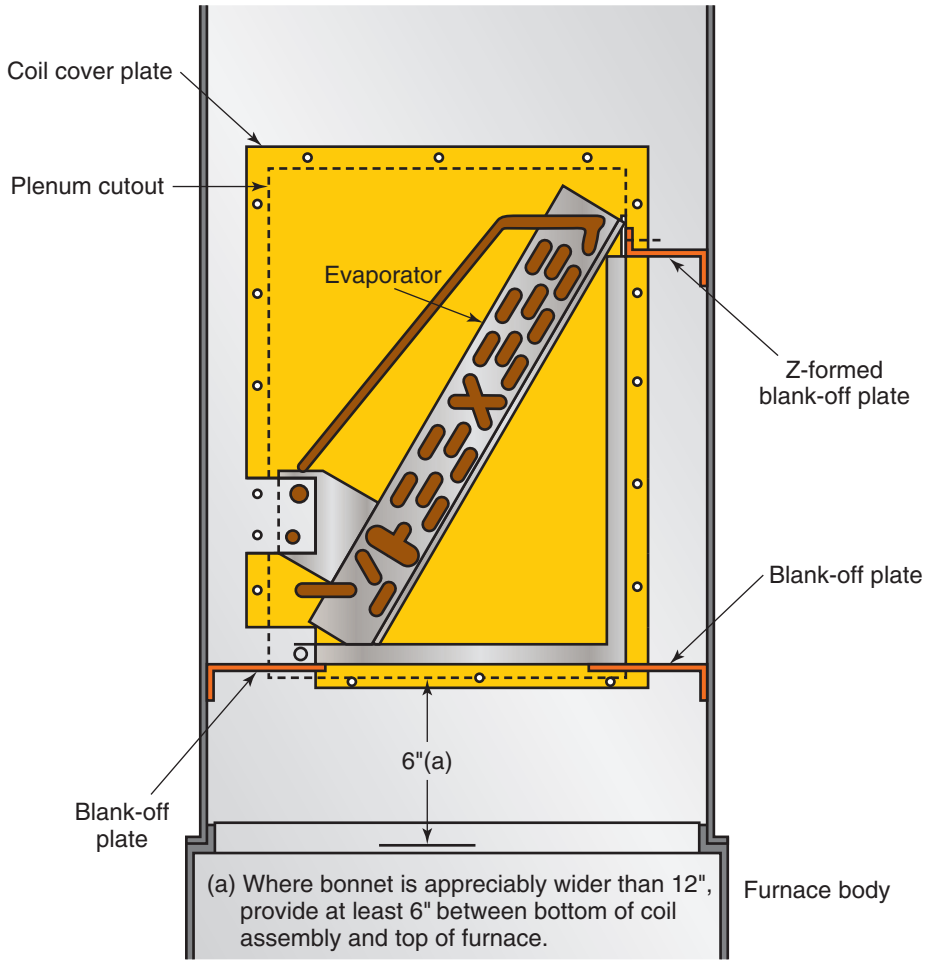
Liquid Line/Capillary Tube Installation

Some systems use the liquid line as the capillary tube. Larger-bore (ID) tubing reduces the chance of clogging from dirt or moisture. To ensure proper operation, do not shorten or lengthen a combination liquid line/capillary tube during installation.

Once refrigerant lines are installed, check the refrigerant lines and evaporator for leaks. Repair any leaks. Evacuate the refrigerant lines and evaporator. Next, charge the system with refrigerant. If the condensing unit is precharged, the isolation valves are opened and the charge is allowed to fill the system. If the condensing unit did not come precharged, the proper charge must be weighed in. General leak testing, evacuation, and charging procedures were described in Chapter 11, *Working with Refrigerants*. Always follow the manufacturer's recommendations.

32.4.4 Installing Electrical Wiring

The wiring requirements for central air-conditioning systems vary from system to system. The electrical installation must be completed as shown in the wiring diagram furnished with the system. The wiring requirements usually consist of providing a 240 V connection to power the condensing unit and a 24 V



Goodheart-Willcox Publisher

Figure 32-18. A slant evaporator installed in a furnace plenum. The blank-off plates support the coil and direct all air through the evaporator coil.

Copyright Goodheart-Willcox Co., Inc. 2017

connection from the thermostat to control the condensing unit. The 240 V circuit is equipped with an electrical disconnect so the system can be quickly disconnected for service, **Figure 32-19**.

Code Alert

Disconnecting Means

According to the National Electrical Code, a condensing unit's electrical disconnecting means must be within sight from the condensing unit's location and also readily accessible. *Within sight* means that the disconnect can be no more than 50′ away. *Readily accessible* means that personnel will not need to climb, use tools, or remove obstacles to reach the disconnect.

When installing wiring that is to be exposed to outdoors, check that its insulation is properly rated for such use. Outdoor use means that the wiring will be exposed to moisture from precipitation and also to the powerful rays of the sun. Not all wiring is intended to withstand such exposure.

Code Alert

Electrical Wiring

Electrical circuits must be installed in accordance with local building codes, which often specify that work be done in accordance with the National Electrical Code. Consult your local electrical utility concerning the primary service capacity.

Goodheart-Willcox Publisher

Figure 32-19. Electrical disconnect box. Note that the pullout contact can be pulled out or flipped upside down to disconnect the condensing unit so it can be serviced.

32.5 Inspecting Central Air-Conditioning Systems

The first step in inspecting and evaluating a central air-conditioning system is to write down the

Service Call Scenario

32A: Residential Central Air Conditioning—No Cooling

Customer Complaint: No Cooling

Possible Causes: Defective condenser fan motor, defective run capacitor, dirty condenser coil.

Description of Problem: The owner of a 2300 ft^2 residence, Mr. Andrews, has reported that his air conditioning is not providing cooling. Prior to arriving at the jobsite, the technician, Tim, reviews the work order. Upon arriving at the residence, he identifies himself to Mr. Andrews and listens carefully to his comments.

Testing: Tim places the wall thermostat to call for cooling. He then proceeds to install the gauge manifold to determine system pressures. While outdoors, he observes that the compressor is operating; however, the condenser fan is not. He then notes that the high-side pressure is extremely high and that the compressor is shutting off. With this in mind, Tim shuts off all electrical power to the unit. He then checks the condenser fan motor for resistance and records an infinite ohm reading. This indicates that the windings of the fan motor are open and that the fan must be replaced. Tim informs Mr. Andrews of the issues and offers solutions and costs. He agrees to have Tim perform the services.

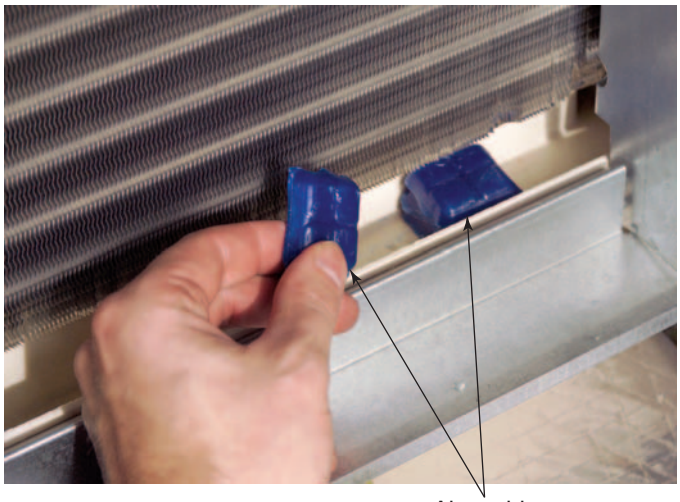
Solution: With the electrical disconnect turned off, Tim disconnects the fan motor wiring from the contactor and the run capacitor. Next, he removes the fan blades from the condenser fan motor shaft. He then removes the motor. The new condenser fan is installed and motor rotation is checked. Tim initiates a start-up of the system and notes all operations are now restored to normal. The unit is now cooling. Tim provides Mr. Andrews with the bill and informs him that a follow-up call will occur.

Safety: Remember, when testing resistance, all checks must be performed with the power source off. When restoring the electrical source, keep a safe distance from all revolving equipment such as fan motors and fan blades.

Copyright Goodheart-Willcox Co., Inc. 2017

system settings. There are basically ten steps that a technician will follow after writing down the system settings:

1. Check the ground surrounding the condensing unit for signs of erosion. Clear away any plants, shrubs, and branches from the outdoor part of the unit so there will be good airflow across the condenser coil.
2. Visually check both the front and back of the evaporator and condensing coils. Spray the coils with self-rinsing coil cleaner. An outdoor condensing coil can be cleaned and rinsed with clear water rather than the self-rinsing coil cleaner.
3. Disconnect the drain line near the evaporator. Use a wet-dry vacuum to remove any water or particles of dirt from the drain outlet. If the drain line is clogged or dirty, replace it with new clear plastic tubing. Reinstall the drain line.
4. Vacuum the drain pan. Place algaecide tablets in the pan. See **Figure 32-20**.
5. Visually check the condensing unit contact points for excessive burn. Any contactors that have been used will have a noticeable marking.
6. If the unit has auxiliary resistance heat, take a current draw measurement on each element with the heat turned on. Make sure the current draw is within the manufacturer's specification.



DiversiTech Corporation

Figure 32-20. Placing algaecide tablets in the condensate drain pan.

7. Disconnect and reconnect any time delays that have been installed. Check the starting time and verify that the unit is meeting the customer requirements for run time.

Service Call Scenario

32B: Residential Central Air Conditioning—No Cooling

Customer Complaint: No Cooling

Possible Causes: Dirty air filter, defective indoor fan motor, incorrect ductwork sizing.

Description of Problem: Mrs. Parker, the owner of an 1800 ft^2 residential home, has reported that her air-conditioning system is not cooling. Prior to arriving at the jobsite, the technician, Sean, reviews the work order. Upon arriving at the residence, he identifies himself to Mrs. Parker and listens carefully to her comments. He notes that the air conditioning unit is running. However, the thermostat indicates that it is set for 72°F, yet the temperature in the home is 81°F.

Testing: Sean sets the wall thermostat to a call for cooling. He visually observes the system's operation. Using his gauge manifold, he reads the system's pressures. Performing a temperature split, he takes the air supply and the return air temperatures and notes that the temperature split is higher than would normally be expected. The systems low-side pressure is lower than normal. Attempting to determine the cause for this malfunction, Sean inspects the evaporator coil and notices that the coil has a thin layer of ice on it. He then inspects the air filter and notes that the air filter is completely covered with dirt and debris. He informs Mrs. Parker of the issues and offers solutions and the costs for such. She agrees to have Sean perform the services.

Solution: A new air filter is installed, and the evaporator is thawed. To prevent the possibility of further airflow problems, Sean cleans the evaporator with a biodegradable coil cleaning solution. He next inspects the condition of the indoor blower motor for cleanliness and ensures good operation. He again checks the temperature split. All pressures and temperatures have returned to normal. The unit is now cooling. He cleans the work area prior to leaving, as the cleaning solutions can leave residue and slippery conditions. Sean educates the owner as to how to install air filters correctly with the arrow facing the furnace in the direction of the return airflow. He provides Mrs. Parker with the bill and informs her that a follow-up call will occur.

Safety: Always follow manufacturer's procedures when using any chemical solutions. Remember to wear protective devices such as safety glasses and protective gloves.

Copyright Goodheart-Willcox Co., Inc. 2017

8. Measure and record the air temperature differential between the evaporator inlet and outlet. It should be between 16°F (9°C) and 20°F (11°C).
9. Visually check the ducts for leaks. Check for open joints and broken diverters. Repair all leaks with mastic.
10. Return the system and its devices to the original settings noted before the inspection.

32.6 Servicing Central Air-Conditioning Systems

Economical operation and system dependability are based on proper servicing. The basic servicing and troubleshooting procedures for central air-conditioning systems are similar in many ways to those for servicing and troubleshooting small domestic appliances.

There are several possible causes of comfort cooling–related service calls:

- No cooling or insufficient cooling.
- Indoor air too humid.
- Air in building is stuffy (stale).
- Excessive (indoor or outdoor) noise.
- High cost of operation.
- System will not start.

Begin a service call by checking the general condition of the system. Check for leaks, proper refrigerant charge, and malfunctioning refrigerant controls and motor controls. Check also for moisture in the system. Moisture in the refrigerant can form ice in the metering device, resulting in a gradual decrease in performance as the system operates.

Often the same blower, filter, and duct system are used during both the cooling and heating seasons. It is essential that the blower be cleaned at least once a year. The motor should be lubricated (a few drops of SAE 30 oil) once or twice a year, if applicable. Air filters should be inspected monthly and cleaned or replaced as needed. The blower's motor speed is often faster (high) for summer comfort cooling and slower (low) for winter heating. Belts on belt-driven blowers should be inspected and replaced if glazed or cracked.

A condensing unit should be cleaned once a year. The condenser, especially, should be blown clean of debris. Any bent fins should be straightened. A carbon dioxide blower or vacuum cleaner can be used to clean the unit. Pressurized washing wands are useful to clean the coils from the inside out, **Figure 32-21**.

Evaporator coils should also be cleaned of any lint and have any bent fins straightened. Check condensate drainage. Condensate that escapes the drain pan may drip on the furnace heat exchanger, corroding (rusting) it. If the condensate drain is clogged, it may be possible to blow out the blockage using compressed gas, **Figure 32-22**.

Service Call Scenario

32C: Residential Central Air Conditioning—No Cooling

Customer Complaint: No Cooling

Possible Causes: Open fuses, defective circuit breakers, thermostat, defective contactor coil.

Description of Problem: A homeowner, Ms. Sellers, has reported that her air conditioner is not cooling. Prior to arriving at the jobsite, the technician, Brad, reviews the work order. Upon arriving at the residence, he identifies himself to Ms. Sellers and listens carefully to her comments.

Testing: Brad places the thermostat on a call for cooling. He walks to the outdoor unit and installs his gauge manifold to read the system's pressures. He notices that the outdoor unit is not turning on. Brad performs a voltage check at the contactor coil. His voltmeter registers 24 volts at the coil. Next, he isolates the contactor coil and measures the resistance. The reading is infinite ohms. This indicates the coil is opened and needs to be replaced. Brad informs Ms. Sellers of the need to replace the contactor and the cost. She agrees to have him perform the service.

Solution: Brad shuts off the electrical power to the unit. Next, he disconnects the wiring to the contactor. He removes the bad contactor. A new contactor is installed and the system is started. The system starts and operates satisfactorily. The unit is now cooling. Brad then provides Ms. Sellers with the bill and informs her that a follow-up call will occur.

Safety: Air-conditioning units operate under high voltages. Always use care when connecting and disconnecting electrical wiring.

Copyright Goodheart-Willcox Co., Inc. 2017

Service Call Scenario

32D: Residential Central Air Conditioning—No Cooling

Customer Complaint: No Cooling

Possible Causes: Severed thermostat cable, defective transformer, open high-side pressure switch, defective thermostat.

Description of Problem: A homeowner, Mr. Richards, has reported that his air-conditioning system is not cooling. Prior to arriving at the home, the technician, Kyle, reviews the work order. Upon arriving at the residence, he identifies himself to Mr. Richards and listens carefully to his comments.

Testing: Kyle initiates cooling using the wall thermostat. He notes that the furnace indoor blower motor has started. The starting of the indoor blower motor assures him that source voltage and low voltage are present at the furnace. He walks outside to observe the outdoor unit. The unit is not in operation. While removing the unit's electrical cover, he notices that the two-strand thermostat cable has been severed and the connection to the contactor coil is broken. Kyle notifies Mr. Richards of the situation and recommends that a new two-strand cable be installed.

Solution: Kyle installs new cable and makes all of the electrical connections to the contactor. He checks the contactor for proper operation. The contactor coil is energized and the unit starts. All pressures are checked and all are in the correct range. The system is now cooling. Kyle provides Mr. Richards with the bill and informs him that a follow-up call will occur.

Safety: Remember, high and low voltages are needed to operate most heating and air-conditioning equipment. Under the right conditions, low voltage can become fatal. Always follow safety precautions when working with live circuits.

SpeedClean

Figure 32-21. This technician is using a pressurized mix of chemicals and water flowing outward through the condenser coils.

DiversiTech Corporation

Figure 32-22. This drain cleaning gun blows away drain blockages using dry, compressed carbon dioxide.

10

Copyright Goodheart-Willcox Co., Inc. 2017

The best and most thorough way to clean an evaporator coil with clogged cooling fins is to remove it from the system for cleaning. This requires the refrigerant charge to be recovered or pumped down into the high side. All refrigerant should be removed from the evaporator before removing the coil. Plug all system refrigerant connections once opened. Then, either steam-clean or use hot water and detergent to scrub the fins and tubes. Steam is the best cleaner, although high-pressure warm water and detergent also work well.

Pro Tip

Preventing Evaporator Icing

Instruct occupants not to adjust their thermostat too low for summer cooling. The evaporator may freeze the condensate. This will restrict airflow through the evaporator, resulting in even more ice buildup.

Inspect all ductwork for leaks and broken dampers. Make sure that all supply ducts and returns are not obstructed and that sufficient airflow is observed. If ducts have dirt and dust buildup, semiannual duct cleaning may be needed. Duct cleaning should include sanitizing of all lines and a thorough inspection of all trunk lines, supply, and return ducts.

Always record and mark the date on the furnace or condensing unit when service has been performed. Record refrigerant charge, suction, and head pressure if the refrigerant system has been accessed.

Thinking Green

Flushing a System

An HVAC system's refrigerant circuit must be flushed in the case of a hermetic compressor motor burnout or if the system is being retrofitted for another refrigerant and the existing line set is going to be reused. In the past, an R-11 flush was commonly used to clean such a system. Today, alternative flushing agents are available.

32.7 Variable Refrigerant Flow (VRF) Systems

Split system, forced-air heat pumps use one outdoor condensing unit connected to an indoor coil mounted in an air handler. Conditioned air is then blown to each room via ductwork. Multizone ductless split systems utilize an outdoor condensing unit with refrigerant tubing to each indoor coil. The amount of refrigerant tubing used in a multi-split system can be extensive. Variable refrigerant flow systems use one outdoor unit and a single set of refrigerant tubes that connect each indoor coil in parallel. This greatly reduces the amount of tubing required. **Figure 32-23** illustrates a multizone ductless split system and a variable refrigerant flow (VRF) ductless split system.

During a normal heating or cooling season, the average ambient temperature is approximately 70% of the load for which a system is designed. Traditional

Service Call Scenario

32E: Residential Central Air Conditioning—No Cooling

Customer Complaint: No Cooling

Possible Causes: Low charge, leaks in system.

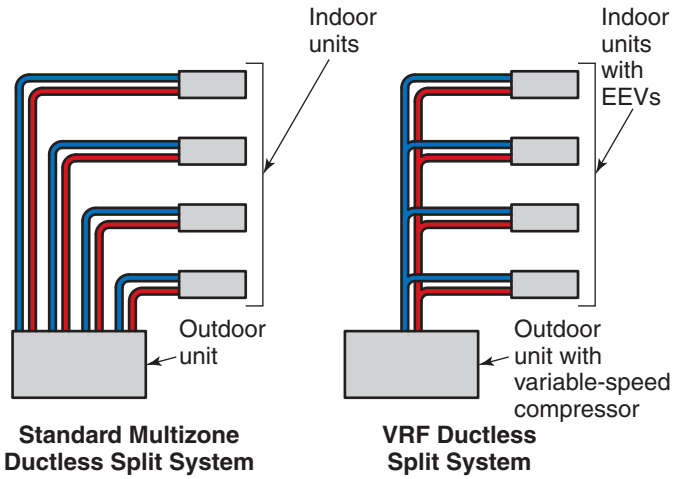
Description of Problem: Mr. Temrowski, the owner of a 2500 ft^2 home, has reported that the air conditioner is not cooling. Prior to arriving at the jobsite, the technician, Sharon, reviews the work order. Upon arriving at the home, Sharon identifies herself to Mr. Temrowski and listens carefully to his comments.

Testing: Sharon installs her gauge manifold to read the system's pressures. The low-side gauge is reading lower than normal pressures. She performs a superheat reading and it indicates a high superheat. It appears the evaporator is being starved of refrigerant. Therefore, Sharon inspects the evaporator. She notes that the sensing bulb of the TXV metering device has lost its charge. This is causing the TXV to close, resulting in the stoppage of refrigerant flow to the evaporator.

Solution: Sharon first recovers the refrigerant. She removes the defective TXV and installs a new valve. Since she has opened the unit, she must install a new liquid line filter-drier to protect the system from contaminants and moisture. Sharon starts the system and confirms all pressures and temperatures have returned to normal. The system is now cooling. Sharon provides Mr. Temrowski with the bill and informs him that a follow-up call will occur.

Safety: Remember, when you are opening a system to replace components, be sure to check the conditions of the system's oil for signs of contaminants. Wear eye and hand protection—some system lubricants may be toxic and acidic. Wear the same protective equipment when charging refrigerants.

Copyright Goodheart-Willcox Co., Inc. 2017



Goodheart-Willcox Publisher

Figure 32-23. Comparison of a standard ductless split system and a VRF system. A standard multizone split system has separate refrigerant lines between each indoor coil and the outdoor unit. A variable refrigerant flow (VRF) system uses a main line set that includes a suction line trunk and a liquid line trunk. Parallel refrigerant lines for each indoor coil branch off from the main line set.

air-conditioning systems use a fixed-speed compressor, fixed-speed blower motor, and a TXV or orifice metering device. Components with a fixed speed or capacity always operate at the maximum design rate. Conditioned space temperature is maintained by cycling the system on and off with fixed components operating at maximum. The efficiency of a system can be greatly improved if compressor speed is reduced to modulate the refrigerant flow to match the heating or cooling load. This type of operation is known as variable refrigerant flow (VRF). It is also referred to as variable refrigerant volume (VRV). Many VRF systems are charged with R-410A. Variable refrigerant flow (VRF) systems use the following components to regulate refrigerant flow and airflow:

- Inverter-driven variable-speed compressor.
- Variable-speed indoor and outdoor fan motors.
- Electronic expansion valve (EEV).

The benefits of VRF systems is that they are able to maintain each room set point more efficiently than a standard HVAC system by distributing the exact amount of refrigerant necessary and only to the zones that are calling for heating or cooling. Each zone has its own temperature control and variable-speed fan that precisely control the climate of their conditioned space. Indoor units may be floor-mounted, wall-mounted, ceiling-mounted, or placed in ductwork where applicable. **Figure 32-24** shows a typical residential VRF outdoor coil and several types of indoor coils.

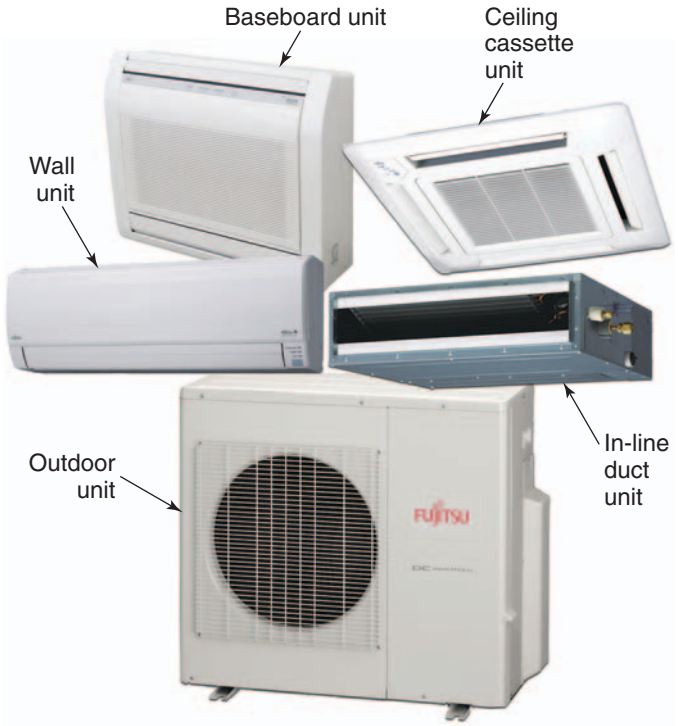
One disadvantage of VRF systems is that they do not regulate humidity or outside air changes. Ventilation and humidity control can be added to VRF systems by adding ductwork, humidifiers, and an air handler.

32.7.1 Inverter-Driven Compressors

Most compressors are fixed speed. They operate using single-phase or three-phase alternating current (ac) as their power source. Rather than using line voltage, a variable-speed compressor has an inverter supply its electrical signal. An inverter varies the frequency of the voltage supplied to a compressor's motor. Remember that ac motor speed is based on two factors:

- Number of poles in the motor.
- Frequency of the voltage signal.

Many inverters provide compressors with a voltage signal that can have a range of frequency values. By reducing or increasing the frequency, the speed at which the motor rotates is reduced or increased. The slower a compressor's motor turns, the less refrigerant it pumps. The faster a compressor's motor turns, the more refrigerant it pumps. By varying the frequency, an inverter varies the refrigerant flow through the system.



Fujitsu General America, Inc.

Figure 32-24. Residential VRF system with various indoor units above and outdoor unit below.

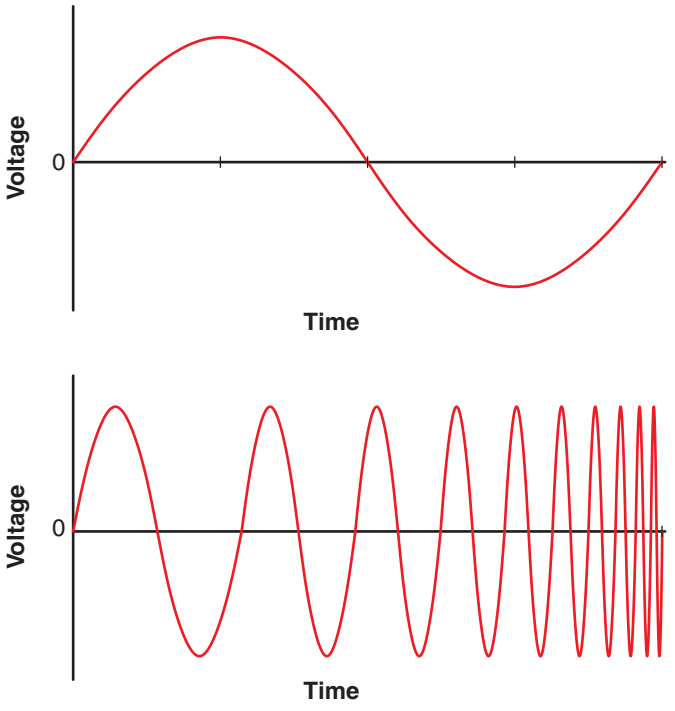
10

Copyright Goodheart-Willcox Co., Inc. 2017

Single-phase line voltage passes through a bridge rectifier to create a modified direct current signal. This voltage is then passed through capacitors resulting in a smooth, straight dc signal. This dc voltage can be used to power dc components, such as an electronic expansion valve (EEV), certain fan motors, and control circuitry, **Figure 32-25**.

An inverter passes the dc signal through six switches that are operating multiple times per second. This produces a three-phase signal. This three-phase ac signal then passes through a frequency drive that controls the frequency of the signal. Remember that single-speed compressors operate at one speed because the frequency of their power is a constant 60 cycles per second. An inverter can change a signal's frequency down to 30 cycles per second and up through 310 cycles per second to slow or speed the compressor. Frequency determines motor speed, **Figure 32-26**.

A traditional single-speed compressor is either on or off (operating at 0% or 100%), but a variable-speed compressor can operate as low as 10% of rated speed and up through 100%. Variable-speed compressors have a minimum speed below which they do not operate. Keeping operation above the minimum speed ensures that refrigerant and oil are circulated back to the compressor to maintain cooling and lubrication.



Goodheart-Willcox Publisher

Copyright Goodheart-Willcox Co., Inc. 2017

An inverter can be used to produce a low-frequency signal to a compressor for slow start-up or a soft start. This low frequency produces less initial starting torque compared to the frequency and voltage applied to a single-speed compressor. Beginning start up at a low frequency saves energy. Inverter control can be applied to different builds of compressors, such as rotary, scroll, reciprocating, and centrifugal.

32.7.2 Residential VRF Systems

Variable refrigerant flow (VRF) systems may be used in residential applications to provide precise temperature control of various rooms throughout a home. The outdoor coil and compressor assembly supply refrigerant to indoor coils in each room of the house. Most VRF systems are heat pump units with the reversing valve mounted in the outdoor coil. Each indoor unit contains a refrigerant coil, an electronic expansion valve (EEV), a coil thermistor, and a room thermistor.

Each indoor unit operates a separate zone under a different load. The inverter-driven compressor speeds or slows to supply the capacity needed in each zone. The amount of refrigerant and its flow rate is regulated to each zone by each unit's EEV.

The refrigerant tubing for each zone may be branched off from the main line set using a ***Y tube*** or branch tube. Each indoor coil is branched off in parallel from the main trunk line.

Each zone in a VRF system has its own temperature and blower control. The control can either be wall mounted or a wireless remote control. VRF systems are able to tightly control temperature within a zone by using a controller inside each indoor unit.

Each indoor unit controller monitors room set point, fan speed, and also air direction through the use of oscillating louvers. The use of a variable-speed compressor in the outdoor unit and variable-speed fan motors in the indoor units allows for a wide range of capacity control. By lowering capacity, a compressor can run longer and avoid continuously cycling on and off. Fans can be operated at their minimum speed to maintain a constant level of comfort. On these lower settings, VRF systems are known to operate very quietly relative to other types of systems.

Service Call Scenario

32F: Residential Air Conditioning—Lack of Cooling

Customer Complaint: Lack of cooling

Possible Causes: Dirty condenser coil resulting in restricted airflow, overcharged unit, faulty compressor, faulty fan motor, bent fan blade.

Description of Problem: Mr. Rodriguez, the owner of a 2000 ft^2 residence, has reported that the air conditioner is not cooling. The unit runs for a short period and then shuts down. Prior to arriving at the jobsite, the technician, Juan, reviews the work order. Upon arriving at the home, he identifies himself to Mr. Rodriguez and listens carefully to his comments.

Testing: Juan places the wall thermostat on a call for cooling. He goes outdoors to observe the unit. Juan installs his gauge manifold to read the system's pressures. A very high high-side pressure is indicated. While observing the unit, Juan notes that the condenser coil is extremely dirty—covered with leaves and grass clippings. He knows that a dirty condenser results in restricted airflow, which increases high-side pressure, resulting in the unit shutting off on internal overload. Juan waits momentarily and soon the compressor shuts off. When the unit was operating, the temperature split across the condenser was quite high. Juan informs Mr. Rodriguez of the situation. Juan recommends that the condenser coil be cleaned and indicates the cost for such. He also suggests that Mr. Rodriguez trim back the trees in this area and ensure grass clippings are blown away from the area. Mr. Rodriguez agrees to have Juan perform the needed service.

Solution: Juan thoroughly cleans the condenser coil with a coil-cleaning solution. He starts the unit and checks the system's pressures. The high-side pressure is now in the normal operating range and the unit is now running without shutting down on overload. Juan reviews with Mr. Rodriguez the importance of maintenance and the importance of keeping debris away from the compressor. He provides Mr. Rodriguez with the bill and informs him that a follow-up call will occur.

Safety: Be cautious when working with a compressor operating with extreme high-side pressures. The compressor temperature and the discharge line will become extremely hot and can cause serious burns. Use caution as a fracture may release highly pressurized refrigerant and oil. Always wear proper eye and hand protection!

Copyright Goodheart-Willcox Co., Inc. 2017

Chapter Review

Summary

- Central air conditioning refers to a centrally located system that is capable of providing heating, cooling, and humidity control to multiple spaces. The conditioned air is typically routed to the desired spaces through a network of air ducts.
- A single combination heating and cooling thermostat is often used in central air-conditioning systems. In some systems, a humidistat controls the relative humidity in the conditioned space.
- Unitary central air-conditioning systems are manufactured complete and ready for assembly. In field-erected air-conditioning systems, all components are purchased separately and assembled on-site.
- A split system has its condensing unit outdoors and its evaporator indoors.
- Comfort cooling systems are equipped with operating controls and safety controls. Operating controls, such as thermostats, pressure switches, humidistats, motor starters, and relays, regulate the normal operation of the system. Safety controls monitor conditions and shut off the system or specific components to protect system components and building occupants.
- Installing central cooling onto an existing furnace is done in four steps: installing the condensing unit, mounting the evaporator, installing the refrigerant lines, and making the electrical connections.
- Servicing a central air-conditioning system begins with a check of the system's general condition. During this inspection, check for leaks, malfunctioning controls, and moisture-related problems. Fans and motors should be cleaned and lubricated, worn belts should be replaced, and the condenser and evaporator coils should be cleaned. Record any service work in company records and system records for the home owner.
- Variable refrigerant flow (VRF) technology has been incorporated into some residential air-conditioning systems. This is primarily in multizone ductless split systems. A single outdoor unit controls the amount of refrigerant that flows to multiple indoor units throughout a building. Indoor units are connected in parallel using Y tubes to branch off the main line set.
- A VRF system matches system operation to the heat load capacity using electronic expansion valves in each indoor unit, variable-speed motors in outdoor and indoor units, and an inverter-driven, variable-speed compressor. These features respond to the temperature controls in each indoor unit so they control a different zone in a building.
- An inverter takes line voltage and modifies the electrical signal to vary its frequency. By reducing or increasing an electrical signal's frequency, an inverter can reduce or increase motor speed. This determines how much refrigerant is pumped by the compressor.

Review Questions

Answer the following questions using the information in this chapter.

1. A standard split system that provides central air-conditioning includes which one of the following system components?
   A. An air handler.
   B. A chiller water pump.
   C. An inverter.
   D. A Y tube.
2. Which of the following best describes a field-erected air-conditioning system?
   A. All parts of the system are bundled together by the manufacturer, but assembled on-site.
   B. The parts of the system are purchased separately and then assembled on-site.
   C. The system is preassembled by the manufacturer, and installation requires only electrical connections.
   D. The system is constructed in the middle of a field.
3. Which of the following statements regarding split systems is *not* true?
   A. The air handler, furnace, and evaporator coil are installed indoors and the condensing unit is installed outdoors.
   B. An evaporator coil can be installed in the supply plenum of a forced-air heating system in order to add cooling capability.
   C. In a split system, the supply and return ductwork must pass through the building's exterior wall.
   D. All of the above.

Copyright Goodheart-Willcox Co., Inc. 2017

4. An air-cooled condensing unit should be installed _____.
   A. beside a building along an inside corner with two outer walls no more than 3″ away
   B. beyond a building's roof overhang and eaves
   C. inside a well-insulated and unventilated room within a building
   D. tightly surrounded on all sides by tall, thick bushes
5. The purpose of blank-off plates is to _____.
   A. block the evaporator so air does not pass through when the furnace is operating
   B. block off areas of the plenum so all the air passes through the evaporator
   C. prevent airflow-related noises in the ductwork
   D. provide access to the evaporator for service
6. Which of the following statements regarding refrigerant lines is *not* true?
   A. A liquid line should be insulated to prevent condensation.
   B. Refrigerant lines may be connected with flare connections.
   C. Refrigerant lines should be kept as short as possible.
   D. All of the above.
7. The electrical connections to a central air-conditioning condensing unit typically include a 240 V connection for powering the compressor and a _____ connection for control.
   A. 24 V
   B. 36 V
   C. 100 V
   D. 480 V
8. The best and most thorough way to clean an evaporator coil with clogged cooling fins is to _____.
   A. leave the coil in the plenum chamber and spray it with a mild acid solution to dissolve the dirt
   B. leave the coil in the plenum chamber and rap on it with a ball peen hammer to dislodge blockages
   C. remove the coil from the plenum chamber and soak it in vinegar
   D. remove the coil from the plenum chamber and steam clean it
9. An inverter controls a variable-speed compressor by changing the electrical signal's _____.
   A. amps
   B. frequency
   C. poles
   D. voltage
10. Refrigerant flow through indoor units of VRF systems is typically controlled by a(n) _____.
   A. automatic expansion valve
   B. capillary tube
   C. electronic expansion valve
   D. low-side float valve

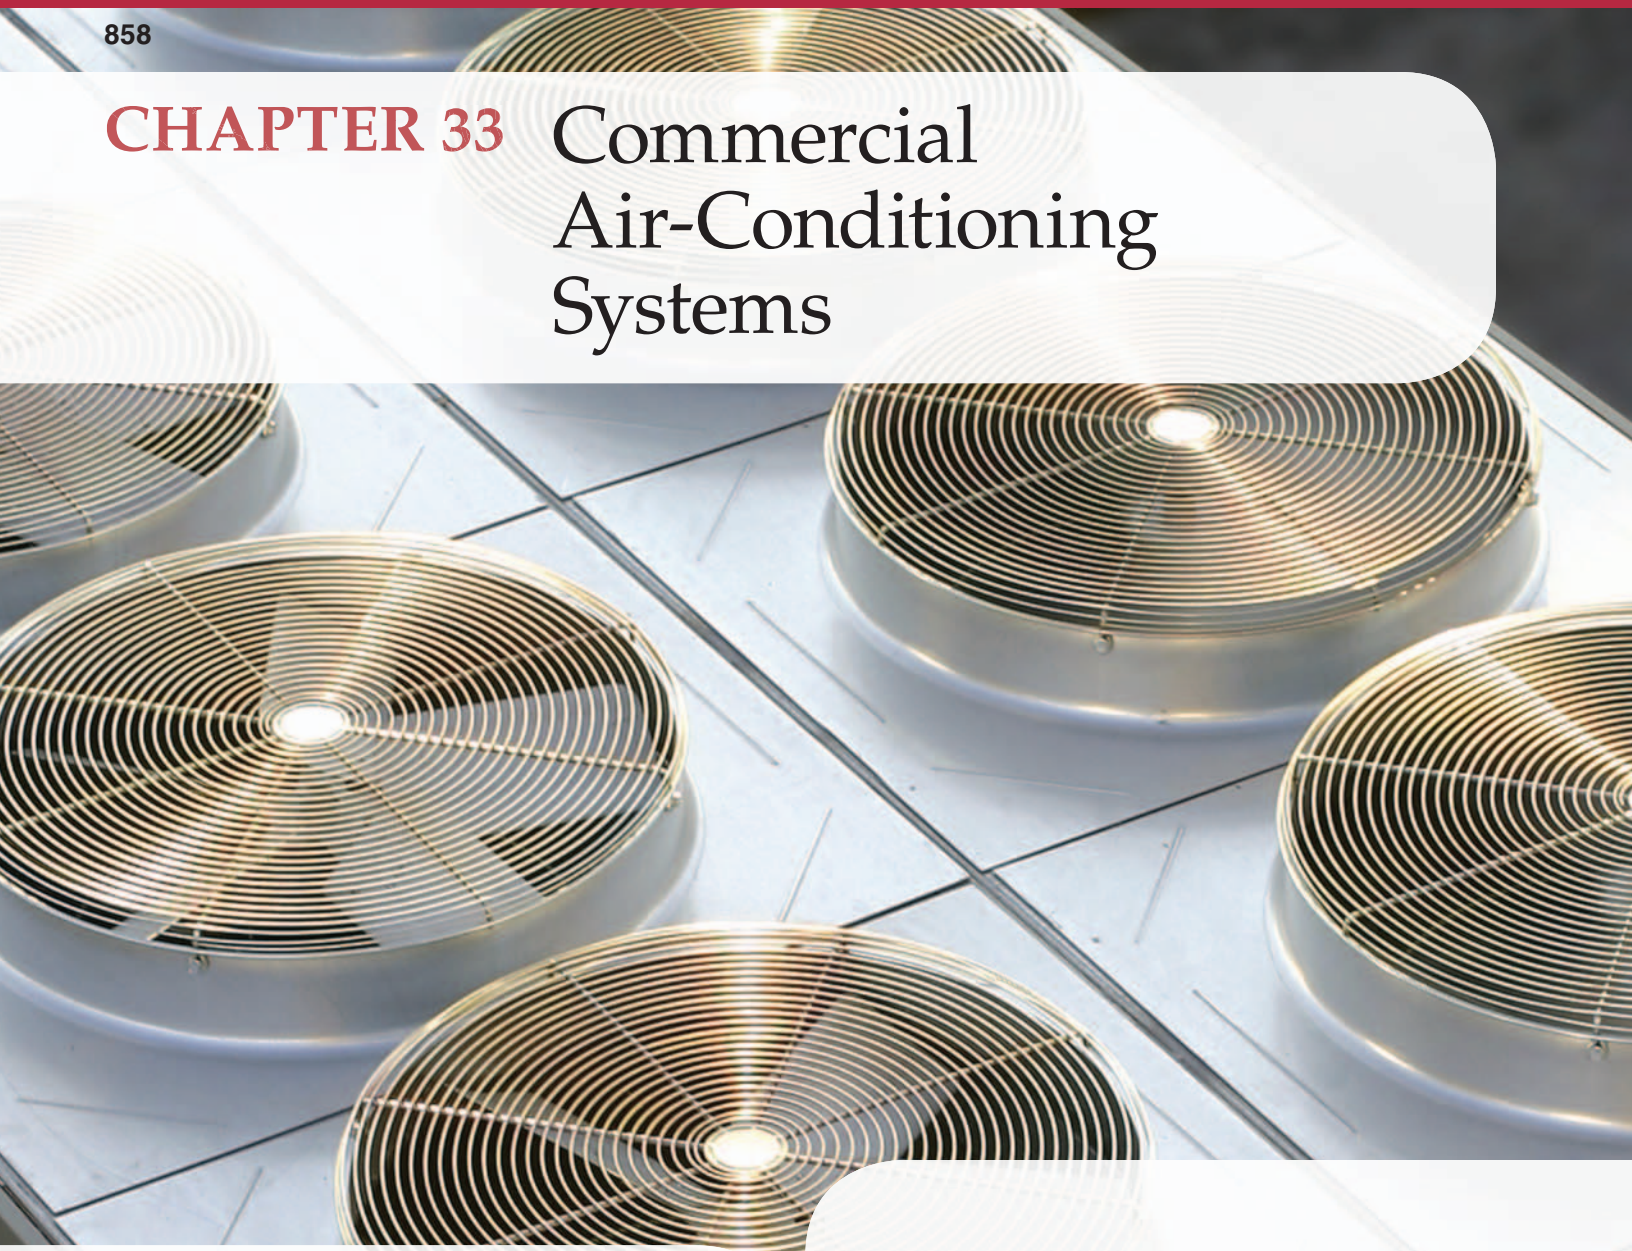
CHAPTER 33 Commercial Air-Conditioning Systems



Chapter Outline

33.1 Rooftop and Outdoor Units
- 33.1.1 RTU Heating System
- 33.1.2 RTU Air Circulation
- 33.1.3 Comfort Cooling Controls
- 33.1.4 Installing Rooftop Units
- 33.1.5 Servicing Rooftop Units Safely
- 33.1.6 Variable Refrigerant Flow (VRF) Systems

33.2 Chillers
- 33.2.1 High-Pressure Compression Chillers
- 33.2.2 Low-Pressure Compression Chillers
- 33.2.3 Chiller Compressors

33.3 Cooling Towers
- 33.3.1 Cooling Tower Construction
- 33.3.2 Cooling Tower Operational Considerations
- 33.3.3 Water Valves

Learning Objectives

Information in this chapter will enable you to:

- Summarize the features of rooftop units and packaged outdoor air-conditioning units.
- Identify the types of controls commonly used in commercial air-conditioning systems.
- Explain how variable refrigerant flow is incorporated into commercial air-conditioning applications.
- Explain the basic operation of a chiller system.
- Compare the different types of compressors that can be used in chiller systems.
- Explain the basic function and operation of a cooling tower.
- Understand the operation and purpose of the different types of water valves used with water-cooled condensers and cooling towers in commercial air-conditioning systems.

wet decks

Review of Key Concepts

Reviewing these concepts from earlier chapters will help you understand new concepts presented in this chapter:

- A split air-conditioning system divides up its components into two or more separate locations. A split system's condensing unit may be placed outdoors, and its evaporating unit may be placed indoors. (Chapter 31)
- Variable refrigerant flow (VRF) units may be used to operate multiple temperature zones throughout a building. (Chapter 31)
- Many compressors use unloaders to reduce their load during start-up or to modulate compressor's capacity. (Chapter 18)
- Two methods for determining a refrigeration system's charge are checking the system's subcooling or superheat. Systems using a TXV should be checked using subcooling. Systems using a fixed orifice metering device should be checked using superheat. (Chapter 11)
- Active recovery processes use a recovery machine to remove refrigerant from a system in either vapor or liquid form. (Chapter 11)
- After any internal component is replaced, a refrigeration system must be evacuated and recharged. (Chapter 11)

Introduction

Commercial air conditioning differs from residential air conditioning in several ways. A commercial conditioned space is generally larger than a residential conditioned space. This does not just mean more square footage. It may also mean having a higher ceiling. Compare the height of a home's kitchen ceiling to that of a department store ceiling. This increase of square footage and having a higher ceiling can equate to a very large volume of conditioned space.

Another major difference is how a building is used and accessed. A busy store or supermarket may have people going in and out frequently. This opening and closing of doors can mean much more heat and humidity entering a building than a residence that is accessed many fewer times throughout a day. This results in an increase of sensible and latent heat that must be removed.

The amount of heat in Btu that must be moved is generally more in commercial than in residential. Because of these two differences, commercial air conditioning may employ different methods of transferring heat, such as using chillers.

Much of commercial air conditioning uses forced-air systems. The benefit of using forced-air is that ventilation needs can also be addressed within the same system. Chillers often have greater potential for heat absorption, but they do not always have ventilation capabilities. These may need to be incorporated using other components.

Copyright Goodheart-Willcox Co., Inc. 2017

33.1 Rooftop and Outdoor Units

Rooftop units (RTUs) are packaged air-conditioning systems designed specifically to be installed on the roof of a building. Rooftop units are often designed to provide both cooling and heating. However, some may be built to provide only one of these features. They also often feature fresh air inlet options to help maintain indoor air quality. Distribution of conditioned air is done through a blower within the RTU. **Figure 33-1** shows how a rooftop system is connected to a duct distribution system.

Packaged outdoor air-conditioning units are similar to rooftop units in construction and operation. However, instead of being installed on the roof of a building, they are installed on a concrete pad or supporting structure adjacent to the building. Supply and return ductwork and wiring run through the exterior wall of the building, **Figure 33-2**.

The RTU design was first developed for flat-roofed commercial structures, such as supermarkets and office buildings. RTUs are convenient because they are factory-assembled and tested. They are also easily installed once hoisted to the site.

Installation of commercial rooftop units often requires a rigging company to hoist the unit to the rooftop. Heavy lift helicopters are sometimes used in cases where access to the rooftop is restricted. However, large cranes are more frequently used, depending on access and the height of the building, **Figure 33-3**.

Although RTUs are relatively easy to install and do not take up valuable interior space in a building, they do have certain requirements and specifications that should be thoroughly considered.

- The roof must be strong enough to uphold the weight of the unit.
- Openings in the roof, on which the units are mounted, could develop leaks over time.
- Units must be designed for ease of service even in severe weather.
- Weather, including strong winds, can affect their operation.
- RTUs require technicians to carry tools and supplies up to the roof.
- The equipment used to service these systems must function properly in all kinds of weather (for RTUs that provide both cooling and heating).

Goodheart-Willcox Publisher

Figure 33-2. Airflow through an outdoor unit.

Many RTUs come completely equipped with factory-installed heating units. Heat can be produced by an integrated gas-fired furnace, oil-fired furnace, or electric resistance heating elements. **Figure 33-4** shows a typical rooftop unit used for both heating and cooling.

Goodheart-Willcox Publisher

Figure 33-4. This rooftop unit provides both heating and cooling. It has a gas-fired furnace. The side access panel has been removed for service.

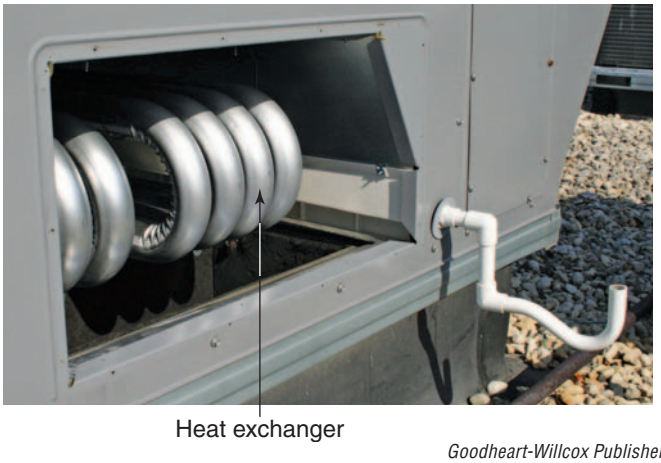
10

Copyright Goodheart-Willcox Co., Inc. 2017

Rooftop units are designed to be weatherproof since they are exposed to all kinds of weather. Access doors for inspection are designed to open and then stay open safely under high wind conditions. **Figure 33-5** shows a rooftop unit with all the access doors open to reveal the various components in the system.

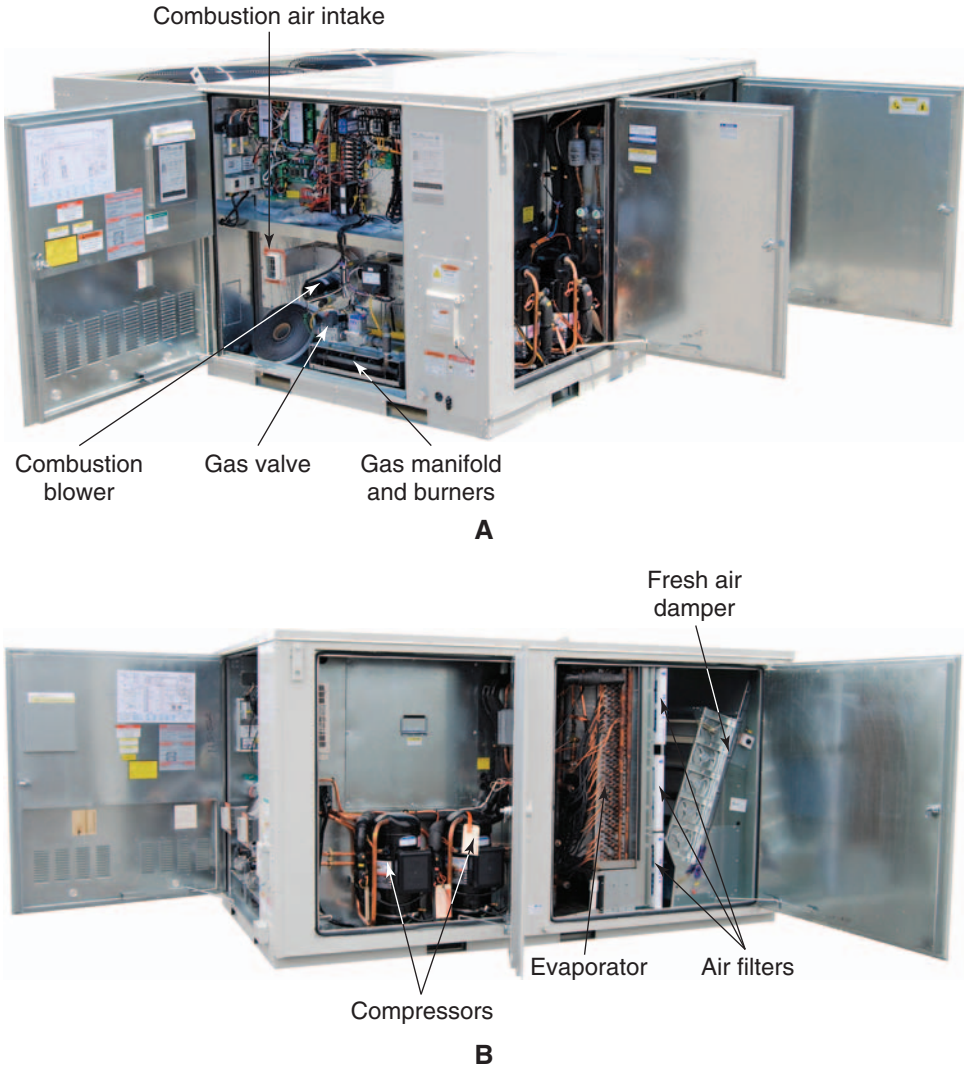
33.1.1 RTU Heating System

Many rooftop units are equipped with gas-fired furnaces. Like a standard gas-fired furnace, RTUs are equipped with an electric ignition system. The heat exchanger of an RTU with a gas-fired furnace typically can be reached through an access door or panel, **Figure 33-6**.



Goodheart-Willcox Publisher

Figure 33-6. An access panel has been removed from this rooftop unit to reveal the gas-fired furnace's heat exchanger.



AAON

Figure 33-5. Access doors can be opened to access various parts of a rooftop unit for service. A—The burners, gas valve, and combustion blower of the gas-fired furnace are accessible through a door in the front of the unit. B—The compressors, evaporator, air filters, and fresh air damper can be accessed through doors in the side of the unit.

Copyright Goodheart-Willcox Co., Inc. 2017

The furnaces in some rooftop units are oil-fired. Fuel is stored in an underground tank. A lift pump draws oil to a second, smaller tank. This tank may be at the same level as or slightly lower than the oil burner. Under no circumstances should the tank be more than 10′ (3 m) below the burner.

Electric resistance heating elements can also be used in rooftop units. These heating elements are available in various capacities, including 20 kW, 40 kW, and 60 kW. Heating elements are protected by ceramic insulators. The circuit has fuses, fusible links, and thermal cutouts, **Figure 33-7**.

33.1.2 RTU Air Circulation

Airflow through an RTU is controlled by the blower and different dampers. Sensing elements in the mixed-air duct control actuator motors that operate these dampers:

- The return damper.
- The conditioned air damper.
- The exhaust air damper.
- The fresh air damper.

All air circulated by an RTU is filtered as in other air distribution systems. This is not just the air within the building but also the fresh air introduced into the building. **Figure 33-8** shows an RTU's air control system.

Air-Side Economizers

In some cases, activity within a building raises the temperature to a level that would activate the air-conditioning system, even though the outdoor air temperature is below the system set point. If an air-side economizer is part of an HVAC system, it will prevent the compressor from starting. Instead, the system will draw in outdoor air to cool the building. This can save considerable energy, **Figure 33-9**.

An ***air-side economizer*** is a subsystem of an HVAC system that is used to introduce cool outdoor air into a building filled with warm, stuffy air. It is composed of several different controls, a movable louver system, and an actuator to move the louvers, **Figure 33-10**.

An economizer's controls sense and respond to different variables. When certain levels are sensed, the economizer operates. These measured variables may include the following:

- Indoor air temperature.
- Indoor humidity.
- Outdoor air temperature.
- Outdoor humidity.

Note that not all economizers sense all of these variables. They will at least sense indoor air temperature and outdoor air temperature. When these levels are at or below control settings, an economizer begins operation. This involves several different actions:

- The compressor is turned off or prevented from operating.
- The condenser fan is turned off or prevented from operating, as it will not be rejecting any heat.
- Fresh air inlet louvers open on the return air side of the indoor blower.
- The indoor blower turns on to draw in cool, fresh air from outside.

Goodheart-Willcox Publisher

Figure 33-10. This actuator opens and closes fresh air inlet louvers for economizer operation.

Copyright Goodheart-Willcox Co., Inc. 2017

Economizers provide free building cooling by taking advantage of cool outdoor temperature. This often occurs at night, early morning, or during the change of seasons. Anytime outdoor air is cool enough and dry enough, a cooling system can use the economizer to cool a building's conditioned space without running the compressor. This type of operation uses much less electrical power than when a compressor is running. However, it can only be activated during certain times of proper outdoor conditions.

Enthalpy Control

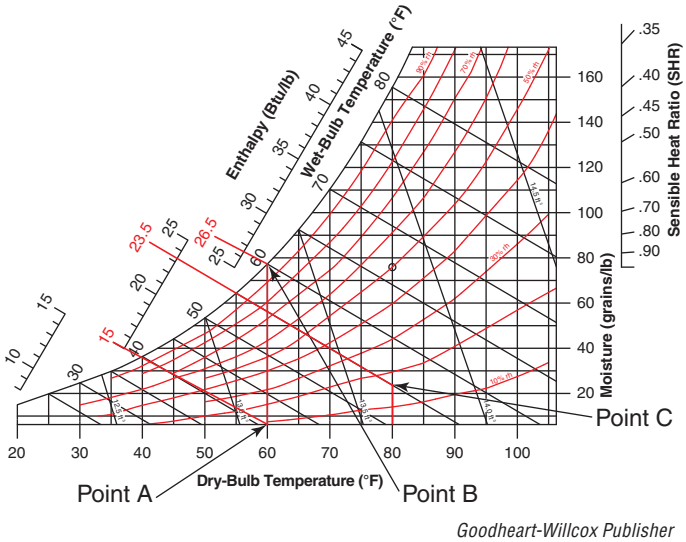
Economizers begin operation based on several different measured variables: indoor air temperature, indoor humidity, outdoor air temperature, and outdoor humidity. If indoor air temperature is already cool enough, an economizer will not cycle on. If outdoor air temperature is too warm, an economizer will not cycle on. Some economizers have a feature called ***enthalpy control***. This means the economizer senses and responds to outdoor air humidity, in addition to outdoor air temperature. If outdoor air humidity is too high, an economizer will not cycle on. Remember that *enthalpy* is a term referring to a substance's total heat content. Humid air, which is saturated with moisture, has a higher heat content than dry air (low humidity).

In the following example, refer to **Figure 33-11**. If indoor air temperature is 80°F and outdoor air is 60°F, economizer operation could cool a building. It would cool a building well if outdoor air had low relative humidity (Point A). Air at this point would have only 15 Btu per pound of heat content. However, if outdoor air was at 100% humidity (Point B), it would have a heat content around 26.5 Btu per pound. If this humid air were drawn into a building by an economizer, it might cool the building, but the humidity level would be too high for comfort. Occupants would need to run the air-conditioning compressor to remove the moisture from the air.

To further show the importance of enthalpy control, look at Point C. It shows indoor air temperature at 80°F around 15% relative humidity. Following this point to the enthalpy scale shows that this indoor air has a heat content around 23.5 Btu per pound. If outdoor air is at 60°F at 100% humidity, it has a heat content of 26.5 Btu per pound. This 60°F air actually has a higher heat content than the 80°F air at 15% relative humidity. Drawing in this outdoor air would result in a loss of efficiency, because the air-conditioning compressor would still need to run to remove all the moisture brought in from outside. This shows the importance of using enthalpy control with an economizer. Humidity matters to human comfort.

Air Sample	Heat Content
60°F at 5% rh	15 Btu/lb
60°F at 100% rh	26.5 Btu/lb
80°F at 15% rh	23.5 Btu/lb

Enthalpy control is important because part of comfort is regulating humidity levels. If outdoor air temperature is low but humidity is high, an economizer could fill a building with moderately cool but humid air. Occupants would want to run the air conditioning to remove the humidity. In such cases, it is usually better to just run the air conditioning to cool indoor air, rather than have to remove so much humidity.



Goodheart-Willcox Publisher

Figure 33-11. A psychrometric chart examining the heat content of outdoor air for use by an economizer. Note how air at 60°F can have different enthalpy (heat content level) based on its relative humidity. Moisture in the air greatly affects heat content and human comfort.

Pro Tip

Stuck Economizer Louvers

If an RTU customer complains about uncomfortable indoor conditions, consider whether their economizer has been properly maintained. Sometimes an economizer's outdoor air intake louvers can become stuck open. Such improper operation of economizers can disrupt indoor climate or at least decrease system efficiency. Economizers should be checked for proper operation at every service call.

33.1.3 Comfort Cooling Controls

Many of the controls used in residential air conditioning are also used in commercial air conditioning. Thermostats monitor indoor air temperature. Various motor controls turn on and off compressors and blower motors. Many similarities exist.

Copyright Goodheart-Willcox Co., Inc. 2017

Some systems cycle off based on low-side pressure. While the thermostat monitors conditioned space temperature, its switch controls a solenoid valve mounted in the liquid line. When room temperature reaches the thermostat's cut-off temperature, the thermostat opens a circuit controlling the solenoid valve. De-energizing this circuit causes the solenoid valve to close and block the liquid line, preventing refrigerant from entering the evaporator.

The compressor continues to run momentarily, pumping down the low-side of the system. This reduces low-side pressure until the low-side pressure switch opens the compressor's motor circuit, stopping the compressor. The low-side pressure control monitors suction pressure and is connected in series with the motor starter's coil. See **Figure 33-12**. HVACR systems with different capacities and different refrigerants will shut off the compressor at different pressures. A high-side pressure switch is also provided in this control. The control will stop the compressor if the high-side pressure exceeds a preset limit.

Controls commonly found in comfort cooling systems include the following:

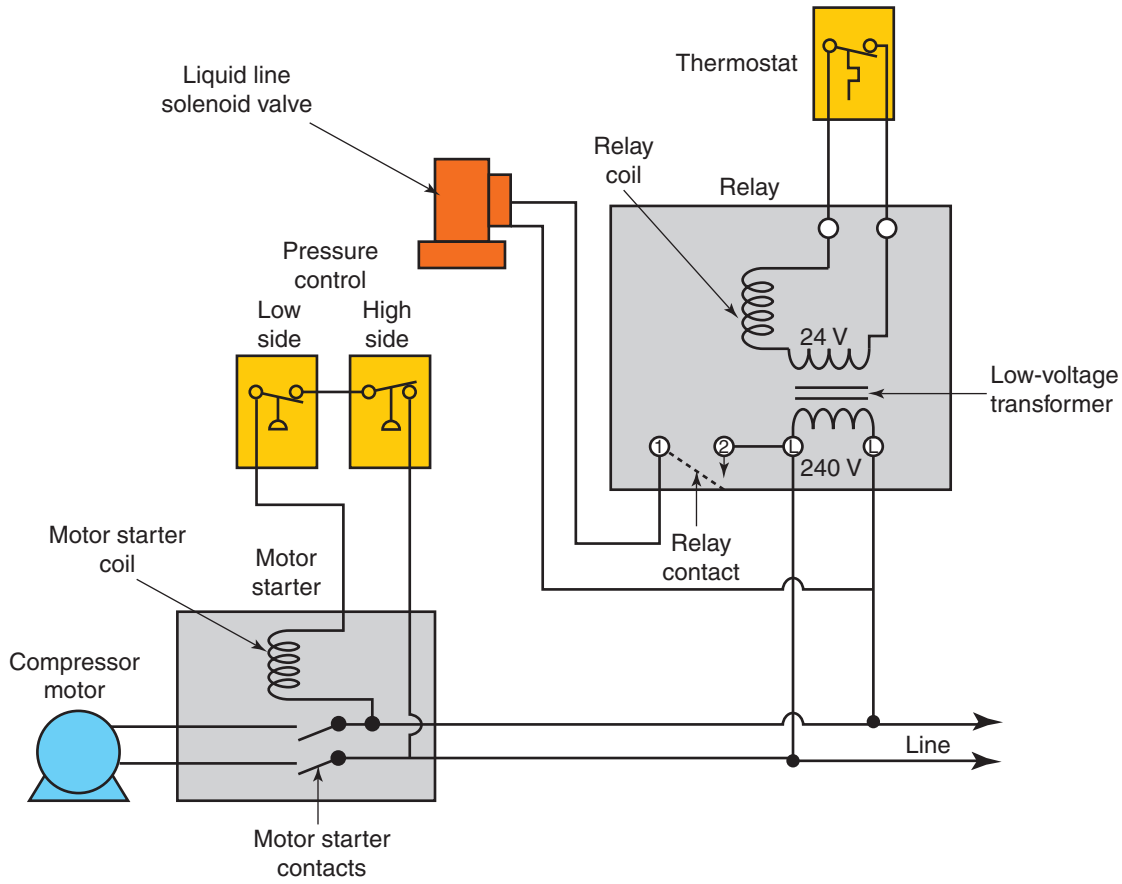
- Thermostat (24 V or 120 V) to control temperature within the conditioned space.
- Evaporator ice monitoring control (freezestat), two-wire 24 V or 120 V, to control dampers, valves, or compressors when the evaporator temperature approaches 32°F (0°C).
- Multiple compressor sequence starting controls.
- Multicylinder compressor unloading sequencing controls.
- Zoning damper controls.

Limit Controls

Comfort cooling systems use several types of limit controls:

- Motor limit controls.
- Pressure limit controls.
- Temperature limit controls.

Commercial systems are usually equipped with pressure controls. The low-side and high-side pressure controls are usually designed to lock the compressor



Goodheart-Willcox Publisher

Figure 33-12. Comfort cooling system wiring diagram. Note that the thermostat operates the solenoid valve. The system cycles as low-side pressures vary. The compressor low-pressure cut-out is reached once the refrigerant solenoid valve closes. Cut-out pressures are determined by the cooling capacity and type of refrigerant used in the system.

Copyright Goodheart-Willcox Co., Inc. 2017

circuit open if any unusual pressures occur. These controls are safety devices. They operate only if a potential problem develops. They prevent devices, such as the compressor, from being damaged. If a control deactivates a system, the operator should carefully check the system for faults before turning it back on. A combination low-pressure and high-pressure control is shown in **Figure 33-13**.

Caution

Manual Reset Controls

Do not replace manual reset controls with automatic reset controls. A manual reset demands the attention of the operator and signals something is wrong and should be corrected.

Motor limit controls will stop a motor if current draw becomes too high. They will also stop the motor if the motor temperature rises to a dangerous level. Motor limit controls, also called motor protection devices, are described in detail in Chapter 16, *Electrical Control Systems*.

Anti-icing control is another type of temperature limit control. Anti-icing control is often called a *freezestat*. It monitors the temperature of the evaporator. If ice accumulates on the evaporator, this control stops the cooling system, allowing the ice to melt.

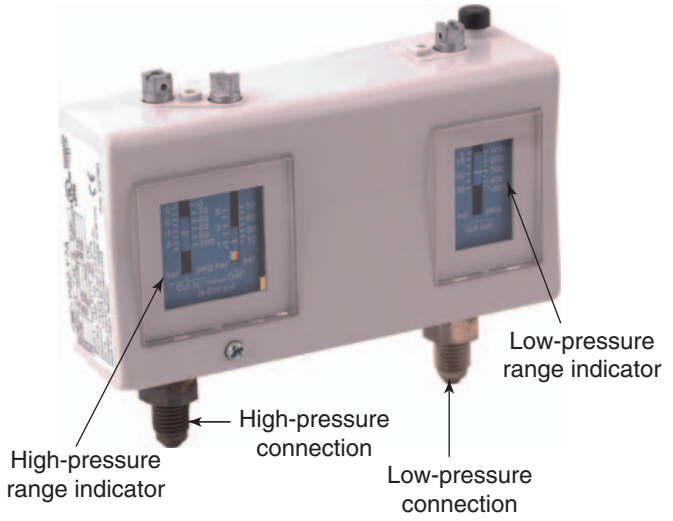
Sequential Controls

Sequencing adjusts equipment operation to meet demand so the system performs at peak efficiency. Large cooling systems use sequencing to operate multiple compressors or condenser fans. These systems are controlled by microprocessors, which determine the amount of cooling required. If the cooling load is low, only one compressor and condenser fan are energized. When the cooling load is high, the second compressor and condenser are energized. **Figure 33-14** shows the electrical controls of a condensing unit that contains two compressors and two condensers.

Pneumatic Control Systems

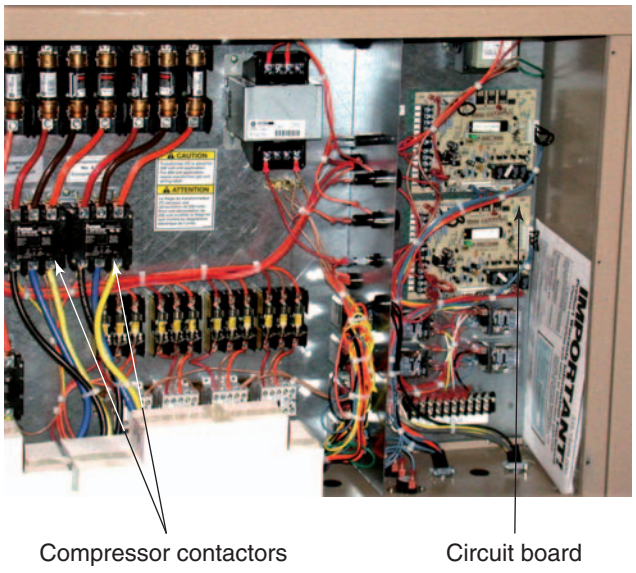
Many HVACR systems use electrical and electronic control systems. However, this is not the only way to control a system. Some commercial air-conditioning systems use pneumatic control systems. ***Pneumatics*** is the use of pressurized air to perform certain mechanical actions.

A pneumatic system's three main parts are pressure-sensing devices, pneumatic controllers, and pneumatic actuators. The main line supply pressures typically used are either 12 psig or 24 psig (83 kPa or 166 kPa). However, some systems operate at a vacuum.



Emerson Climate Technologies

Figure 33-13. Combination low-pressure and high-pressure control will shut off the compressor motor if system pressure reaches the low or high limits.



York International Corp., Unitary Products Group

Figure 33-14. Electrical control panel for condensing unit with multiple compressors.

The 12 psig system uses an operating pressure of 3 psig to 15 psig (20 kPa to 100 kPa). The 24 psig system uses an operating pressure of 3 psig to 27 psig (20 kPa to 185 kPa). Pressure regulators reduce the supply air pressure. The supply air pressure for these systems is as follows:

- 12 psig system = 18 psig to 20 psig (125 kPa to 140 kPa)
- 24 psig system = 30 psig to 35 psig (205 kPa to 240 kPa)

Copyright Goodheart-Willcox Co., Inc. 2017

Pneumatic thermostats are controlled by a pressurized air line. Air in pneumatic lines can be used to operate ***pneumatic motors***. These consist of a piston in a cylinder or pressing against a diaphragm. Pneumatic motors can be used to operate dampers, valves, and switches. Pneumatic signals can also be conditioned to provide a signal to system controls. Pneumatic controls are often used in large commercial and industrial systems. These control systems should be thoroughly checked each month.

33.1.4 Installing Rooftop Units

Rooftop units are heavy. They often contain all the heating and cooling equipment for part of a building in a single package. Heavy equipment is needed to move RTUs up to a rooftop. Riggers usually handle their initial installation, removal, and replacement, **Figure 33-15**.

Rooftop units must be installed using methods that will provide a leakproof roof connection. Installation is usually made as shown in **Figure 33-16**.

Acoustical material is often used for deadening sound. A resilient (flexible) gasket is installed between the rooftop base rail and the top edge of the roof curb. This gasket is very important. If it is not tightly installed, there may be leaks. One method used to make the roof leakproof is shown in **Figure 33-17**.

The electrical connections to a rooftop unit must comply with local codes. The control system is usually the responsibility of a refrigeration installation technician. A diagram of the control system of a typical rooftop unit is shown in **Figure 33-18**.

If the rooftop system has a gas furnace, the gas piping must be installed according to the appropriate code. Pipes must be supported and protected. **Figure 33-19** shows a typical installation for a 1 1/4″ gas line. Note that two

Goodheart-Willcox Publisher

Figure 33-15. Riggers securing straps to a rooftop unit before it is moved using a crane.

Service Call Scenario

33A: Commercial Rooftop Unit—No Cooling

Customer Complaint: No Cooling

Possible Causes: Blown fuses, power outage, defective circuit breakers in electrical panel.

Description of Problem: Mr. Turner, owner of a 4000 ft^2 commercial building, has reported that the rooftop air conditioner is not cooling. Prior to arriving at the jobsite, the technician, Keith, reviews the work order. Upon arriving at the building, he identifies himself to Mr. Turner and listens carefully to his comments.

Testing: Keith places the wall thermostat to call for cooling. Next, he sets his ladder correctly to reach the roof. He observes the system's operation. He notes very quickly that both the compressor and the condenser fan motor are not in operation. This triggers Keith to perform a voltage check at the unit's electrical disconnect. He finds that the supply source voltage is present, but that the cartridge fuses have been blown. To confirm his diagnosis, he removes the fuses and tests them for continuity. The readings read infinity, indicating an open fuse element. After consulting with Mr. Turner, Keith is informed that the unit had been operating during an electrical storm, and stopped working thereafter. He then informs Mr. Turner of the issues and offers solutions and the costs. Mr. Turner agrees to have Keith perform the needed service.

Solution: Keith replaces the fuses and starts up the system. He checks all operations upon starting and restarting and notes no complication. The unit's temperatures and pressures are within normal ranges. The unit is now cooling. Keith provides Mr. Turner with the bill and informs him that a follow-up call will occur.

Safety: Remember to always practice good electrical safety procedures when accessing electrical panels. When using a ladder, be certain to follow approved safety procedures.

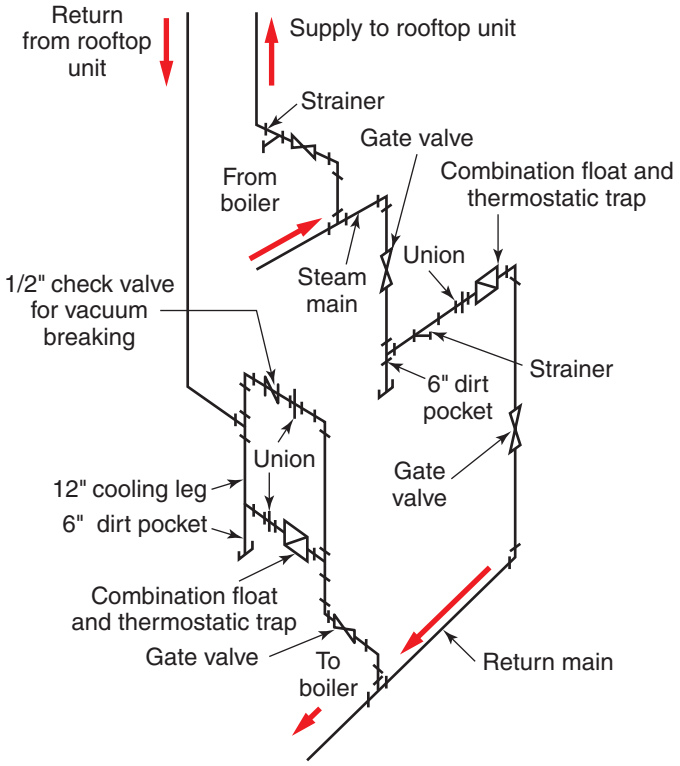
hand shutoff valves are used. One is located outside the rooftop unit's case. It will permit emergency shutdown of the furnace in case of accident or fire.

Code Alert

Gas Piping to a Rooftop Unit

According to the International Fuel Gas Code, gas piping installed outdoors (including on rooftops) must be elevated at least 3 1/2″ above the roof surface. It should also be securely supported and installed in a way that it is protected from physical damage. Where gas pipe passes through an outside wall, it should be protected from corrosion by coating or wrapping it with an inert material. When piping is in a protective sleeve, the space between the piping and sleeve must be sealed.

Some RTUs use piped-in hot water or steam to provide heating. Piping for these systems must be carefully installed to avoid air traps and freezing. Hot water systems usually use a nonfreezing solution composed of water and ethylene glycol. **Figure 33-20** shows the piping for a steam system.



Goodheart-Willcox Publisher

Figure 33-20. Steam pipe installation for steam heating system used on rooftop unit. More than one steam path is provided. This helps prevent restricted flow if one section is partially closed. Balance is improved.

33.1.5 Servicing Rooftop Units Safely

Rooftop units include the same basic components as traditional refrigeration systems: evaporator, compressor, condenser, and metering device. Some rooftop units operate as heat pumps. Other units include components for gas or electric heating. The service procedures performed on a rooftop unit are essentially the same as those performed on ground level heating and cooling systems. However, since the system is located on the top of a building, additional care must be taken to perform the work safely.

Use all possible safety precautions when climbing to the roof. If a portable ladder is used, it must be securely and firmly based on the ground. It must lean against the building at a moderate angle with its base 1′ away from the vertical wall for every 4′ of vertical rise. This will keep it from falling away from the building. It also must extend 3′ above the roof edge.

Use both hands on the ladder when climbing or descending a ladder. A portable ladder should not be used in high or gusty wind conditions. Be especially careful if it is raining or snowing. Do not attempt to carry equipment or supplies up or down a ladder. Lift tool boxes, refrigerant cylinders, and other objects with a rope. The rope should be guided from below.

Extreme caution must be used while working on or near electrical circuits. Hinged panels must be secured in the open position. Otherwise, the wind may swing them violently and injure someone. Loose panels must be held down securely to prevent wind blowing them off the roof. If a system is equipped with gas or oil burners, avoid breathing fumes coming out of the flue.

When working on rooftop units in cold weather, use gloves and hand warmers. Some technicians prefer portable heaters. In windy weather, set up a windbreak to provide wind shelter. If the wind is strong, use a safety belt. The belt should be attached to a solid part of the unit.

When working on rooftop units in hot, sunny weather, shield the tools from the sun. Metal can become so hot it will burn your hands. When working under sunny conditions, be sure to wear sunblock and drink enough water. Wear gloves when handling sun-heated access panels. Wear a hard hat and goggles under all conditions and rubber gloves when working on electrical circuits.

33.1.6 Variable Refrigerant Flow (VRF) Systems

As discussed in previous chapters, variable refrigerant flow (VRF) systems are very efficient and quiet. They continuously vary compressor and fan operation to match the refrigerant flow needed for cooling capacity. VRF systems can be used to meet the needs of many

Copyright Goodheart-Willcox Co., Inc. 2017

occupants in a large commercial building. Examples include buildings that have offices with workers on different hours or groups that may work on a weekend while the majority of the building is vacant.

Typical outdoor VRF units can connect to multiple indoor coils. These systems are especially well-suited for building environments in which individual floors or rooms require zoning. Multiple outdoor units may be roof mounted to provide heating and cooling to large office complexes, **Figure 33-21**.

VRF systems are also efficient at regulating the heating or cooling in one set of offices that may have a greater solar load than another set of offices on the other side of the building. **Figure 33-22** illustrates the zoning that is possible in an office building that uses a VRF system.

The length of piping is an important design consideration in VRF systems. Pumping of refrigerant above 150′ in height results in too great of a pressure drop in the lines. Large office towers that exceed this may split the arrangement of outdoor units. Rooftop units are used to supply the upper floors. Ground units feed the lower floors.

Heating and cooling multiple zones in a VRF system is accomplished a number of different ways. Some VRF units use electric heaters or energy recovery modules. Other systems use heat recovery. This method uses a third tube between indoor and outdoor units that allows refrigerant flow to be directed for the transfer of refrigerant between the indoor coils. As some indoor coils are operating as evaporators, other indoor coils are operating as condensers, **Figure 33-23**.

Ventilation in commercial buildings is a critical component in maintaining a healthy indoor environment. ASHRAE standards require a certain amount of outside air to be brought into a room per hour and also specify the number of air changes based on occupancy of a building. VRF systems in large buildings can achieve air filtration, ventilation, and humidity control through the use of air handlers. Ductwork is significantly smaller in new construction VRF applications as it serves only for air circulation and humidification.

33.2 Chillers

Chillers are cooling systems that use a loop of chilled water (instead of forced air) to provide cooling to a conditioned area. In a chiller system, a refrigeration system is used to cool water. This refrigeration system can be either a mechanical system (using a compressor) or an absorption system. The cold water is circulated through a building to provide cooling to the occupied spaces. Chillers are primarily used

in larger industrial and commercial air-conditioning and refrigeration applications. Chillers can range from 20-ton to 2000-ton capacity. The popularity of chillers is due in large part to their cost-effectiveness as a result of low energy consumption during part-load and full-load operation.

Pro Tip

Hybrid Chiller Systems

In some regions, it may be cost-effective to install a hybrid gas and electric chiller system. This type of system allows the owners to switch between gas and electric chillers, depending on which energy source is the least expensive at a given time.

There are two main types of chillers: compression chillers and absorption chillers. Compression chillers are discussed in this chapter. Absorption chillers are discussed in Chapter 34, *Absorption and Evaporative Cooling Systems*.

Compression chillers use two different refrigerants: a primary refrigerant and a secondary refrigerant. The ***secondary refrigerant*** is a fluid that is circulated to absorb heat from a conditioned space. Water is commonly used as the secondary refrigerant in chillers designed for comfort cooling applications. Water is fluid, inexpensive, nontoxic, and mostly noncorrosive, making it an excellent secondary refrigerant. As a chiller circulates cool water through a building, the water absorbs and removes heat from the conditioned spaces.

Other secondary refrigerants commonly used in chillers include salt-based brines (calcium-chloride and sodium-chloride), glycol-based fluids (ethylene and propylene glycols), and solutions for low-temperature heat transfer (methylene chloride, trichloroethylene, and acetone). Brines are often used as secondary refrigerants for low-temperature refrigeration systems.

The ***primary refrigerant*** in a chiller system absorbs heat from the secondary refrigerant and rejects the heat from the system. A number of common refrigerants are used as primary refrigerants in chillers, such as R-22 and R-123, R-134a, and ammonia. The phaseout of R-22 has resulted in the introduction of chillers designed for use with R-134a, R-410A, and R-407C. The efficiency of an R-410A system is actually higher than the efficiency of the R-22 system that it replaces. R-134a can be used as a retrofit refrigerant for systems that used R-22.

Caution

Refrigerant System Pressures

Refrigeration systems using R-407C and R-410A operate at higher pressures than R-22 systems. R-407C and R-410A should only be used in systems designed specifically for their use.

Service Call Scenario

33B: Commercial Packaged Unit—Insufficient Cooling

Customer Complaint: Insufficient Cooling

Possible Causes: Low refrigerant charge, defective metering device, defective filter drier.

Description of Problem: Mr. Atek, owner of a commercial building, reports that the air-conditioning unit does not appear to be cooling. Prior to arrival at the location, the technician, Matt, reviews the work order. Upon arriving at the business, he identifies himself to Mr. Atek and listens carefully to his comments.

Testing: With the thermostat calling for cooling, Matt installs his gauge manifold and observes the system pressures. He visually inspects the entire unit. He notes frosting at the outlet of the liquid line filter-drier. A check of the system's pressures reveals that both the low- and high-side pressures are dropping along with the compressor amperage. Matt determines that this could be caused by a plugged filter-drier that may be restricting refrigerant flow. He notifies Mr. Atek of the issue and recommends that the filter-drier be replaced and the system be recharged. Mr. Atek agrees to have him perform these services.

Solution: Matt recovers the refrigerant, removes the plugged filter-drier, and brazes in a new filter-drier. He then evacuates the system and recharges it to system specifications. System pressures and temperatures are checked and all operations are within normal readings. The system is now cooling satisfactorily. Matt then provides Mr. Atek with a bill and informs him that a follow-up call will occur.

Safety: When working with high-pressure systems, remember protection is needed for eyes and hands. When using torches, follow all safety precautions, and make sure all refrigerant has been recovered. When refrigerant and open flame are combined, toxic and fatal gases are produced. Good ventilation is required.

Copyright Goodheart-Willcox Co., Inc. 2017

A compression chiller has many of the same basic components as a standard mechanical air conditioner: compressor, condenser, refrigerant metering device, and evaporator. These components are larger in a compression chiller in order to accommodate the increased amount of refrigerant in the system. In a chiller system, the evaporator, compressor suction line, and chilled liquid lines are always insulated. The evaporator cools the water. This cold water is then pumped to the conditioned spaces of a building, where it absorbs heat.

The compressors used in chiller systems can be hermetic, semi-hermetic, external direct drive, or open drive. Condensers can be evaporative, air-cooled, or water-cooled. Air-cooled and water-cooled are the most common. Thermostatic expansion valves (TXVs) are the most popular type of refrigerant metering device used in chillers. Other components used in chiller systems can include liquid receivers, water-side economizers, and subcoolers. Optional accessories include an oil cooler, oil separator, purge unit, oil pump, and refrigerant transfer unit.

Chillers can be used for large industrial process cooling or to cool large commercial buildings. Several chiller units can be connected in parallel to provide adequate capacity for large cooling loads. A single chiller might use multiple compressors connected in parallel and one refrigerant circuit. Such systems require sophisticated control for optimum efficiency. **Figure 33-24** shows a chiller with multiple compressors and an air-cooled condenser used for an ice arena.

The evaporators used in chiller systems are usually the direct-expansion (dry) type. In a ***direct-expansion evaporator,*** refrigerant is fed into the evaporator at the same rate that it evaporates. This prevents large amounts of liquid refrigerant from pooling in the evaporator. Water flowing around the evaporator coil is cooled as the refrigerant evaporates inside the coil. The chilled water is then distributed to cooling loops throughout the building, **Figure 33-25**.

Heat from inside a building transfers to the cool water inside the cooling loops, lowering the room temperature and raising the temperature of the cooling water. The warm water returns to the chiller, where it is once again cooled and recirculated.

Many chillers use a water-cooled condenser in combination with a cooling tower. The water circuit for the condenser is completely separate from the evaporator's water circuit. These two groups never meet or mix. See **Figure 33-26**.

Cooling tower water enters a water-cooled condenser where it absorbs heat from the condensing refrigerant. The water is then sent to a cooling tower in which the water is drained or sprayed from the top. As the water falls toward the bottom, it is cooled by evaporation. Occasionally, forced-air fans are used in a cooling tower to aid evaporation. The cooled water returns through water pumps back to the condenser. **Figure 33-27** shows the flow of the water through a water-cooled condenser and cooling tower.

Chiller efficiency is determined by the temperature of chilled water leaving the chiller and the temperature of return water entering the chiller. The AHRI standard recommends that chiller evaporators

Service Call Scenario

33C: Commercial Rooftop Unit—Lack of Cooling

Customer Complaint: Lack of Cooling

Possible Causes: Overcharged system, malfunctioning compressor, defective condenser fan motor.

Description of Problem: Mr. Sharma, owner of a small machinery shop, has reported that the rooftop unit is not cooling. Prior to arriving at the jobsite, the technician, Aroon, reviews the work order. Upon arriving at the building, Aroon identifies himself to Mr. Sharma and listens carefully to his comments. Mr. Sharma shares that the unit has been experiencing difficulty lately and that he had, in fact, had another company out for repairs. He indicates that the other company was unable to repair the unit and expresses his dissatisfaction with that company.

Testing: Aroon installs his gauge manifold to determine the system pressures. The high-side pressure is very high and is drawing a high amperage. The low-side pressure is also higher than normal. Aroon concludes that the unit is extremely overcharged. He informs Mr. Sharma of the issue and offers a solution and the cost for such. Mr. Sharma agrees to have Aroon perform the needed service.

Solution: Aroon begins by recovering the refrigerant. He then evacuates the system and recharges using the subcooling method. The remaining system operations are examined and all appear to be operational. The pressures have returned to normal and the system is now producing a cooling effect. Aroon provides Mr. Sharma with the bill and informs him that a follow-up call will occur.

Safety: Always wear eye protection and gloves when charging refrigerant. Most refrigerants need to be liquid charged, and if not careful when charging, they could cause instant frostbite to skin or eyes. Eye and hand protection can prevent serious injuries.

Figure 33-25. In this chiller system, the water leaves the chiller's evaporator at 45°F (7°C). It circulates throughout the building, picking up heat, and returns to the evaporator at 55°F (13°C). This chiller system uses a water-cooled condenser and cooling tower to reject heat to the outside of the building.

operate at a 44°F (7°C) chilled water temperature with a water inlet temperature at 54°F (12°C). The efficiency of a chiller's matching water-cooled condenser is also monitored. It should have a condenser inlet water temperature of 85°F (29°C) and an outlet water temperature of 94°F (34°C). These temperatures can be used in order to determine if the chiller is operating within design parameters.

33.2.1 High-Pressure Compression Chillers

Chillers can be categorized by their operating pressures. They are either high-pressure or low-pressure. ***High-pressure chillers*** are compression chillers that operate under high pressures. They are used primarily for commercial and industrial process cooling. The high operational pressure will determine the size of the unit needed to accomplish the cooling task. For example, a 400-ton unit may be required in order to maintain the desired temperatures in a 20-story commercial office building.

33.2.2 Low-Pressure Compression Chillers

Low-pressure chillers are typically centrifugal chillers charged with R-123. A portion of these systems

operate under low atmospheric pressures (200 kPa) while operating at typical conditions for cooling. This enables them to produce very low evaporator temperatures. Most of the components in a low-pressure chiller are similar to those of the high-pressure system. Therefore, the operation is very similar. High-pressure and low-pressure centrifugal chillers are almost identical. However, due to lower operating pressures, low-pressure chillers are not as heavily constructed as high-pressure systems.

Purge Units

The evaporators in some low-pressure chillers operate in a vacuum. Since it is difficult to have a perfectly sealed system, some air and moisture are likely to leak in over time. Noncondensables, such as air and moisture, that enter a system reduce the system's cooling capacity. The compressor must still perform work to move the noncondensables through the system, but they do not contribute to the cooling effect. Noncondensables in the system tubing also reduce the heat exchanging capability of the system. Any moisture in the system can form acids, which increase corrosion and can lead to compressor failure.

A ***purge unit*** is an auxiliary component designed to remove noncondensables in order to preserve system efficiency and prevent damage. The drawbacks of purge units are that they are another component that requires service, and they also release small amounts of refrigerant to the atmosphere as they remove the noncondensables. Due to the increasing price of refrigerants and the ever-increasing emphasis on the environment, high-efficiency purge units have been developed.

Most high-efficiency purge units come with microprocessor-based data logging and diagnostic capabilities. The function of a purge unit is to maintain a system free of air and moisture. Moisture can cause the formation of acids that will attack the system's internal components. Removing noncondensables from a system restores peak efficiency and prevents the damage associated with acid formation. A purge unit runs only when needed, and should pump out noncondensables within 2 to 3 minutes. Cycle times that exceed this may indicate that the system has developed a significant leak.

Thinking Green

Upgrading to High-Efficiency Purge Units

Purge unit efficiency is determined in accordance with AHRI Standard 580. Older, inefficient purge units could release as much as 10 lb of refrigerant for every 1 lb of air removed. Some of today's high-efficiency purge units release less than 0.1 lb of refrigerant for every 1 lb of air purged.

Secondary Emission-Collection Devices

As previously mentioned, when purge units remove air from a system, a certain amount of refrigerant is removed with it. If the air is purged to the atmosphere, so is the refrigerant. If a secondary emission-collection device like a charcoal canister or molecular sieve canister is installed between the purge unit and vent, it can capture most of the refrigerant that escapes during the purging operation, preventing it from being released to the atmosphere. If a charcoal canister is used, the refrigerant it captures is nonrecoverable. The canister has a specific capacity and is replaced once it has reached that limit.

Thinking Green

Secondary Emission-Collection Devices

By using a secondary emission-collection device, like a charcoal canister, in combination with a high-efficiency purge unit, it is possible to reduce purging-related refrigerant emissions to less than 0.0005 lb of refrigerant for every pound of air purged from the system.

33.2.3 Chiller Compressors

Various types of compressors are used in chillers. Some of the more common types (reciprocating, scroll, screw, and centrifugal) are discussed in the following sections. Additional information on compressors can be found in Chapter 18, *Compressors*. As stated, the major difference between compressors used in chillers and those used in other applications is their size. Chiller compressors are generally much larger. The basic operation of the compressors is the same, however. The type of compressor used in an installation depends on the number of tons of air conditioning needed.

The motors that are used to drive chiller compressors can be either open-drive or closed-drive types. Open-drive motors are exposed and are cooled by air in the room. Open-drive motors produce a large amount of heat, which must be exhausted from the equipment room.

Closed-drive motors are hermetically sealed inside a case and are cooled by refrigerant. This reduces the amount of motor heat that radiates into the equipment room. Closed-drive motors are frequently used in 80-ton to 2000-ton systems.

Natural gas engines can also be used to drive chiller compressors. Scroll compressors and reciprocating compressors are used with natural gas engines in low-capacity systems of 30 tons or less. An engine-driven chiller system operates the same as any other chiller system. The only difference is the type of drive, **Figure 33-28**.

Zero Zone, Inc.

Figure 33-29. Chiller system using multiple reciprocating compressors.

Reciprocating Compressor Chillers

Large reciprocating compressors operate like other reciprocating compressors. They are used in chiller systems with capacities ranging from 10 to 150 tons. These compressors can be either hermetic or semi-hermetic. The main benefits of reciprocating compressors are simple controls, low cost, and efficiency in low-capacity applications. However, the drawbacks to reciprocating compressors are greater maintenance requirements due to numerous moving parts and high levels of noise and vibration.

As many as twelve cylinders may be needed on a large reciprocating compressor in order to produce the needed pumping capacity. This makes large reciprocating compressors more costly and less energy efficient than other types of compressors with equivalent capacity. Therefore, most manufacturers no longer use one large reciprocating compressor in a system. Instead, multiple smaller compressors are used. This arrangement provides a backup if one compressor should fail. Multiple compressors also allow for increased capacity control and give operators the ability to maintain or service one compressor while the others remain in operation, **Figure 33-29**.

The refrigerants most frequently used with reciprocating systems are R-500, R-502, and R-134a. The elimination of R-12 and phaseout of R-22 has resulted in newer, more-efficient systems that operate on R-410A and R-407C.

Reciprocating compressors have many moving parts that create a lot of friction. A pressure lubrication system is included on all reciprocating compressors 5 hp and over. The majority of wear on a compressor occurs during start-up because the oil pressure has not yet been established. The compressor must be running in order for lubricants to reach many of the high-friction areas of the compressor. It is necessary to reduce pumping capacity on start-up in order to reduce the load on poorly lubricated surfaces and to alleviate temperature fluctuations and unnecessary cycling of the unit.

Cylinder Unloading

Cylinder unloading is the disabling or reducing of a reciprocating compressor's cylinder pumping ability. Unloading one or more of the compressor cylinders reduces the overall capacity of a reciprocating chiller. For example, if a compressor has eight cylinders and the cylinders are unloaded in pairs, the capacity would decrease by 25% per unloading step:

- 8 cylinders operating = 100% capacity
- 6 operating, 2 unloaded = 75% capacity
- 4 operating, 4 unloaded = 50% capacity
- 2 operating, 6 unloaded = 25% capacity

Compressors are designed so that it is not possible to unload all of the cylinders at the same time. If all of the cylinders were unloaded, the compressor could not move any refrigerant through the system. As a result, no oil would circulate back to the compressor. Since it would be without proper lubrication, the compressor would be damaged quickly.

Copyright Goodheart-Willcox Co., Inc. 2017

Compressors will usually unload down to 25% to 50% of their full-load pumping capacity. Cylinder unloading reduces power consumption, since power consumption is directly related to amperage draw of the compressor motor. Pumping less refrigerant requires less compressor motor amperage, which reduces electrical power consumption.

There are different methods of cylinder unloading. Two common methods are to block a cylinder's intake passage or to hold open a cylinder's suction intake valve. A cylinder can be unloaded by using a solenoid valve to block the suction passage to a cylinder. This prevents vapor from reaching the cylinder, **Figure 33-30**.

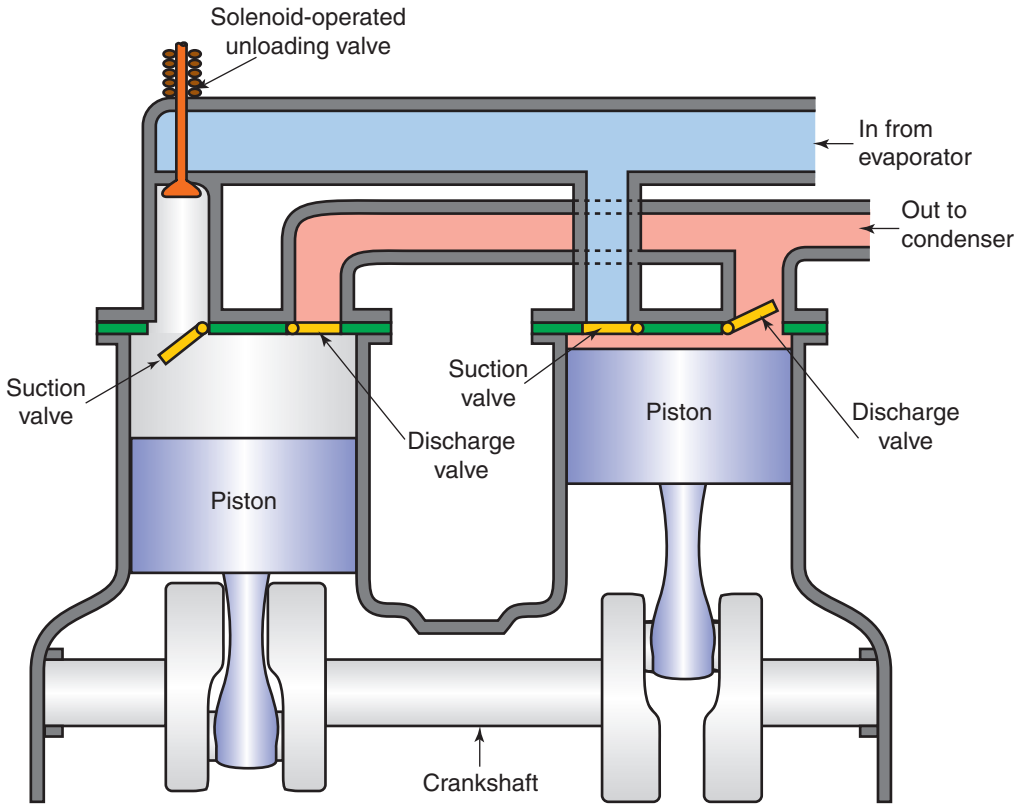
Suction valve lifting refers to holding the suction valve open while the compressor is pumping. When the suction valve is held open, refrigerant is drawn into the cylinder normally on the intake stroke, but is forced back through the suction valve during the compression stroke. Since pressure is lower on the suction side where the intake valve is held open, refrigerant flows back, rather than pushing through into the discharge line. This action causes that cylinder to quit pumping.

With either unloading method, the pressure on the cylinder walls and bearings in the compressor is reduced, decreasing friction. This helps reduce wear on the compressor during start-up. Because the piston still moves up and down, oil pressure builds, and the lubrication system begins working even though the cylinder is not pumping. When the oil pressure reaches normal levels, the cylinder unloader can be deactivated so that the cylinder will begin pumping normally again. In addition to reducing load during start-up, cylinder unloaders can also be used to decrease system capacity in order to reduce refrigeration effect when it is not needed. Unloaders can also be used to reduce electrical power consumption.

Scroll Compressor Chillers

Scroll compressors are positive-displacement compressors. They are welded-hermetic units and have capacities in the 10- to 25-ton range. In multiple-compressor chiller systems, capacity control is maintained by cycling the compressors on and off in increments of 10 and 15 tons. For example, a 25-ton chiller would be equipped with a 10-ton and a 15-ton compressor. Capacity would be controlled by running both compressors, running just the 10-ton compressor, or running just the 15-ton compressor. See **Figure 33-31**.

A scroll compressor contains two matching spiral scrolls. One is attached to a flat base and faces one direction. The other scroll faces the other direction and is connected to the motor by a turning assembly, **Figure 33-32**.



Goodheart-Willcox Publisher

Figure 33-30. In this cylinder unloader, a solenoid-operated valve closes the intake passage.

Copyright Goodheart-Willcox Co., Inc. 2017

The two scrolls are sandwiched together, which creates pockets of space along the scroll walls. One scroll orbits around the stationary scroll. As gas enters the scroll, it is progressively compressed into a smaller pocket (volume). When the refrigerant vapor arrives at the center of the scrolls, it is compressed to the maximum capabilities of the compressor. It is then discharged out of compressor, **Figure 33-33**.

Scroll compressors are becoming increasingly popular in comfort cooling. This is due in large part to their small size, light weight, smooth operation, and relatively high efficiency. They are also quiet, have few moving parts, and can pump small amounts of liquid refrigerant without compressor damage. The primary drawbacks of scroll compressors are that they cannot be repaired and that they may lose oil at low temperature.

Lubrication for a scroll compressor is provided by an oil pump located at the bottom of the crankshaft. A scroll compressor has a check valve to prevent backward flow of refrigerant when the system is shut down. This check valve is necessary to prevent an equalization of the high side to the low side of the system during the Off cycle.

Bitzer

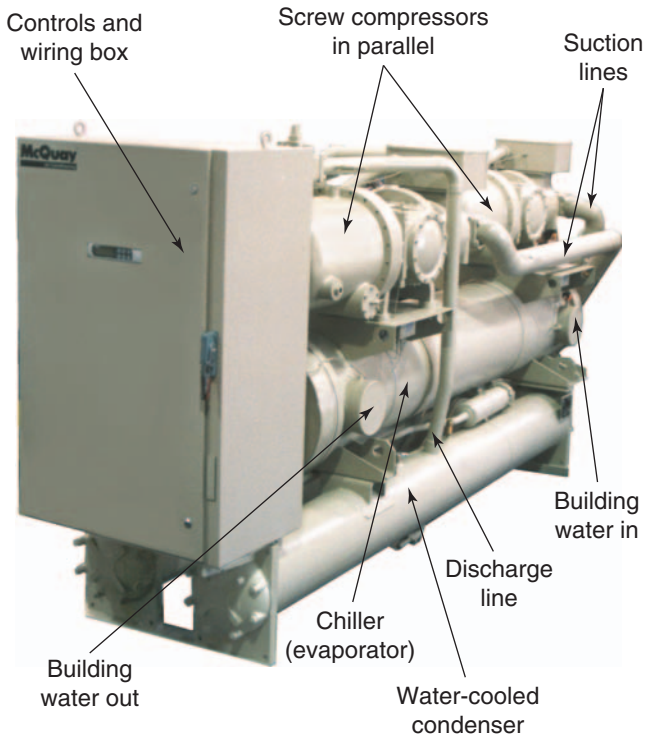
Screw Compressor Chillers

Screw compressors are most often used for larger-capacity chiller applications. These compressors are available in capacities up to 750 tons and require the use of high-pressure refrigerants. There are a number of benefits associated with screw compressors. These include a high output capacity, few moving parts, and the ability to pump some liquid refrigerant without being damaged. Since few compressors are needed to achieve high output, they offer greater piping flexibility. In addition, such systems require less interconnecting piping, thereby lowering assembly time and costs, **Figure 33-34**.

The capacity of most screw compressors is controlled with a slide valve. The slide valve blocks suction gas prior to its entering the screws. The slide valve can adjust capacity from 10% to 100% of the load.

Screw compressors pump a large amount of oil while compressing refrigerant. Excessive oil in the system will result in poor heat exchange and a loss of capacity. An oil separator is used to return oil to the compressor reservoir. Pressure differential moves the oil through the rotating parts of the compressor.



McQuay International

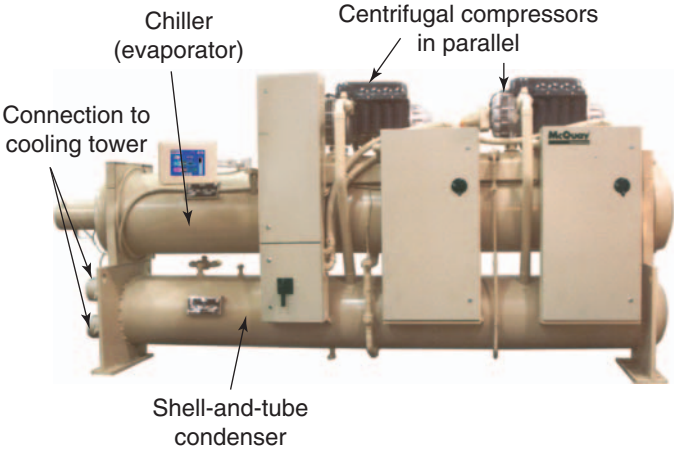
Figure 33-34. Chiller using two screw compressors connected in parallel and a water-cooled condenser that connects to a cooling tower.

Centrifugal Compressor Chillers

Many large comfort cooling installations use centrifugal compressors due to their cost effectiveness for large loads (150 tons and up). An additional benefit of these compressors is their simple design and small number of moving parts. Centrifugal compressor chillers can provide up to 2000 tons of cooling capacity with a single compressor assembly; however, assemblies can have more than one compressor, **Figure 33-35**.

Centrifugal compressor chillers use low-pressure refrigerants, such as R-123. The evaporator in a system with a centrifugal compressor operates at below-atmospheric pressure. These chillers have the capability of handling large volumes of refrigerant. They use centrifugal force to compress the refrigerant and move it from the low side to the high side of the system. An impeller similar to a large fan creates a pressure differential from one side of the compressor (inlet pipe) to the other (outlet pipe), **Figure 33-36**.

A high rotational speed is needed to generate sufficient centrifugal force to adequately compress the refrigerant vapor. In order to achieve that speed, a gearbox is installed between the motor and compressor. The gearbox has two gears: a drive gear and a driven gear. The drive gear is the larger gear, and the driven gear is the smaller gear. Being smaller, the driven gear turns the faster of the two. The shaft of the motor is connected to the drive gear, and the compressor's impeller shaft is connected to the driven gear. Because of the gearbox, the motor is able to turn the compressor impeller at approximately 20,000–25,000 rpm. This is much faster than the motor itself spins.



McQuay International

Figure 33-35. Chiller using two centrifugal compressors connected in parallel and a water-cooled condenser that connects to a cooling tower.

McQuay International

Figure 33-36. This cutaway shows the inner parts of a centrifugal compressor. The motor turns the impeller, which draws in and compresses refrigerant. Because the drive gear is much larger than the driven gear, the impeller spins much faster than the motor turns.

Figure 33-37 shows a typical centrifugal compressor chiller system. Both the condenser and the evaporator have a shell-and-tube type build. The compressor is a two-stage (dual compressor) centrifugal unit, driven by a hermetically sealed motor. Two-stage chillers take up less floor space and are less expensive to install than a setup of multiple single-stage compressors with the same capacity. This is due to elimination of piping to a second chiller and pumps, fewer valves and controls, and less rigging costs. Since multiple stages are used, each stage has less work to do. The lower compression ratios in each stage result in lower operating temperatures and greater efficiency.

A ***compression chiller economizer*** improves system efficiency by subcooling high-side refrigerant before it enters the evaporator. Refrigerant from the compressor passes through a metering device before it enters the economizer. This reduces the pressure of the liquid refrigerant. Some of the refrigerant flashes off, which subcools the remaining refrigerant. The flash gas is diverted to the space between the first stage and second stage of the compressor, where it mixes with the refrigerant vapor leaving the first compressor stage. The cooled liquid from the economizer passes through a second metering device and enters the evaporator. Since the refrigerant has been subcooled in the economizer, it is able to absorb more heat before vaporizing in the evaporator.

Lubrication System

A separate motor drives an oil pump that provides lubrication to a centrifugal compressor. This is usually accomplished by a 1/4 hp, three-phase motor inside the oil sump. Because the oil pump is driven by a separate motor, the lubrication system can deliver oil to the critical parts of the compressor and gearbox even before the compressor motor begins spinning and while the compressor is coasting down at the end of the compression cycle.

The lubrication system is a sealed system. Oil is not mixed with the refrigerant. A heater is located in the oil sump to help reduce refrigerant migration when the system is off. However, some liquid refrigerant will migrate to the sump, causing foaming for a few minutes after start-up. The compressor should be run at a reduced load until the foaming in the oil is reduced.

During operation, the oil is heated as it passes through the system lubrication components. The oil also absorbs heat from the bearings. The oil in the sump will reach 140°F to 160°F (60°C to 71°C). An oil cooler prevents the oil from overheating during operation. In the oil cooler, the oil is cooled to approximately 120°F (49°C).

Pro Tip

Centrifugal Compressor with Magnetic Bearings

Some centrifugal compressors ride on frictionless magnetic bearings. These compressors require no lubricant. They are driven by a direct-drive variable speed dc motor. Capacities of this type of compressor range from 60 to 300 tons. Such units are designed for indoor nonfreezing installation only.

Capacity Control

The capacity of a centrifugal compressor is controlled by adjusting guide vanes at the center of the impeller eye. The guide vanes are often referred to as inlet guide vanes, and they serve two purposes. They control the amount of refrigerant allowed to enter the compressor, and they create a rotational flow in the refrigerant that matches the rotation of the impeller. This reduces the drag on the compressor as the refrigerant enters.

A controller notes the operating conditions and sets the position of the inlet guide vanes accordingly. The guide vanes are operated by a pneumatic or electric motor. As vanes close, the entry angle of the gas to the impeller changes. This reduces gas flow as well as compressor capacity. When the guide vanes are closed,

Figure 33-37. This drawing shows the arrangement of the centrifugal compressor, condenser, and evaporator in a chiller system. A compression chiller economizer is often used to allow removal of flash gas in the evaporator, increasing the effect of each pound of refrigerant and reducing the compressor power requirement.

the compressor pumps at 15%–20% of its rated capacity. When the guide vanes are open, the compressor pumps at 100% of its capacity. Inlet guide vanes are automatically closed during start-up to reduce the starting load.

Operation

Most centrifugal compressor chillers use a controller to adjust the refrigerant cycle as needed. Fluid flow controls stop the system if chilled water flow ceases in a chiller. Pressure sensors and thermistors are placed throughout the system to monitor conditions. Controls may be interfaced with a personal computer to operate and maintain a chiller system.

Caution

Centrifugal Compressor Motor Rotation

The direction of motor rotation is critical in a centrifugal compressor chiller. If a motor starts in the wrong direction, it could damage the compressor. These motors produce a large amount of heat, which must be exhausted from the equipment room.

33.3 Cooling Towers

Some water-cooled condensers use tap water for cooling. This water is circulated through the condenser's water circuit and then discharged into the sewer. Such an arrangement uses large amounts of water, which is wasteful and may be expensive. Moreover, many places do not allow the use of tap water for cooling condensers. Rather than consuming a constant demand for fresh water, engineers have devised methods of using a set amount of water for cooling a condenser over and over again. This device is a cooling tower.

A ***cooling tower*** is a structure that removes heat from the cooling water of an HVACR system using the evaporation of water. Cooling water used in water-cooled condensers is circulated through a cooling tower to be cooled and recirculated for reuse. Water exposed to flowing air promotes evaporation. As water evaporates, it absorbs heat, which produces the cooling effect passed on to the remaining water, **Figure 33-38**.

A cooling tower is a housing or shed into which air is drawn. It has a series of spray nozzles or drain

Baltimore Aircoil Company

Figure 33-38. Diagram showing the operation of a typical cooling tower.

holes and baffled material fill. Water from the condenser is routed through the cooling tower, where it is drops through the tower. As the water is exposed to the stream of air, some of it evaporates, and the rest of the water cools.

The cooled water collects in a reservoir at the bottom of the cooling tower. A float in the reservoir controls a shutoff valve in a water supply line. If the water level in the reservoir drops below a minimum level, the float opens the water supply shutoff valve, allowing water to fill the reservoir. As the reservoir fills, the float rises, gradually closing the shutoff valve. A water pump draws cooled water from the reservoir and circulates it through the condenser, **Figure 33-39**.

Cooling towers are available in a great range of sizes. Small ones may be used to cool the water-cooled condensers for a medium-sized commercial air conditioner. Very large ones are required for cooling the condenser water in large steam power plants. **Figure 33-40** shows a complete air-conditioning system equipped with a cooling tower.

Cooling towers use evaporation to reduce the temperature of the water circulating through a condenser. The effectiveness of a cooling tower is partly dependent on the humidity of the air flowing through it. The less humid the air is, the greater the cooling potential provided through evaporation. Because of the cooling effect of evaporation, a cooling tower can cool water to a level below that of the surrounding air temperature. An equal amount of water can transfer more Btus heat than an equal amount of air. For these reasons, water makes an excellent cooling medium in HVACR applications.

For many cooling tower systems, hot vapor refrigerant condenses in the condenser around 105°F (40.5°C). Cooling tower water enters the condenser at 85°F (29.4°C). It absorbs about 10°F (6°C) of sensible heat in the condenser before circulating back to the cooling tower at 95°F (35°C). Through evaporation, the remaining water cools 10°F (6°C) back to 85°F (29.4°C), before flowing through the cycle again. When outdoor air temperature is cooler, water temperature can drop even more. In general, the cooler the cooling water to the condenser, the more heat it can absorb. The more heat that can be absorbed by the cooling water, the greater the subcooling and the more efficient system operation becomes.

As a cooling tower operates, water is lost in a variety of ways. Some water evaporates while cooling the rest of the water. Some water is broken into droplets small enough to be caught in a draft and carried out through the louvers. Water loss in this manner is called ***drift***. Some water is intentionally drained for the purpose of reducing certain mineral concentrations in the water. This is called ***blowdown***. Water vapor, drift, and blowdown eventually lower the water level in the cooling tower sump enough that a float switch opens a valve to allow ***makeup water*** to replace what was lost.

Figure 33-39. The operation of a typical cooling tower is shown here. The cooling tower cools the condenser water, which is then circulated through a condenser to condense and subcool the refrigerant.

Thinking Green

Old and New Water Cooling Systems

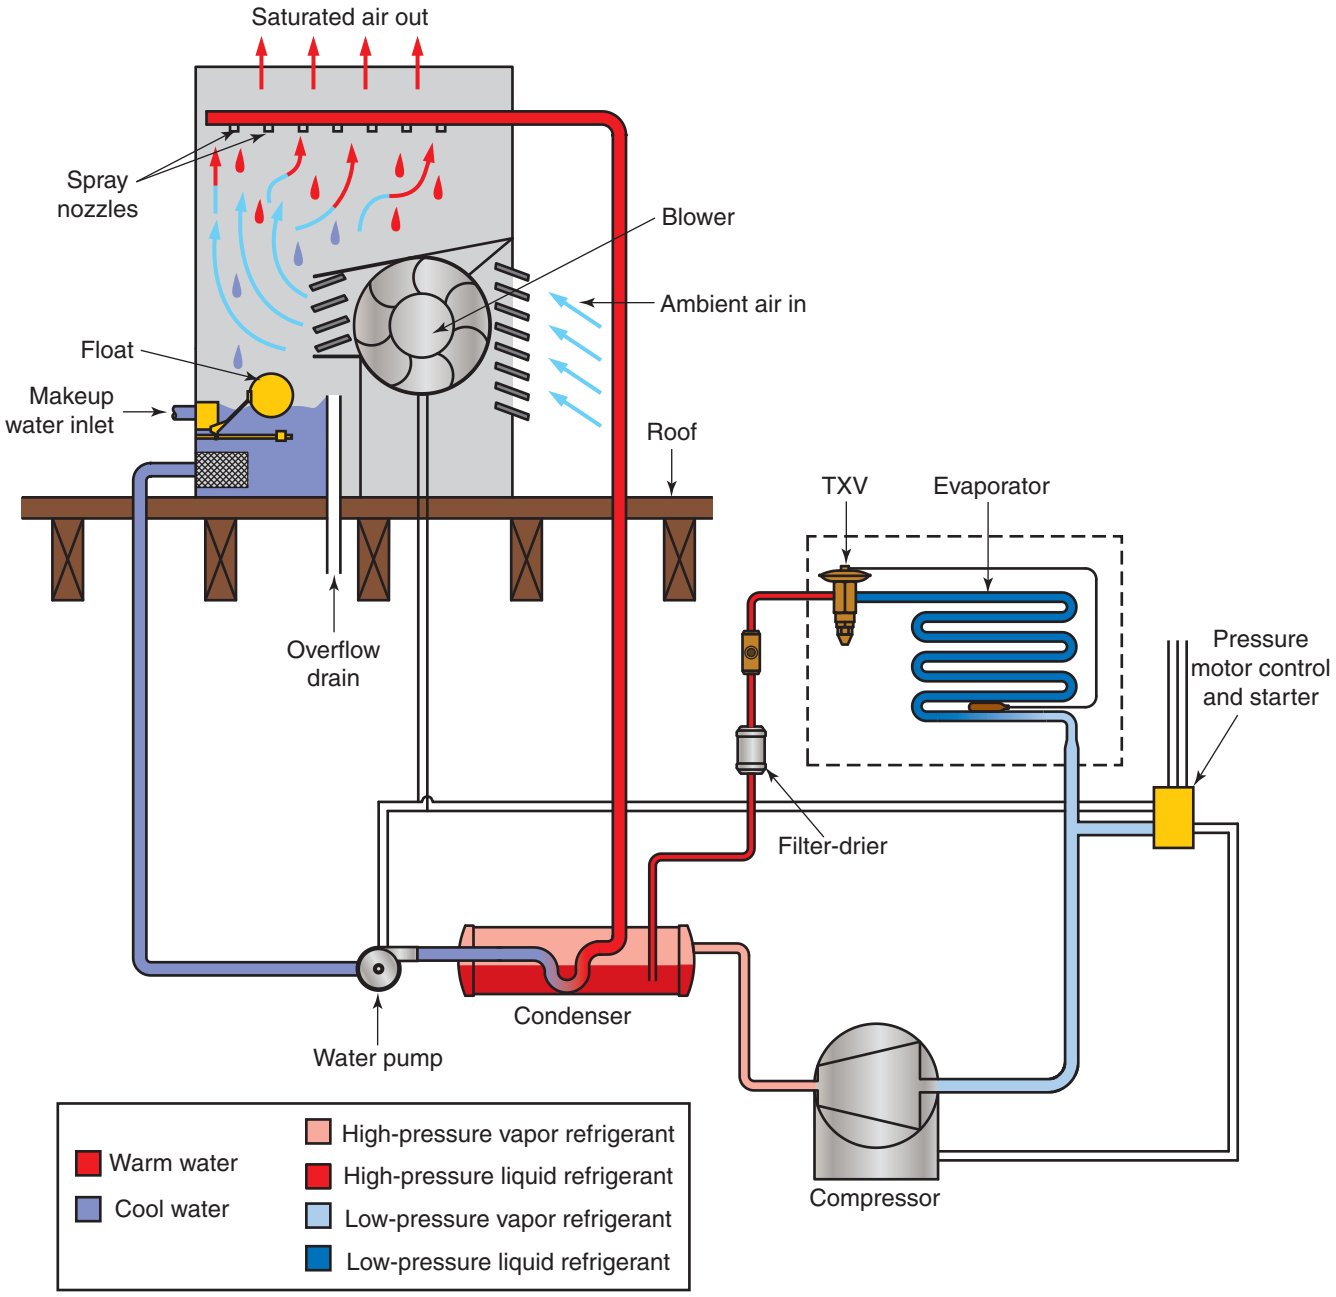
Older cooling systems only cycled water through their systems once before exhausting or draining the water. Compared to older systems, modern cooling towers use significantly less water by cooling and recirculating the same water over and over. Reusing cooled water is more environmentally conscious and cost-efficient than older water-cooled systems.

33.3.1 Cooling Tower Construction

For cooling and evaporation to occur, moving air must contact cooling tower water. The larger the amount of water surface area that flowing air contacts, the more evaporation will occur. To increase contact between air and water, structures called ***wet decks*** are placed within cooling towers, **Figure 33-41**.

Wet decks are designed to maximize water and air contact. They are made of components called fill.

Copyright Goodheart-Willcox Co., Inc. 2017



Goodheart-Willcox Publisher

Figure 33-40. An air-conditioning installation using cooling tower.

Fill is a specially designed sheet or structure with different ridges, corrugations, or designs used to increase air-water contact with the lowest possible air-pressure drop. Fill can be wood slats, thin plastic sheets, or other materials. The more water surface in contact with the air flowing through a cooling tower, the more efficient the cooling.

Some installations use the surface of the unit for a water trough. These applications may use wave-formed sheets of galvanized or stainless steel or slats of plastic or wood. Fill made of these materials is designed to be more open to prevent clogging and allow easy access for cleaning by maintenance personnel.

Water in a cooling tower can be distributed over the fill by one of two methods: pressured water system or gravity flow basin. A ***pressured water system*** is a collection of components used in a cooling tower that pumps water through pipes and out of spray heads along the top of wet decks, **Figure 33-42**.

A ***gravity flow basin*** is a water-filled container on top of a cooling tower that has precision holes through which accumulated water flows onto wet

Figure 33-42. Counterflow cooling tower cutaway shows wet deck fill onto which the spray nozzles release water for cooling.

decks, **Figure 33-43**. Either type of water distribution system must be inspected regularly and kept clean in order to distribute the water evenly. Proper distribution ensures full thermal performance and prevents scale buildup.

Cooling towers are made of corrosion-resistant materials. Combinations of materials are increasingly popular, such as welded type 304 stainless steel basins with the remainder of the tower above the water line fabricated of galvanized steel. Coatings are also used over galvanized steel to help extend equipment life. The most common materials are galvanized steel, stainless steel, fiberglass, plastic, and treated wood, **Figure 33-44**.

Code Alert

Rooftop Cooling Tower Construction

The International Building Code (IBC) specifies certain restrictions regarding rooftop cooling towers. Rooftop cooling towers with over 250 ft^2 of capacity or being taller than 15′ must be constructed of noncombustible materials. The exception is fill made of wood at least 1″ thick may be used as long as the exterior of the tower is a noncombustible material. Also, the base of a rooftop cooling tower cannot be greater than 1/3 of the area of the supporting roof deck.

Cooling Tower Water Circuits

Cooling towers are designed to have one of two types of water circuits: open loop or closed loop. In an ***open-loop cooling tower,*** the water from the condenser flows into the cooling tower and over the wet decks and fill directly. This water is then recirculated through the condenser before returning to the cooling tower. The condenser and cooling tower share the same water. In open-loop circuits, some of the water will be lost to evaporation, drafts, or draining.

Copyright Goodheart-Willcox Co., Inc. 2017

SPX Corporation

Figure 33-44. This crossflow cooling tower with vertical discharge has a fiberglass construction.

SPX Corporation

Figure 33-45. Counterflow cooling towers have air inlets near the bottom of their structure. Air flows upward against the downward flow of the water from above.

In a ***closed-loop cooling tower***, the water in the condenser carries its absorbed heat into a heat exchanger that passes the heat into a separate stream of water that flows through the cooling tower. This separate cooling tower water flows over the wet decks and fill to release the heat from the system. Condenser water and cooling tower water are separate and exclusive. They never mix or contact each other. Condenser water remains in a single circuit, consisting of the condenser and one part of the heat exchanger. Cooling tower water remains in a single circuit, consisting of the cooling tower and the other part of the heat exchanger.

A closed-loop circuit allows far fewer contaminants into the condenser water loop than an open-loop circuit. In a closed-loop system, condenser tube cleaning can be performed much less frequently than in an open-loop system.

Cooling Tower Airflow Designs

Cooling towers can have one of two different airflow designs. In a ***counterflow cooling tower***, air and water travel in opposite directions. Water enters from above and drops downward to the sump or cold water basin. Air enters from the lower part of the tower and flows upward to exit at the top. Air and water flow counter to each other (in opposite directions), **Figure 33-45**.

In a ***crossflow cooling tower***, air flows across the wet deck from side to side, while water drops downward from above. The air and water cross each other's path. Crossflow cooling towers can often be identified as using entire side walls as air inlets, **Figure 33-46**.

Baltimore Aircoil Company

Figure 33-46. A dual inlet crossflow cooling tower with vertical discharge.

Cooling Tower Draft Options

A ***natural-draft cooling tower*** relies on wind and natural convection to blow through the tower to aid evaporation. A natural-draft tower must be bigger than a forced-draft cooling tower in order to have the same amount of cooling capacity. However, natural-draft towers have a lower operating cost, as no energy is consumed in moving air through the tower.

Copyright Goodheart-Willcox Co., Inc. 2017

An ***induced-draft cooling tower*** uses a fan placed at the air exhaust to draw air into the tower through a louver on an opposing side, across the wet deck, and out of the tower through the fan. Induced-draft fans always blow outward and away from the cooling tower. An induced-draft crossflow cooling tower would have its fan along the side wall that air exits the tower. An induced-draft counterflow cooling tower would have its fan mounted along the top of the tower.

A ***forced-draft cooling tower*** uses a fan placed at the air inlet. It draws air in through itself and blows it through and out of the tower. Forced-draft fans always blow directly into the tower. A forced-draft crossflow cooling tower would have its fan along the side wall where air enters the cooling tower. A forced-draft counterflow cooling tower would have its fan mounted on the lower part of the tower where air enters.

Thinking Green

Cooling Tower Efficiency

Cooling tower efficiency can be maximized by using variable speed fans rather than adjustable louvers to control airflow through the tower. Controlling airflow by restricting the air intake is inefficient and places an unnecessary load on the fan motors. Also, ensure that there is good water distribution through the tower. Replace any restricted spray nozzles with clog-resistant, corrosion-resistant nozzles.

33.3.2 Cooling Tower Operational Considerations

Cooling towers are an efficient way to release heat from an HVACR system or an industrial process. However, it is important for building owners and operators to be aware of the various aspects of maintenance and environmental concerns that are necessary for continuous operation.

Air and water vapor absorb latent and sensible heat from the water in cooling towers. When ambient air is already hot, less heat transfer occurs. To adjust for increased ambient temperature, either airflow or water flow must be increased. Humid air absorbs less heat, because it already has a high moisture content, making evaporation more difficult. Dry air is better for cooling tower operation, because it can absorb moisture more easily.

Code Alert

Cooling Towers

Because the vapor plumes from cooling towers can drift in the wind and affect other areas, the positioning of cooling towers is typically strictly regulated by local building codes. Codes also dictate proper anchorage and support of the tower and proper water supply and drainage piping to the tower.

Cooling Towers in Seasonally Cold Climates

Cold ambient temperatures and a low heat load can cause cooling tower water to freeze. Freezing typically starts in the corners with reduced heat load. Ice formation, which causes increased structural load, can damage cooling tower components. One solution is to continuously operate the tower with 40°F (4°C) water leaving the tower. ***Basin heaters*** are available to keep the water temperature up if the system is shut down in freezing temperatures. Piping may need insulation or electric heat tracing. Some systems have water reservoirs inside the building to protect the water from freezing weather. The reservoirs must be large enough to hold all the water in the system. In cold weather, chemicals can be added to the water in the condenser loop of closed systems; however, these chemicals usually are not added to cooling tower water. Do not run fans in reverse for de-icing.

Cooling Tower Capacity Controls

Airflow control can be used to change the cooling capacity as well as to protect the unit as outside air temperature drops. Airflow through a cooling tower can be controlled by cycling fan motors, using multispeed motors or variable frequency drives, or modulating the position of cooling tower louvers. To reduce cooling capacity, close cooling tower louvers, slow fan speed, or turn off fans. These are all ways of stopping or reducing the movement of air, which impedes evaporation and cooling.

Some cooling towers use a thermostatic water mixing valve that maintains a specific head pressure to control water-cooled condenser capacity. By regulating the temperature of the water returning from a cooling tower, condenser head pressure can be held constant. Water temperature regulation is done by mixing some of the cooled return water with hot condenser water that has not yet entered the cooling tower. Temperature is monitored at the condenser water inlet.

33.3.3 Water Valves

Water valves are used in systems having water-cooled condensers. ***Water valves*** stop, allow, and regulate the flow of water. In some cases, they can vary the amount of water proportional to the requirement of the system. A water valve is located between the water supply and the condenser. Usually, it is mounted on the condenser base.

Copyright Goodheart-Willcox Co., Inc. 2017

Caution

Water Velocity

Water velocity should be 7 fps–10 fps (2 m/s–3 m/s). If flow is too fast, water may remove the oxide coating, causing pitting. If the water velocity is too slow, scaling can occur.

Water valves are categorized into groups by their operational control:

- Electric.
- Pressure.
- Thermostatic.

Pro Tip

Strainer in Water Inlets

It is good practice to install a strainer in the inlet to a water valve, **Figure 33-47**.

Electric Water Valves

Electric water valves may be either metered or nonmetered. Metered valves open the flow passage slowly with actuator rotation. This is useful when variable flow control is important. Non-metered valves open faster and fully so a large flow area is immediately available. Both types offer the benefit of minimal pressure drop in full flow application. Voltage level used for electric water valves may be low voltage or line voltage.

The bodies of electric water valves are normally brass. They are made with either threaded or soldered connections. Plungers are made of noncorrosive steel. Valve seats are usually made of brass or bronze. A special rubber composition is used for the valve face. The movement of an electric water valve's plunger is done by either a solenoid or motor.

Solenoid Water Valve

A ***solenoid water valve*** is an electric water valve that opens and closes by the operation of a solenoid. Like other water valves, it prevents water flow when the compressor is off and allows water flow when the compressor is on. Solenoid water valve operation is based on compressor operation. The moment the compressor starts, the solenoid water valve opens. When the compressor motor circuit is opened, the solenoid is de-energized, and the solenoid water valve closes. See **Figure 33-48**.

A solenoid water valve is either fully open or fully closed. It does not offer variable flow control, so it cannot open partially. **Figure 33-49** illustrates two typical electric water valve circuits. One uses a low-voltage solenoid valve. The other uses a 120 V solenoid valve. Most valves require 120 V.

A solenoid water valve with larger capacity may have the valve stem loosely connected to the plunger. This permits a shock action to open the valve. Gravity and water pressure close the valve when the power is shut off. Large-volume water flow may also be controlled by motor water valves.

Motor Water Valve

A ***motor water valve*** is an electric water valve that opens and closes by a motor. The inside of a motor-actuated water valve has a screen that may be cleaned or replaced by removing the cap on the bottom of the valve. These valves have capacities varying from 1/2" to 4" pipe size, **Figure 33-50**.

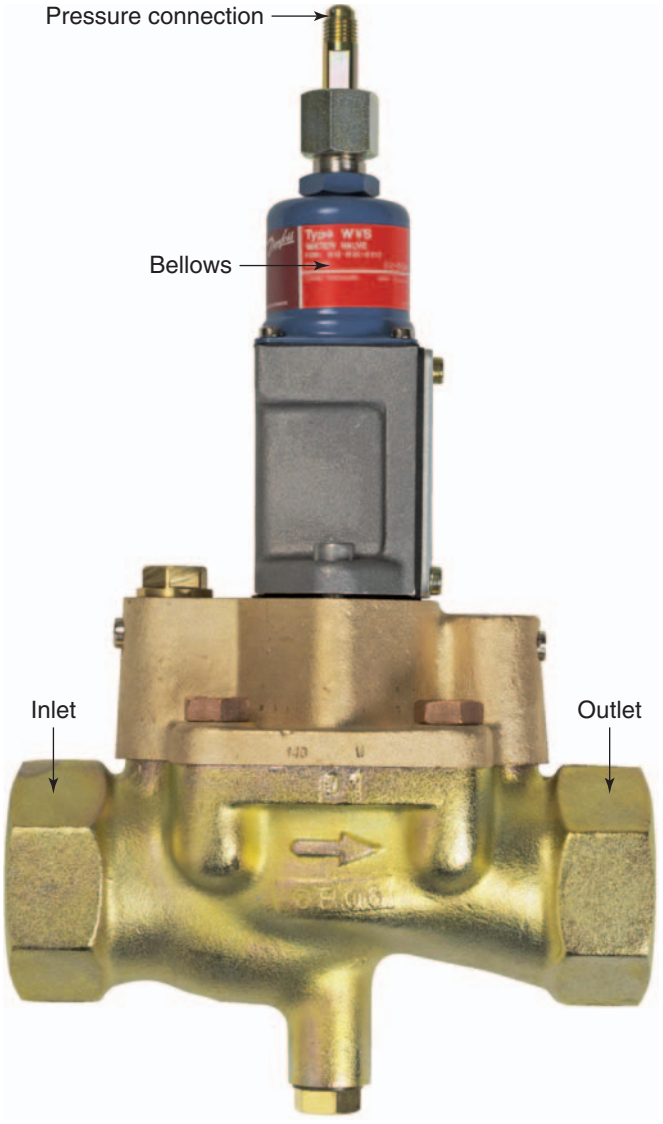
Pressure Water Valves

A ***pressure water valve*** is a water valve that regulates water flow to a water-cooled condenser based on high-side pressure. An advantage of a pressure water valve is that it is able to maintain a constant head pressure. This is because it reacts according to high-side pressure, even when the system is cycled off. A pressure water valve's bellows are attached to high-side pressure, usually at the cylinder head. Pressure water valves are the most widely used water valves, **Figure 33-51**.

Variable control is provided by bellows that sense and react to pressure to control the valves. In other



Danfoss

Figure 33-51. A pressure water valve is connected to the high-pressure side of an HVACR system at the compressor head. The rate of water flow can be varied by adjusting the spring pressure using a screw control on the valve.

Copyright Goodheart-Willcox Co., Inc. 2017

words, the higher the head pressure pushing against the bellows, the more the pressure water valve will open and the more water will flow into the condenser. Instead of just preventing or allowing water flow at full blast, pressure water valves adjust the amount of water allowed to flow, depending on system head pressure.

As high-side pressure rises, the bellows in the water valve contract. Water flows into a condenser to cool and condense a system's high-pressure vapor. Pressure water valves open the water circuit only when cooling is needed, which is sensed when high-side pressure rises. Water flow will continue increasing as long as high-side pressure increases.

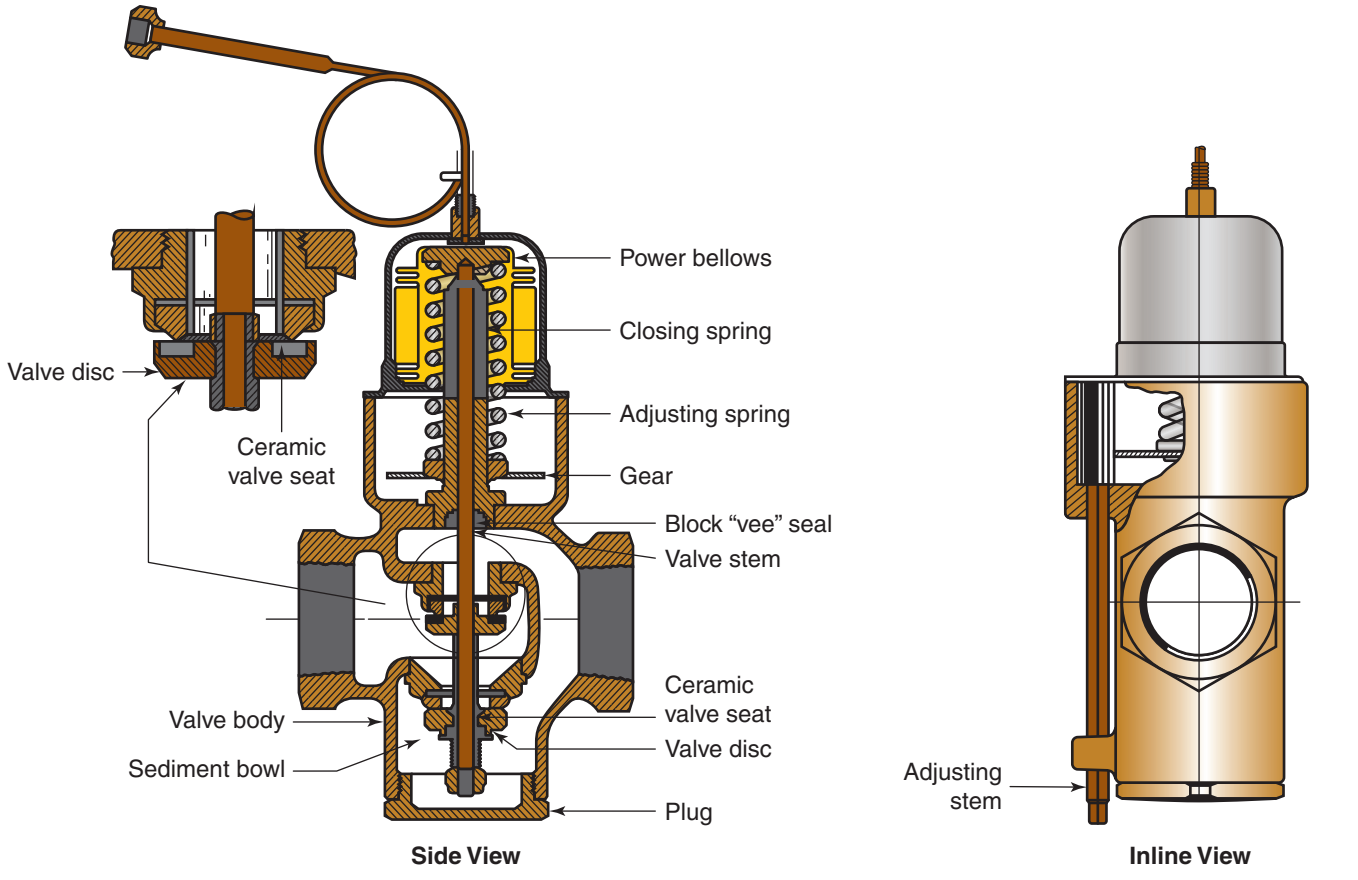
These valves may be adjusted using a heavy spring that presses against the bellows. The valves are set to open at specific head pressures. The pressure depends on the temperature of the water and the refrigerant used. Some pressure-controlled water designs require opening the system to remove the valve. Others may be removed without disturbing the refrigeration system.

The valve face is often made of a hard rubber composition or fiber. The seat is usually made of copper or brass. The valves are equipped with either a packing gland or a bellows. This is located where the water stem goes into the water valve body. The packing must be adjusted occasionally to keep it from leaking.

These valves usually do not depend on the pipe for support. They do, however, have a mounting arrangement or flange. The inlet and the outlet are clearly labeled. Valves are usually threaded for standard pipe connections. Most are constructed so that water pressure tends to keep the valve closed. The valves reduce incoming water pressure for protection of system components and to reduce water consumption. **Figure 33-52** shows a diagram of a large-capacity valve used on 1″ lines. This valve has a gear mechanism for adjusting the pressures.

Thermostatic Water Valves

A ***thermostatic water valve*** is a water valve that regulates water flow to a water-cooled condenser based on the temperature of condenser exhaust water. These valves are similar to pressure water valves except they



Goodheart-Willcox Publisher

Copyright Goodheart-Willcox Co., Inc. 2017

have a thermostatic sensing bulb connected to the bellows operating the valve, **Figure 33-53**.

The sensing bulb is charged with a volatile liquid and mounted in the condenser water line, where it reacts with the heat. Remember that a volatile liquid is one that easily changes into vapor when heat is absorbed. Heat from the condenser water is absorbed by the sensing bulb. The volatile liquid in the sensing bulb vaporizes and expands, pushing against the bellows. In the vaporization of the volatile liquid, heat energy is changed to pressure. As heat is absorbed into the sensing bulb, the pressure rises. This pressure opens the valve when the condenser water becomes warm. As the water cools, pressure is reduced, and the thermostatic water valve closes.

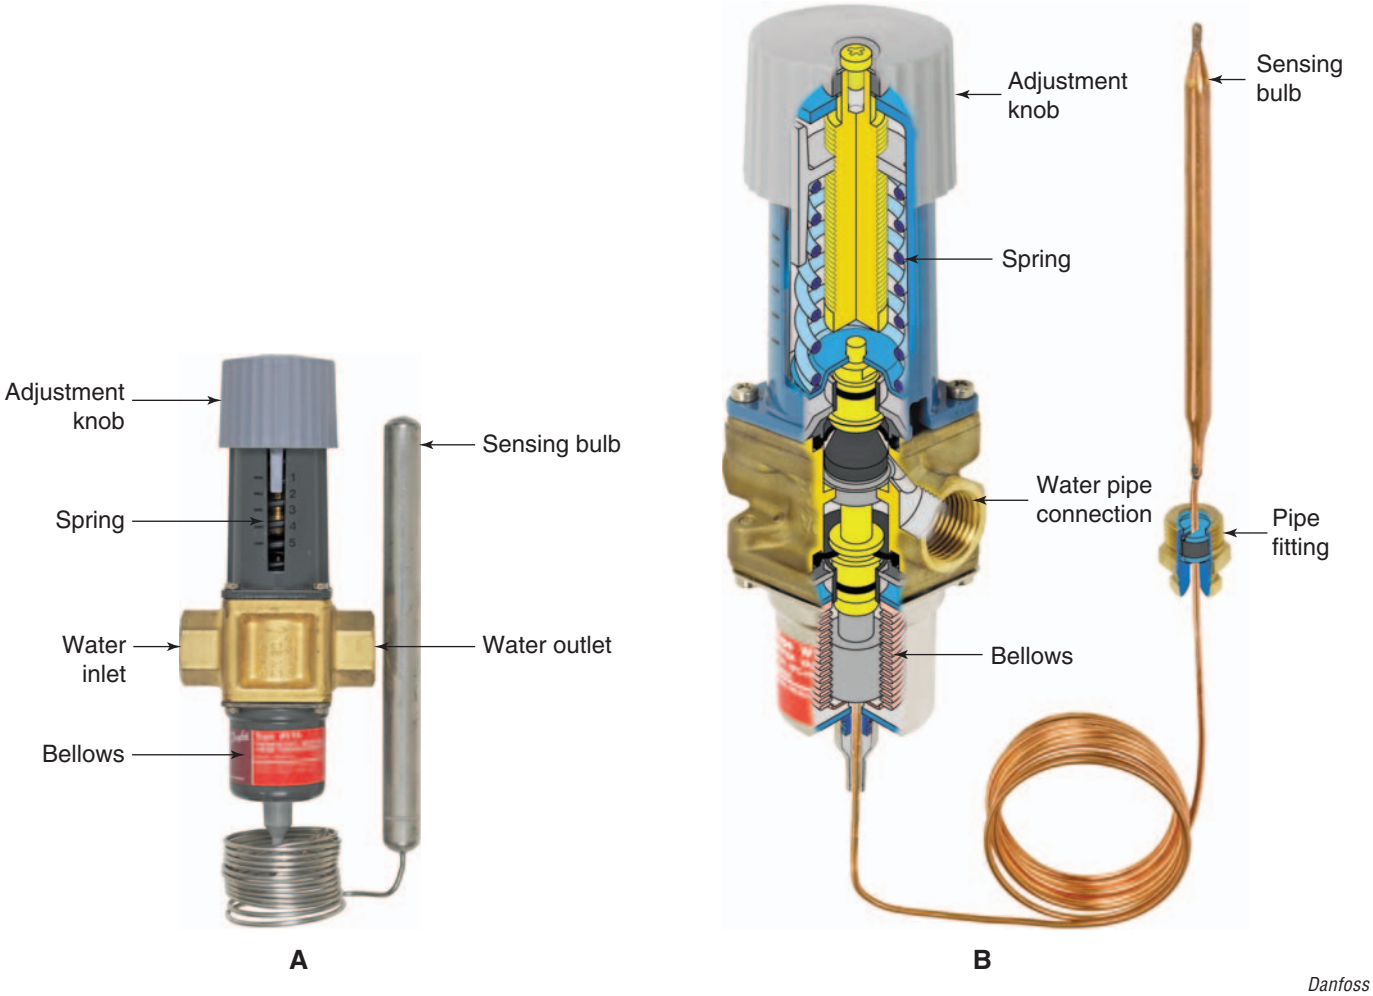

Figure 33-53. Note the sensing bulb and temperature adjustment knob on this thermostatic water valve. A—Thermostatic water valve. B—Cutaway of a thermostatic water valve.

Chapter Review

Summary

- A rooftop unit (RTU) is a packaged air-conditioning system designed specifically to be installed on the roof of a building. Many are designed to provide cooling and heating. Many also have a fresh air inlet to maintain indoor air quality and also an economizer that can provide free cooling when outdoor conditions are right.
- An RTU may provide heat through a gas-fired furnace, an oil-fired furnace, electric heating elements, or by operating as a heat pump. Cooling is provided by its mechanical refrigeration system. Air circulation is provided by a blower with multiple dampers responding to sensors and controls.
- When indoor temperature is warm but outdoor temperature and humidity are low, an RTU's economizer will turn on the blower and also position the dampers to draw in outdoor air for free cooling. Since the compressor does not run during this time, much less electrical power is used for efficient comfort cooling. An outdoor air temperature sensor and an outdoor humidity sensor (enthalpy control) monitor conditions for economizer operation.
- Comfort cooling systems are equipped with multiple controls. Operating controls, such as thermostats, allow the user to adjust conditions in the conditioned space. Motor controls, such as motor starters and starting relays, activate and deactivate the compressor. Limit controls shut down the system or activate an alarm if operating conditions, such as pressure or temperature, exceed safe limits.
- Safety concerns when servicing RTUs include the height of the building, conveying tools and equipment to the roof, and the high winds and weather conditions to which a technician is exposed on a roof.
- Variable refrigerant flow (VRF) systems use multiple indoor cooling units connected to one or more outdoor units. This provides the flexibility of having separately zoned conditioned spaces.
- A chiller is a refrigeration system that uses a mechanical or absorption refrigeration system to cool water, which is then circulated through a building to provide comfort cooling.
- Chillers are classified by their operating pressures: high-pressure or low-pressure. High-pressure compression chillers are used primarily for comfort cooling. Low-pressure chillers are capable of producing very low evaporator temperatures.
- Water circulated through a water-cooled condenser can be cooled and reused through the use of a cooling tower. A cooling tower is a structure that rejects heat from the cooling water of an HVACR system using the evaporation of water.
- Cooling tower water is lost by evaporation, breezes, and blowdown. A float switch refills the sump with makeup water. If a cooling tower must operate in freezing conditions, a basin heater should be used to prevent ice formation. Outdoor piping may require electric heat tracing.
- Water valves control water flow through water-cooled condensers and chillers. Types of water valves include electric, pressure, and thermostatic.

Review Questions

Answer the following questions using the information in this chapter.

1. Which of the following is a trait of a packaged outdoor air-conditioning unit?
   A. The condenser coil is located outdoors, and the evaporator coil and furnace are located indoors.
   B. Rooftop installation is the only location option.
   C. The supply and return ducts pass through the exterior wall of the building.
   D. All of the above.
2. A rooftop unit may provide heat for the indoor climate using the following methods, *except* _____.
   A. electric heating elements
   B. gas-fired furnace
   C. heat pump
   D. solar radiation
3. A rooftop unit can provide "free cooling" if it is equipped with a(n) _____.
   A. cooling tower
   B. economizer
   C. heat pump
   D. variable refrigerant flow

Copyright Goodheart-Willcox Co., Inc. 2017

4. High humidity outdoors can prevent a rooftop unit's free cooling operation when the system has _____ control.
   A. blowdown
   B. enthalpy
   C. purge
   D. VRF
5. In a commercial HVAC system, if the thermostat's switch controls a liquid line solenoid valve, which control usually cycles off the compressor?
   A. Enthalpy control.
   B. High-side pressure control.
   C. Low-side pressure control.
   D. Sequencing control.
6. A pneumatic control system uses _____ for device actuation.
   A. electrical signals
   B. hydraulic fluid
   C. pressurized air
   D. variable refrigerant flow
7. A large RTU is most frequently conveyed to a rooftop using _____.
   A. a crane
   B. on-site assembly
   C. manual rope and pulley system
   D. ramp and rollers
8. A _____ installed between the base rail of a rooftop unit and the top edge of the roof curb prevents water from leaking through the opening.
   A. condensate channel
   B. permeable membrane
   C. resilient gasket
   D. sheet metal drip collector and drain
9. Which of the following is a valid safety precaution for servicing a rooftop unit?
   A. Before working on equipment, secure hinged panels in the open position.
   B. Extend the top of the ladder 3' above the edge of the roof.
   C. Use a rope to lift equipment, tools, and refrigerant cylinders to the roof.
   D. All of the above.
10. VRF in split commercial air-conditioning systems can effectively match cooling capacity by _____.
    A. active air filtration
    B. modulating the flow of refrigerant
    C. opening and closing dampers
    D. passive humidification
11. A chiller system uses a loop of _____ to provide cooling to a conditioned space.
    A. ammonia
    B. cool water
    C. fresh outdoor air
    D. low-pressure refrigerant vapor
12. The secondary refrigerant used in a chiller system _____.
    A. circulates through the conditioned space to provide cooling
    B. circulates through the mechanical refrigerant circuit
    C. precools the primary refrigerant before it enters the condenser
    D. subcools the liquid line
13. Reciprocating compressors are capable of capacity control through _____.
    A. air-side economizers
    B. cylinder unloading
    C. purge unit operation
    D. venting
14. The purpose of a purge unit is to _____.
    B. bypass the compressor when the cut-out temperature is reached
    A. increase the speed at which the system can be evacuated
    C. prevent excessive pressure from building on the high side
    D. remove noncondensables from the system
15. If a chiller system could only use one compressor but needed to provide 2000 tons of cooling capacity, which type of compressor is most likely to be used?
    A. Centrifugal.
    B. Reciprocating.
    C. Screw.
    D. Scroll.
16. A compression chiller economizer improves system efficiency by _____.
    A. modulating refrigerant flow to match cooling capacity
    B. providing free cooling from cool outdoor air
    C. removing noncondensables from the system
    D. subcooling high-side refrigerant

Copyright Goodheart-Willcox Co., Inc. 2017

17. The purpose of a cooling tower connected to an HVAC system is to _____.
    A. cool refrigerant before it is circulated through the conditioned space
    B. cool condenser water
    C. condense refrigerant before it enters the evaporator
    D. None of the above.
18. Basin heaters are used to prevent _____.
    A. chiller freeze-over
    B. ice formation in a cooling tower sump
    C. icing over of RTU evaporators
    D. All of the above.
19. All of the following water valves provide variable water flow control, *except* _____.
    A. pressure water valves
    B. solenoid water valves
    C. thermostatic water valves
    D. All of the above.
20. The operation of a pressure water valve is in reaction to _____.
    A. condenser exhaust water
    B. evaporator temperature
    C. high-side pressure
    D. low-side pressure

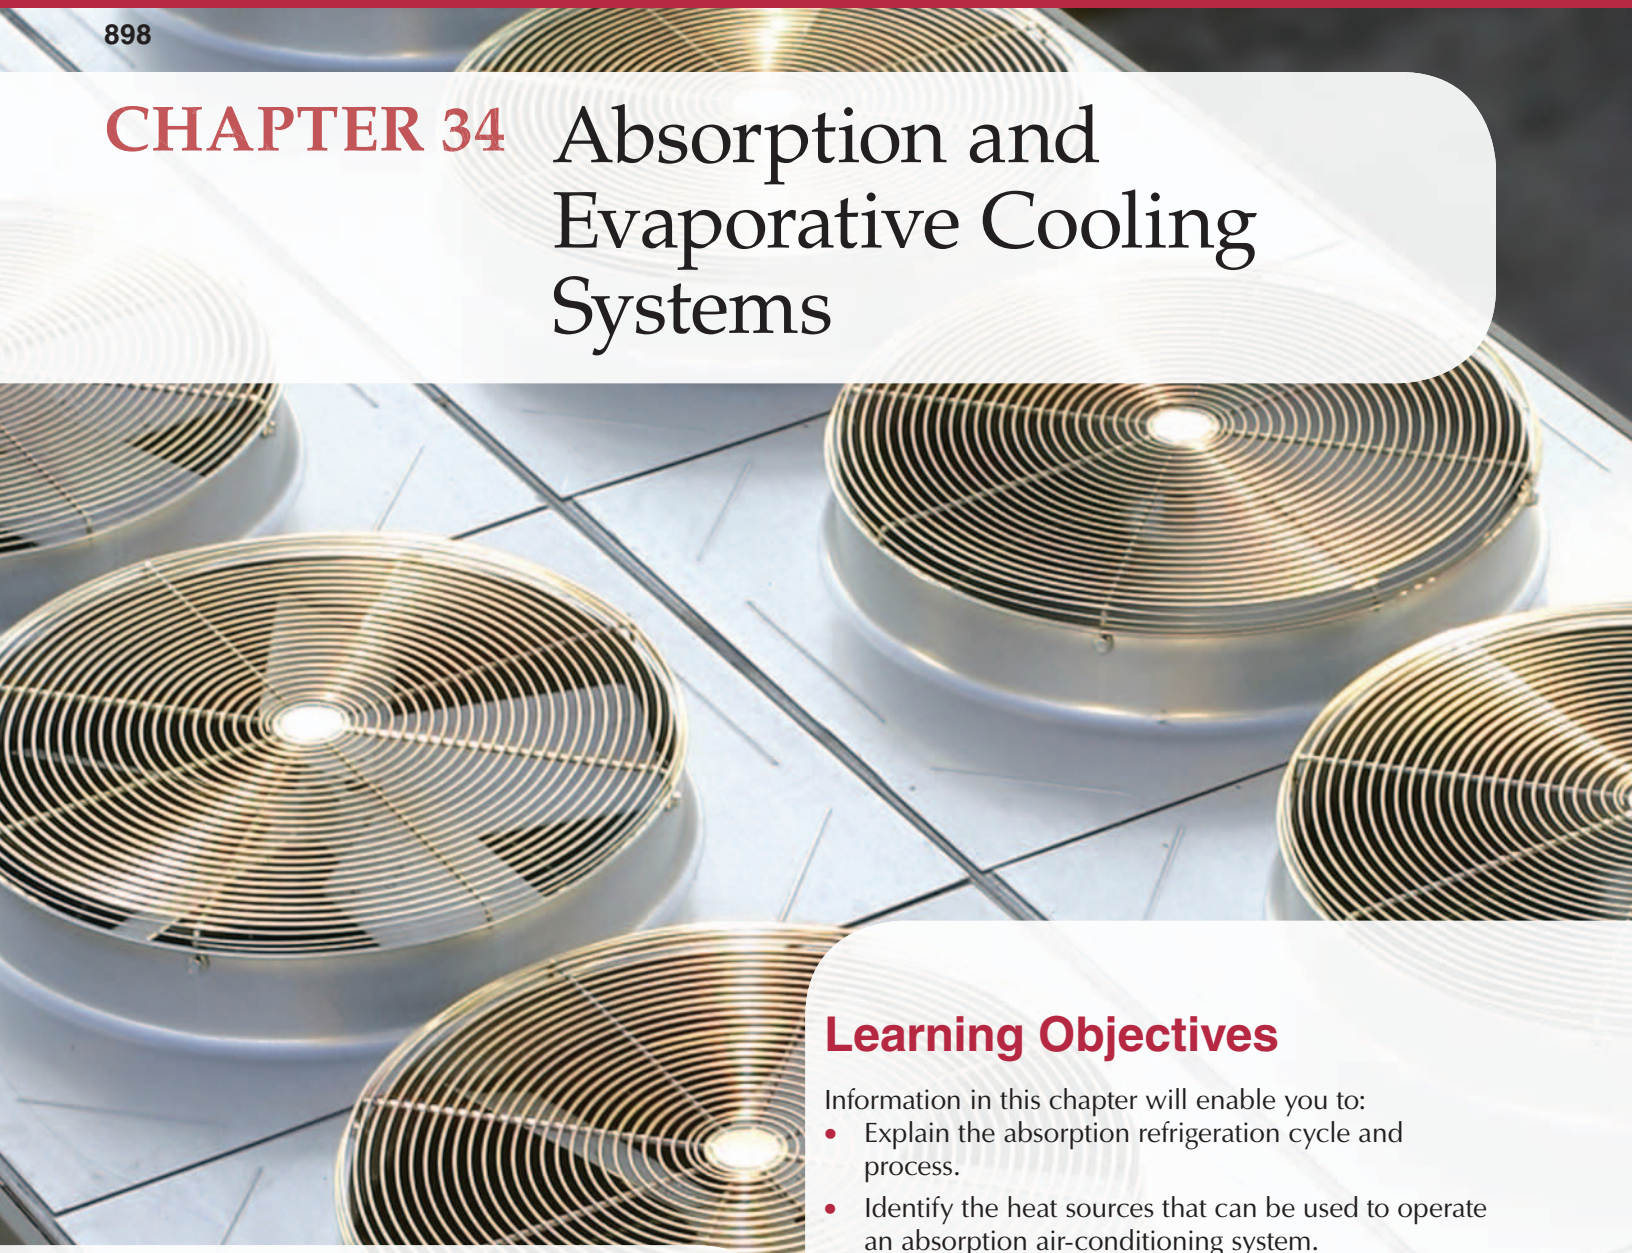
CHAPTER 34 Absorption and Evaporative Cooling Systems



Learning Objectives

Information in this chapter will enable you to:

- Explain the absorption refrigeration cycle and process.
- Identify the heat sources that can be used to operate an absorption air-conditioning system.
- Summarize the operation of residential and commercial absorption chillers.
- Compare direct-fired and indirect fired absorption systems.
- Understand the difference between single-effect and double-effect absorption chillers.
- Explain the differences in operation between ammonia and lithium bromide absorption systems.
- Understand how multiple absorption units can be combined in a multiple unit load system.
- Summarize the energy efficiency advantages of an absorption air-conditioning system.
- Explain the basic concepts behind evaporative cooling.
- Understand how a roof pond works.
- Summarize the function of a roof mist cooling system.
- Summarize the steps involved in absorption cooling system service.

Chapter Outline

34.1 Absorption Refrigeration Systems
34.1.1 Absorbants and Refrigerants
34.1.2 Basic Absorption Refrigeration Cycle
34.1.3 Types of Absorption Systems
34.2 Absorption Cooling Systems
34.2.1 Residential Absorption Chiller Air-Conditioning Systems
34.2.2 Commercial Absorption Systems and Chillers
34.3 Absorption System Service
34.3.1 Servicing Ammonia-Based Absorption Systems
34.3.2 Servicing Lithium Bromide–Based Absorption Systems
34.4 Evaporative Cooling
34.4.1 Indoor Applications
34.4.2 Wet Roof Cooling

Review of Key Concepts

Reviewing these concepts from earlier chapters will help you understand new concepts presented in this chapter:

- The temperature at which a substance changes its state depends on the pressure acting on the substance. The higher the pressure is, the higher the temperature needed to bring about a state change. (Chapter 5)
- Heat transfer is accomplished in refrigeration systems by a refrigerant changing phase between vapor and liquid. As a refrigerant evaporates, it absorbs heat. As it condenses, it releases heat. (Chapter 6)
- The four processes that make up a compression refrigeration system are compressing, condensing, metering, and evaporating. A compression refrigeration system uses mechanical energy to drive the refrigeration process. (Chapter 6)
- Chilled water systems, which are commonly referred to as chillers, are refrigeration systems that cool water, which is then circulated through the building to provide cooling. (Chapter 33)

Introduction

The comfort cooling systems described previously in the book have been based on the familiar compression refrigeration system. In this chapter, you will be introduced to two additional methods of cooling a space. These methods are absorption cooling and evaporative cooling.

10

Copyright Goodheart-Willcox Co., Inc. 2017

34.1 Absorption Refrigeration Systems

Compression refrigeration systems use the mechanical energy of compression to achieve the pressure levels needed for refrigeration. Absorption refrigeration systems use heat energy instead of mechanical energy to achieve refrigeration. Absorption refrigeration systems use heat to change low-temperature, low-pressure vapor into high-pressure vapor.

34.1.1 Absorbants and Refrigerants

In order to accomplish temperature and pressure manipulation, absorption systems use chemicals with specific characteristics. Substances with the right properties can be used as refrigerants and absorbants. A refrigerant is a substance that transfers heat from a conditioned space to an unconditioned space. An ***absorbant*** is a substance that soaks up, or absorbs, a refrigerant and lowers their combined pressure.

Different combinations of substances can be used as an absorbant and refrigerant pair, depending on how the substances interact. If one of the substances tends to absorb the other, it is said to have an ***affinity*** for the other substance. Substances used as absorbants must have an affinity for the substance used as the refrigerant. The absorbant will absorb the refrigerant when cool and release it when heated.

In absorption chillers, the refrigerant is typically water and the absorbant is often a form of sodium. In some systems however, the refrigerant is ammonia and water is the absorbant. As described here, water acts as a refrigerant in one system and as an absorbant in another. The way the substances react to each other determines their use as a refrigerant or absorbant in a given absorption system.

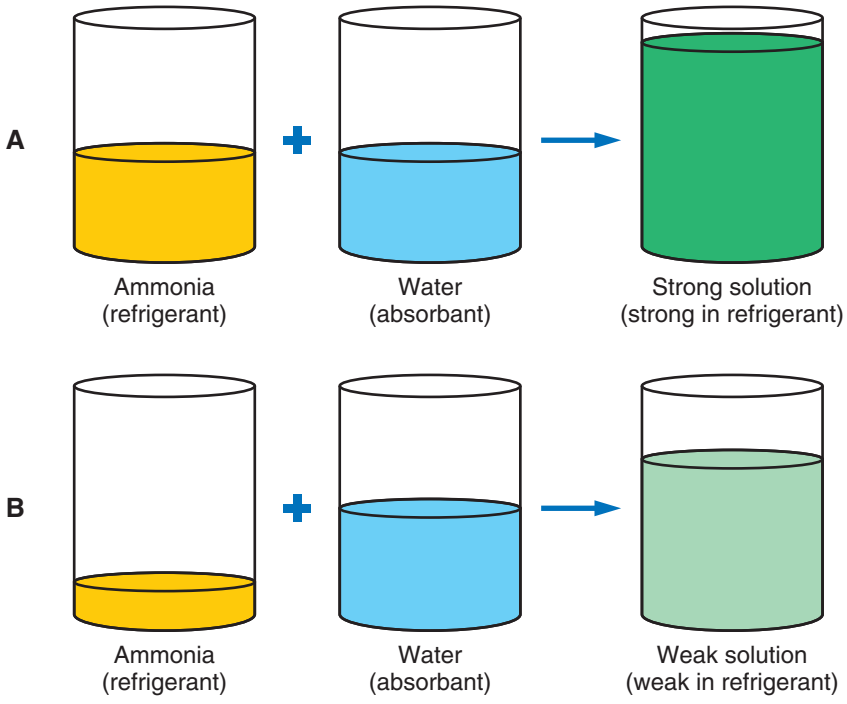
When the absorbant becomes saturated with the refrigerant, it is called a ***strong solution***. When the mixture is not fully saturated, it is referred to as a ***weak solution***. A strong solution contains as much refrigerant as possible. A weak solution contains less refrigerant than a strong solution and is capable of absorbing additional refrigerant.

Pro Tip

Terminology

The terms *strong solution* and *weak solution* can have different meanings in different publications. When these terms are used, it is important to understand whether the term is referring to the ratio of refrigerant to absorbant or referring to the ratio of chemical (lithium bromide or ammonia) to water. In this book, the terms will always refer to the ratio of refrigerant to absorbant.

Figure 34-1 illustrates the difference between a weak and a strong solution. Water has an affinity for ammonia vapor; therefore, water acts as an absorbant.



Goodheart-Willcox Publisher

Figure 34-1. Comparison of a weak solution and a strong solution. A—The water absorbs a large amount of ammonia and becomes saturated, creating a strong solution. B—The water absorbs a small amount of ammonia and has a weak concentration of ammonia.

Copyright Goodheart-Willcox Co., Inc. 2017

In **Figure 34-1A**, water mixes with ammonia until it becomes saturated, creating a strong solution. It no longer has the ability to absorb more ammonia. In **Figure 34-1B**, a smaller amount of ammonia is mixed with water and the solution has the ability to absorb additional ammonia. It is a weak solution.

Pro Tip

Adsorption and Absorption

When a solid attracts and holds another substance on its outer surfaces, the process is called *adsorption*. When one substance attracts and combines with another substance to form a uniform solution, the process is called ***absorption***.

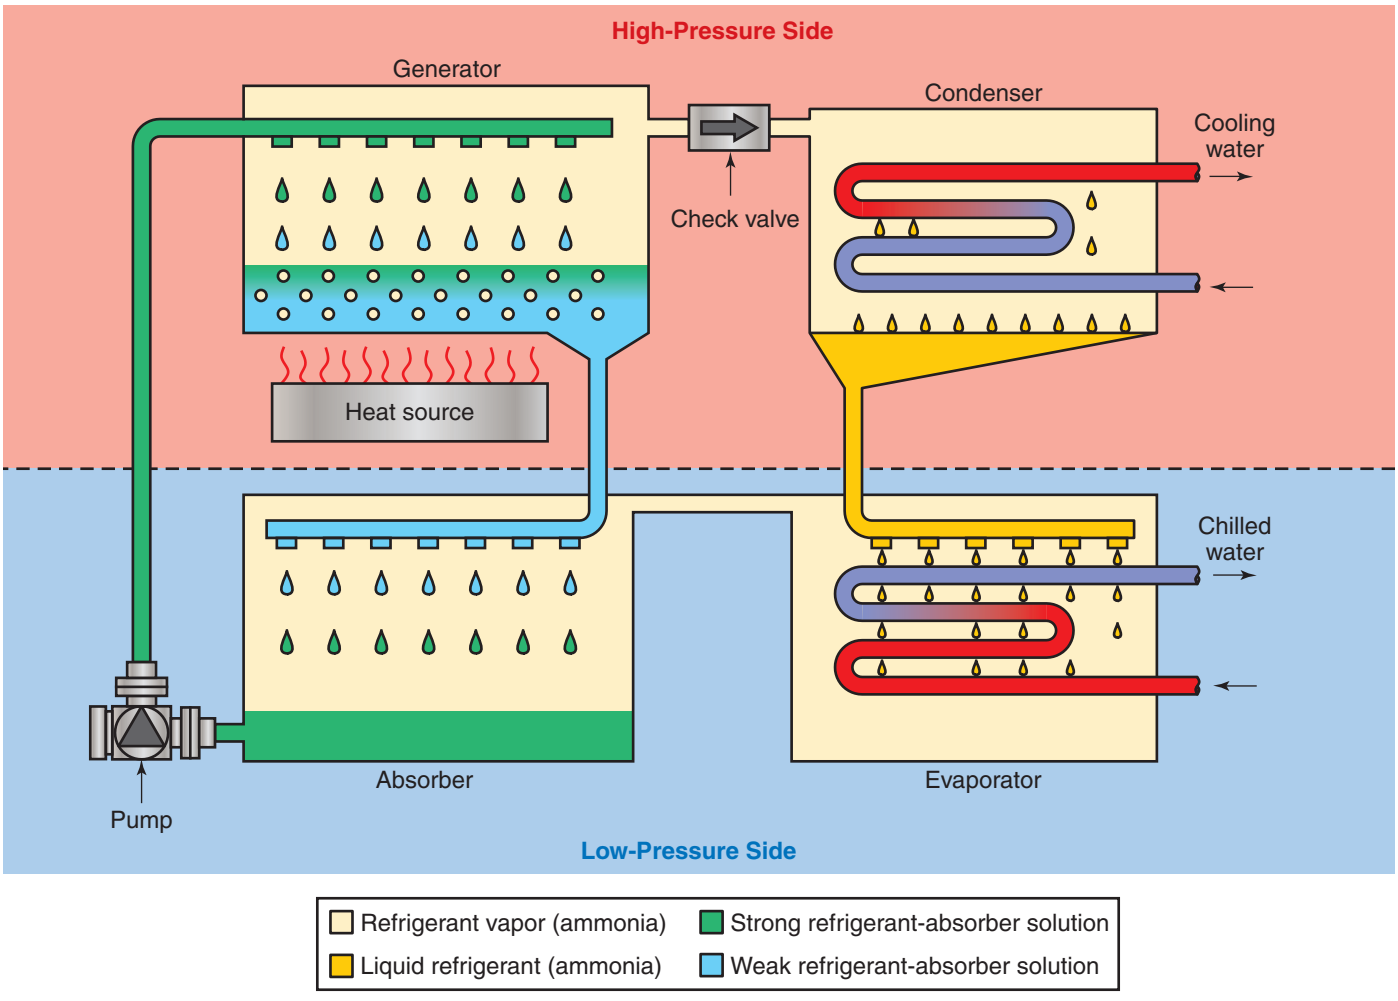
34.1.2 Basic Absorption Refrigeration Cycle

Absorption systems have some similarities to compression systems, but also some significant differences. The system can be divided into four sections including generator, condenser, evaporator, and absorber. A basic absorption refrigeration system is shown in **Figure 34-2**.

In an absorption system, the evaporator and condenser perform essentially the same functions they perform in a compression system. However, a compression system uses a compressor to change a low-pressure vapor into a high-pressure vapor. In an absorption system, the function of the compressor is performed by the following components:

- Generator (heater)—heats the refrigerant, raising its pressure.
- Absorber—combines refrigerant vapor from the solution, lowering its pressure.
- Pump—circulates the refrigerant from the absorber to the generator.

An absorption system operates under two pressures. The high-pressure side, consisting of the generator and condenser, operates at a pressure of 200 psig to 300 psig (1400 kPa to 2100 kPa). The low-pressure side, consisting of the absorber and evaporator, operates at



Goodheart-Willcox Publisher

Figure 34-2. Simple absorption refrigeration system.

Copyright Goodheart-Willcox Co., Inc. 2017

40 psig to 60 psig (275 kPa to 410 kPa). The high and low sides are separated by check valves, liquid traps, a pump, or other controlling devices.

The generator is warmed by a heat source. The heat causes refrigerant to boil out of the refrigerant-absorbant solution. The refrigerant vapor rises to the top of the generator and then flows to the condenser. At the same time, some of the solution at the bottom of the generator passes through an orifice and then flows to the absorber. The orifice reduces the pressure on the solution, which lowers its temperature. As a result, the solution flowing into the absorber is once again able to absorb refrigerant.

Meanwhile, in the condenser, heat is removed from the refrigerant vapor by the cooling medium (water or air). This causes the refrigerant vapor to condense into a liquid. The high pressure in the condenser drives the liquid refrigerant into the evaporator through an orifice.

Water tubes pass through the evaporator. The water flowing through these tubes absorbs heat from the conditioned space and carries it to the evaporator. In the evaporator, heat from the water in these tubes is absorbed by the liquid refrigerant. This lowers the temperature of the water in the tubes. The chilled water is recirculated to the conditioned space. Since the water is at a lower temperature than the air in the conditioned space, it is able to absorb additional heat from the space.

The heat that the liquid refrigerant in the evaporator absorbs from the chilled water circuit causes the refrigerant to boil into a vapor. The refrigerant vapor is drawn back to the absorber and is cooled by the flow of weak solution coming from the generator. In the absorber, the heat in the refrigerant vapor is transferred to the surface of the absorber and then to the outside air, causing the refrigerant vapor to condense. The strong solution that is formed at the bottom of the absorber is pumped back to the generator by the solution pump. There, the process is repeated.

34.1.3 Types of Absorption Systems

Chillers are a primary application of absorption refrigeration systems. Absorption chillers use the heat energy of a flame or heating element to complete the refrigeration cycle. These chillers are used for air conditioning or for industrial process cooling. Absorption systems are also used in industrial refrigeration and air conditioning and domestic and recreational vehicle refrigeration.

Absorption systems are generally classified by their operation cycle:

- Intermittent systems.
- Continuous-cycle systems.

Intermittent Absorption System

As their name implies, ***intermittent absorption systems*** are absorption systems that operate intermittently. Often, one charge of fuel will operate the generator for a short period of time that will run the system for about one day. After their cycle of operation ends, they need to be recharged with fuel. The use of intermittent absorption systems is usually limited to places where other adequate, consistent sources of power are unavailable.

Continuous-Cycle Absorption System

A ***continuous-cycle absorption system*** is operated by the application of a limited amount of heat. This heat is furnished by gas, electricity, or kerosene. Continuous-cycle absorption systems are often used in domestic refrigerators in recreation vehicles and in year-round air conditioning of both homes and larger buildings.

34.2 Absorption Cooling Systems

The number of absorption air-conditioning systems used in residential and commercial buildings has increased. The refrigerants most commonly used in these absorption systems are ammonia and water. In most systems, ammonia is the refrigerant and water is the absorbant. Large commercial chiller systems may use water as the refrigerant and lithium bromide as the absorbant.

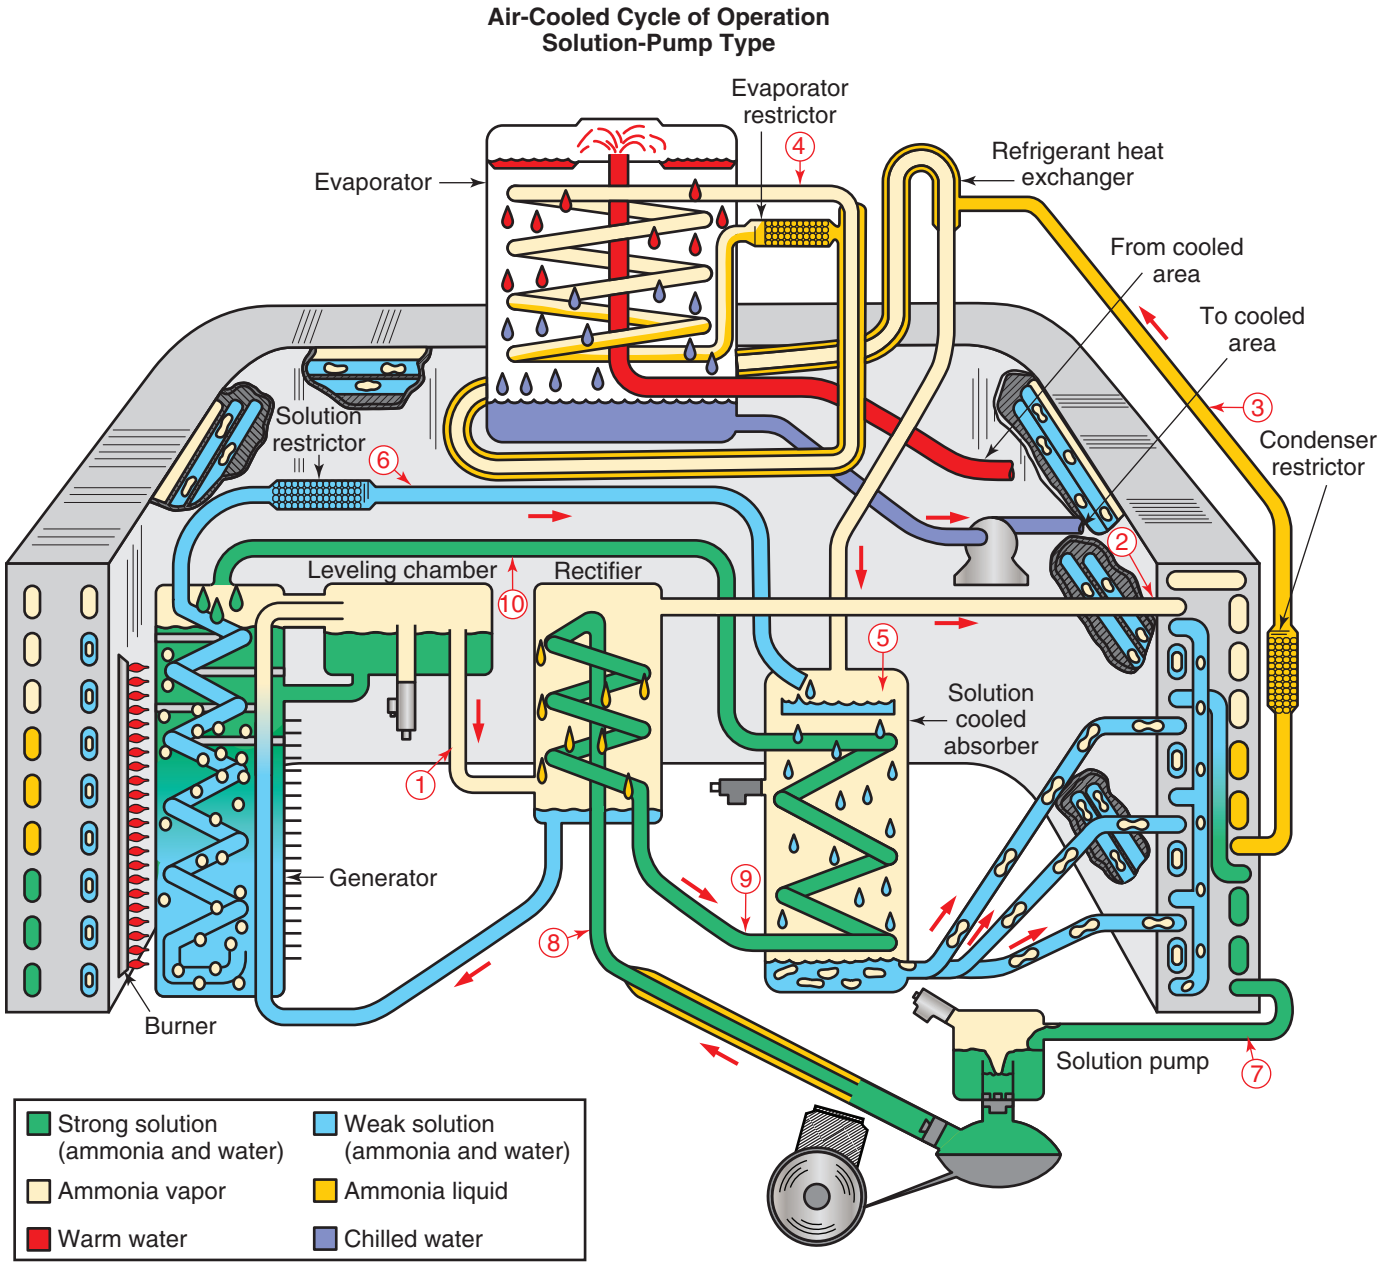
An absorption system may use any number of heat sources. These include natural gas, LP (liquefied petroleum) gas, kerosene, steam, or electricity (resistance heating). Absorption systems have few moving parts. Small systems have moving parts only in the heat source valves and controls. Some larger systems also have circulating pumps and fans.

34.2.1 Residential Absorption Chiller Air-Conditioning Systems

A typical residential absorption chiller air-conditioning system is shown in **Figure 34-3**. The generator has a gas burner that heats a mixture of ammonia and water. The boiling point of ammonia is lower than that of water. Therefore, the ammonia evaporates and flows through the line marked 1. As the ammonia vapor passes through the rectifier, some of it condenses and is returned to the generator. The remaining ammonia vapor passes to the condenser, marked 2, as a high-temperature, high-pressure gas.

As outside air passes over the condenser, it removes heat from the ammonia. The ammonia condenses to a liquid and passes through the line marked 3, to the

Copyright Goodheart-Willcox Co., Inc. 2017



Robur Corporation

Figure 34-3. Refrigeration cycle of a typical residential absorption system. This absorption chiller uses a pump to circulate the solution through the cycle.

refrigerant heat exchanger, also known as a precooler. The heat exchanger reduces the temperature of the liquid ammonia before the ammonia reaches the evaporator. It also heats the cold ammonia vapor leaving the evaporator through line 4.

Pressure drops as liquid ammonia leaving the heat exchanger passes through the evaporator restrictor into the evaporator. Here, it picks up heat from the chilled water circuit and boils to ammonia vapor. Ammonia vapor in line 4 passes through the heat exchanger, where it absorbs heat from the refrigerant coming out of the condenser. After passing through the heat exchanger, the ammonia vapor passes to the solution-cooled absorber, marked 5. In the generator, most of the ammonia boils out, leaving a solution with a weak concentration of ammonia. This solution leaves the generator at a high pressure. It passes through a restrictor in line 6, which meters the flow and separates the high- and low- pressure sides of the system.

The weak solution passes from line 6 into the absorber. Here, the solution temperature is lowered by

Copyright Goodheart-Willcox Co., Inc. 2017

transferring heat to the ammonia vapor in the absorber. The weak solution absorbs the low-pressure ammonia vapor coming from the evaporator, increasing the concentration of ammonia in the solution at the bottom of the absorber.

The solution travels from the absorber, through the condenser, where it loses some of its heat. As the solution cools, its ability to absorb additional ammonia is decreased, so it becomes a strong solution. The strong solution leaves the condenser and is carried to the solution pump through line 7. The pump forces it at a high pressure to the rectifier through line 8. The strong solution absorbs some heat from the ammonia vapor in the rectifier. The strong solution then flows to the absorber through line 9, where it absorbs additional heat. This preheated solution returns through line 10 to the generator. The cycle begins all over again. The same action occurs in larger units except that two burners may be used.

Residential Absorption Air Conditioner Construction

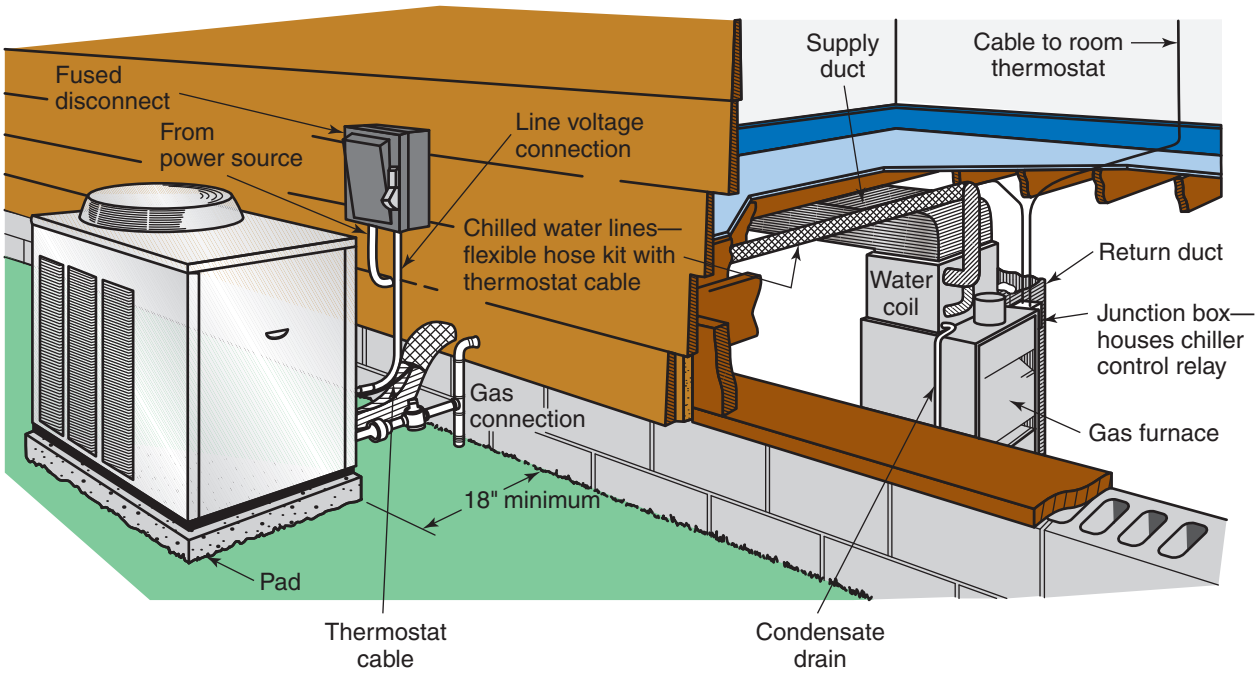
A typical residential gas-fired absorption chiller is shown in **Figure 34-4**. The unit is installed on a concrete pad. On the surface, the installation appears similar to that of a typical compression-type central air-conditioning system. However, the supply and return water lines are flexible hoses that are both covered with hose insulation. The hoses are secured with stainless steel clamps to prevent sound transmission. A water-type cooling coil is installed in the air handler of the forced-air system. If the coil is located in a system that heats during the cold season using a furnace, plastic piping should not be attached directly to the coil. Copper piping extensions should be used to connect the supply and return hoses to the coil. The condensate drain lines must also be insulated.

Code Alert

Absorption System Piping

All piping for gas lines and chilled water circuits must comply with local building codes.

The burner operation of absorption systems is similar to that of a residential gas-fired furnace. The same controls and gas valves are used as in a normal furnace. The burner of the absorption system is generally much smaller than that of a whole house residential furnace. A control transformer applies the power for the control circuit. The circuit includes a gas valve, direct-spark igniter, and time delay switch for both heating and cooling. An electromagnetic ignition system provides a direct-spark ignition to the main burner. It has a ten-second flame detection system.



Robur Corporation

Figure 34-4. Residential absorption chiller combined with a typical forced-air furnace. Note the various insulated lines running between the cooling system and the furnace.

Copyright Goodheart-Willcox Co., Inc. 2017

Residential absorption chillers are equipped with a solid-state time delay. The delay prevents the circulation of refrigeration solution and chilled water until the generator is up to operating temperature. The delay also continues the circulation of solution and water after the thermostat has been satisfied, until the generator has had time to cool down.

The basic system also has numerous safety controls. These include flame detectors, chilled water switches, and heating-side operating controls. These are in addition to basic safety controls, such as high-temperature limits and fused disconnects.

The capacity of air-cooled chillers varies with ambient air temperature and the temperature of the chilled water. A decrease in the temperature of the chilled water leaving the system or an increase in the temperature of the air used to cool the condenser results in a decrease in the overall capacity of the system. The capacity of a system is directly proportional to the temperature of the chilled water leaving the system and inversely proportional to the temperature of the air entering the condenser. **Figure 34-5** shows the relationship between chilled water temperature, condenser temperature, and system capacity for typical models of residential absorption chillers.

An absorption system may have several chilled water coils at different locations throughout a building. The absorption unit produces chilled water, which is then distributed to various fan coils. In this application, the low pressure and temperature of the chilled water system allows the use of PVC piping for the chilled water distribution circuit. The gas-fired absorption units used in such an arrangement operate on single-phase power, 115 V or 230 V. Individual units range from 3 tons to 25 tons.

Safety Note

Absorption System Materials

These internal components of an absorption system are made of steel and aluminum. Use of copper or copper alloys is very dangerous, as it may not be able to handle the corrosive nature of the solution and high pressures. Use of copper pipe or components must be strictly limited to the chilled water circuit. Use of copper materials in any part of the system that circulates refrigerant-absorbant solution could result in an explosion.

Absorption Heat Pumps

Absorption systems can be designed to provide hot water for heating in addition to providing chilled water for cooling. Such systems are equipped with a change-over valve which alters the flow of refrigerant through the system. See **Figure 34-6**.

In cooling mode, the system works as previously described. The generator separates the refrigerant vapor from a strong solution. The refrigerant vapor is condensed in the condenser and then metered into the evaporator. In the evaporator, the refrigerant vaporizes and absorbs heat from the chilled water circuit. The refrigerant vapor is reabsorbed by the weak solution in the absorber. The solution is then pumped back to the generator to repeat the cycle.

In the heating mode, the change-over valve is opened, and the flow of cooling water to the condenser and absorber is shut off. As the generator is

heated, refrigerant vapor fills the system. At the same time, weak solution from the generator flows into the evaporator through the change-over valve. Relatively cool water is passed through the coil in the evaporator. The water in the coil absorbs heat from the hot, high-pressure refrigerant vapor in the evaporator, causing the refrigerant to condense. The condensed refrigerant mixes with the solution at the bottom of the evaporator. The solution is then pumped back to the generator to repeat the process. Since the flow of cooling medium is shut off in the heating mode, no condensation takes place in the condenser or absorber. All the heat is absorbed in the evaporator by the cool water in the coil.

34.2.2 Commercial Absorption Systems and Chillers

Absorption systems are sometimes used for commercial air conditioning. **Figure 34-7** shows an air-cooled absorption unit designed to cool a small commercial building.

Some commercial absorption systems are ***direct-fired***, meaning that they are directly heated by a burner or other heating element. Other commercial absorption systems are ***indirect-fired***, meaning that the heat that powers the system is produced somewhere outside the absorption system and then delivered to the absorption system, such as piped-in steam, hot water, or hot gas. If an absorption system uses waste heat from another industrial process, it is an indirect-fired system. See **Figure 34-8**.

Absorption systems can be further classified as single-effect or double-effect systems. A ***single-effect absorption system*** is a design in which all of the heat released in the condensation of the refrigerant is transferred to the cooling water and then dissipated to the atmosphere in the cooling tower. This type of system has a relatively low operating efficiency, but requires less heat energy to function.

A ***double-effect absorption system*** uses a secondary, smaller, low-temperature generator to recover some of the waste heat from the primary generator. See **Figure 34-9**. A double effect system requires more heat input to operate, but a higher percentage of the heat input to the system is converted to cooling action. The result is a higher operating efficiency than that achieved by a single-effect absorption system. Double-effect absorption systems may use waste heat from industrial operations or solar heat for the secondary generator heat source.

Ammonia Systems

Ammonia absorption systems for commercial applications are very similar in operation to the absorption systems used in residential applications. The primary function of these systems is to produce chilled water. The chilled water, in turn, may be used for various purposes. It may be used for quenching baths in an industrial process or for chilling drinking water. It may also serve as a special coolant to lower the working temperature of welding tips.

Ammonia is typically used as the absorbant in single-effect absorption chillers, but may also be used in double-effect chillers. A double-effect ammonia absorption chiller system capable of both chilling and heating water is shown in **Figure 34-10**. The cooling cycle for this type of chiller system is shown in **Figure 34-10A**.

The refrigerant that is dispersed in the evaporator extracts the heat from the cooling water. As the heat is absorbed, the refrigerant vaporizes and the water in the chilled water coil is cooled. The chilled water is

then recirculated through the conditioned space. The refrigerant vapor is reabsorbed by the solution in the absorber. The solution is returned to the generator to repeat the process.

The heating cycle is shown in **Figure 34-10B**. During the heating cycle, the evaporator functions as a condenser. Hot water in the evaporator tubes absorbs the heat given off during condensation of the refrigerant. The heated water is then recirculated through the conditioned space.

Thinking Green

Use of Waste Heat

Although a direct-fire burner is shown in **Figure 34-10**, the heat for generation could also be supplied by waste heat from another industrial or residential system. Use of waste heat in the absorption system generator greatly increases the building's overall energy efficiency.

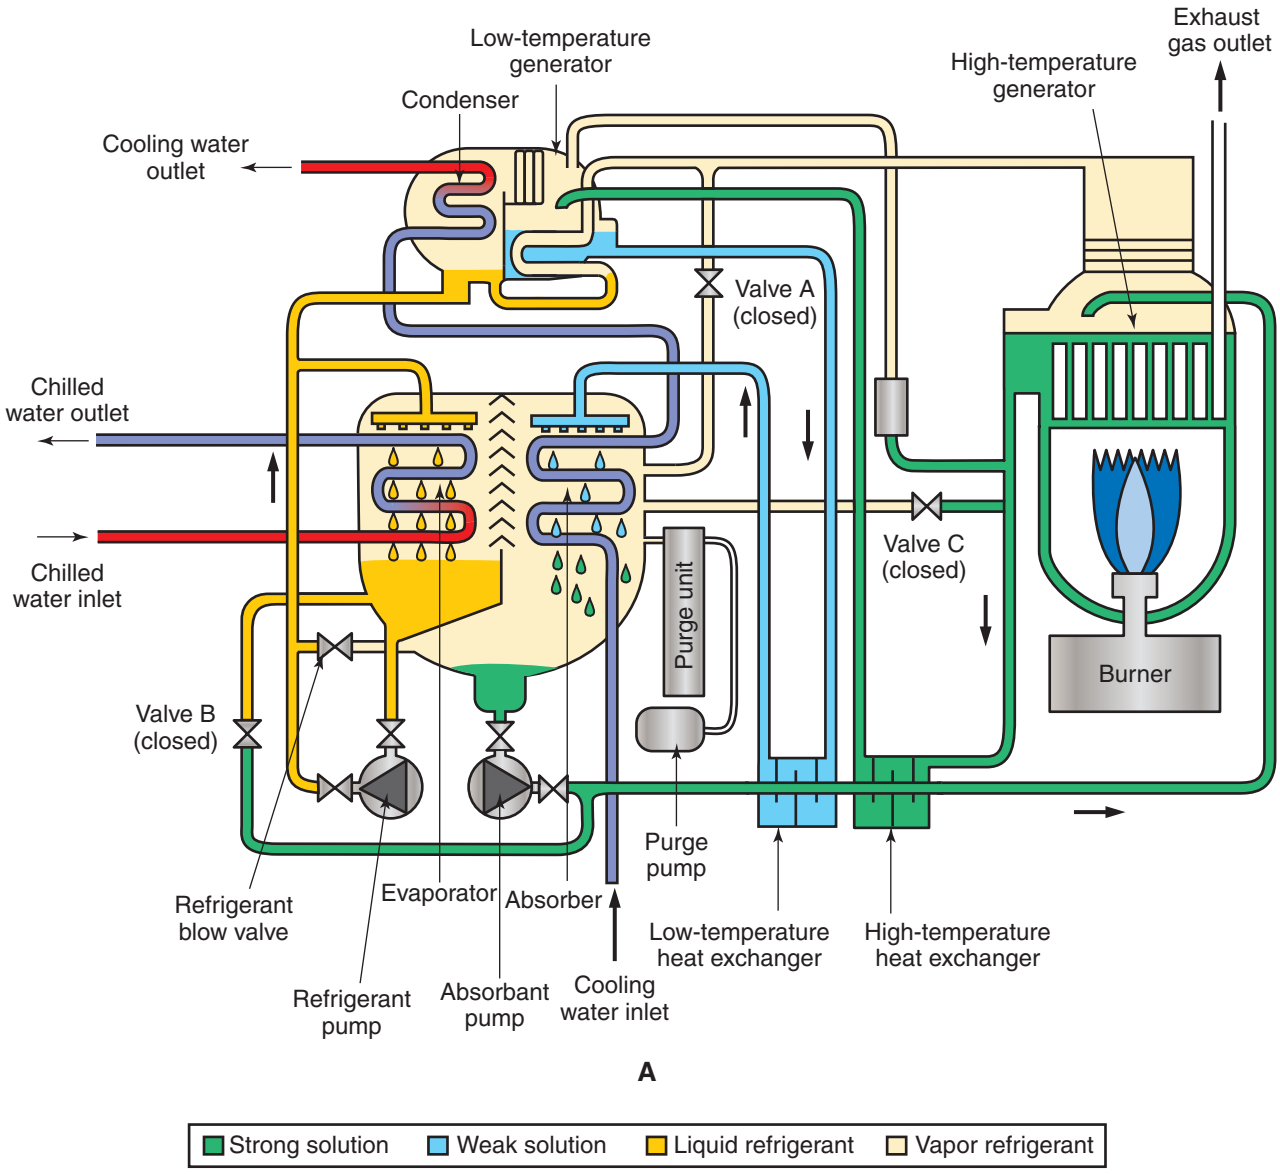
Lithium Bromide Systems

Lithium bromide absorption chillers use water as the refrigerant and lithium bromide (LiBr) as the absorbant. Hydraulic diaphragm pulse pumps or electric motor–driven pumps are frequently used to transfer the solution to various parts of the system. These systems are often used in large-scale industrial and commercial applications to provide comfort cooling and cooling for various industrial processes.

As with all absorption systems, heat energy rather than mechanical energy is input into the system to produce the refrigeration effect. A heater or generator is used in place of a compressor. Lithium bromide chillers operate continuously on low power. The absorbant, lithium bromide, is able to absorb large quantities of water vapor.

The basic design of a lithium bromide absorption chiller consists of an upper shell and a lower shell. The upper shell contains the generator and condenser. The

Copyright Goodheart-Willcox Co., Inc. 2017



Goodheart-Willcox Publisher

Figure 34-10. Schematic diagrams of an ammonia absorption system. A—Cooling cycle. B—Heating cycle.

lower shell contains the absorber and the evaporator. See **Figure 34-11**.

Steam inside the generator tubing bundle boils the solution. The heat from the steam causes the water (refrigerant) to boil out of the solution, weakening the solution. This weak solution returns to the absorber via the heat exchanger. Water vapor released from the solution in the generator travels to the condenser. There, it condenses on the cooling tubes, and returns to the evaporator.

The absorber and evaporator are housed together and operate at the same temperature and pressure. The absorber contains a solution with a high concentration of lithium bromide (weak solution). The evaporator contains water.

A pump circulates the water in the evaporator through an evaporator spray head. The water is sprayed inside the evaporator over the chilled water coil. The chilled water coil is a closed loop that delivers chilled water to the conditioned space that needs to be cooled. The water in the chilled water coil is flash-cooled by the water vaporizing on the outside of the coil. Water vapor from the evaporator flows to the absorber, where it is absorbed by the concentrated lithium bromide (weak) solution. The absorber has a pump to circulate the lithium bromide solution through a spray head, increasing water vapor absorption. As the water vapor is absorbed, the pressure on the remaining water in the evaporator is reduced. This reduced pressure makes it

Copyright Goodheart-Willcox Co., Inc. 2017

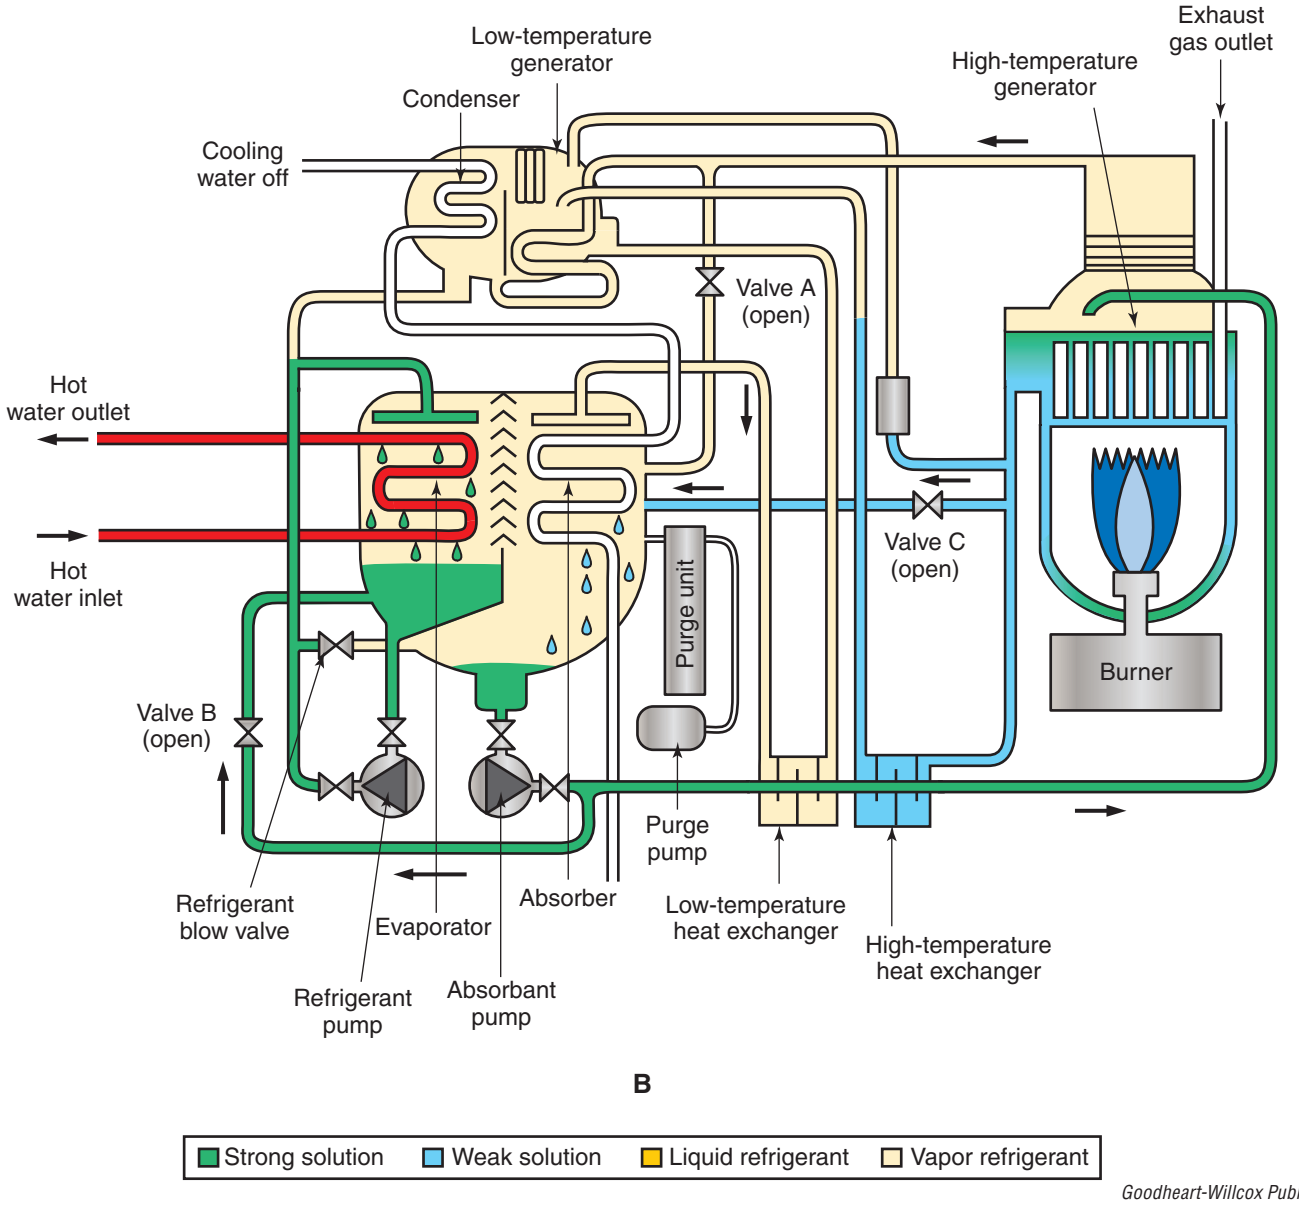


Figure 34-10. (Continued)

easier for the water in the evaporator to boil, generating additional vapor. The generator pump moves the solution from the absorber, pumping it through the heat exchanger and back into the generator.

Figure 34-12 provides a more detailed view of the operation of such a system. Steam or hot water heats the water and lithium bromide solution in the generator. The water turns to water vapor and boils out of the solution. The water vapor is then condensed by a water-cooled condenser. The water flows into the evaporator. There, it evaporates and is absorbed by the concentrated lithium bromide (weak) solution in the absorber.

Three pumps maintain the pressure difference. The absorber pump (1) moves the weak solution. The solution is delivered to the absorber. Strong solution is drawn from the bottom of the absorber toward the absorber pump (1), where it mixes with weak solution returning from the generator. The evaporator pump (2) recycles the water that did not evaporate in the evaporator back to the spray heads. The generator pump (3) moves the strong solution up to the generator.

The temperature changes in the system are marked on the drawing. Cooling water leaves the evaporator at 44°F (7°C). It travels through the cooling coils located in the rooms to be air conditioned (comfort-cooled). The water then returns to the evaporator at 54°F (12°C). If the correct operating conditions

Copyright Goodheart-Willcox Co., Inc. 2017

are maintained, the lithium bromide solution always stays in liquid form. The condenser cooling water also cools the absorber, increasing the solution's ability to absorb water.

The type of lithium bromide absorption system in **Figure 34-11** and **Figure 34-12** uses pumps to circulate the liquids through the system. Some lithium bromide absorption systems rely on gravity to circulate the liquids through the system, **Figure 34-13**.

Steam heat applied to the generator percolates water vapor and weak solution up to the separator. The weak solution then flows by gravity through the heat exchanger. It flows to the absorber where it absorbs water vapor that is exiting the evaporator. The strong solution settles to the bottom of the absorber. It returns to the generator after passing through the heat exchanger. The pressure difference is maintained by the pressure head of the solution.

In the upper half of the system, the water vapor in the separator rises to the condenser. There, it is condensed and becomes liquid water. The water flows by gravity through an orifice into the evaporator. The water evaporates at a low temperature due to a near-perfect vacuum in the system. The water vapor is absorbed by the lithium bromide solution as it enters the absorber.

Note that the absorber and condenser are both cooled by water coils. The condenser water is cooled in a cooling tower and recirculated. Cooling towers were discussed in Chapter 33, *Commercial Air-Conditioning Systems*. The condensing pressure in a system like this is about 50 mm to 60 mm Hg (about 1 psia or 6.9 kPa). The evaporating pressure is 8 mm Hg to 10 mm Hg (about 0.17 psia or 1.2 kPa). Lithium chromate is often used as a corrosion inhibitor.

Chiller Control Centers

Many modern chillers are equipped with a control center. The control center displays performance information, such as inlet and outlet temperatures of

10

the chiller, condenser, and hot water circuits. It also indicates generator pressure and temperature, refrigerant and solution temperatures, and heat input. The panel may display additional information, such as the unit's total operating hours, number of starts, and number of purge cycles completed.

Efficiency Advantages of Absorption Chillers

The application of absorption refrigeration systems in comfort cooling and heating is increasing. Energy efficiency is critical in most commercial applications, and an absorption system offers increased energy efficiency in many situations.

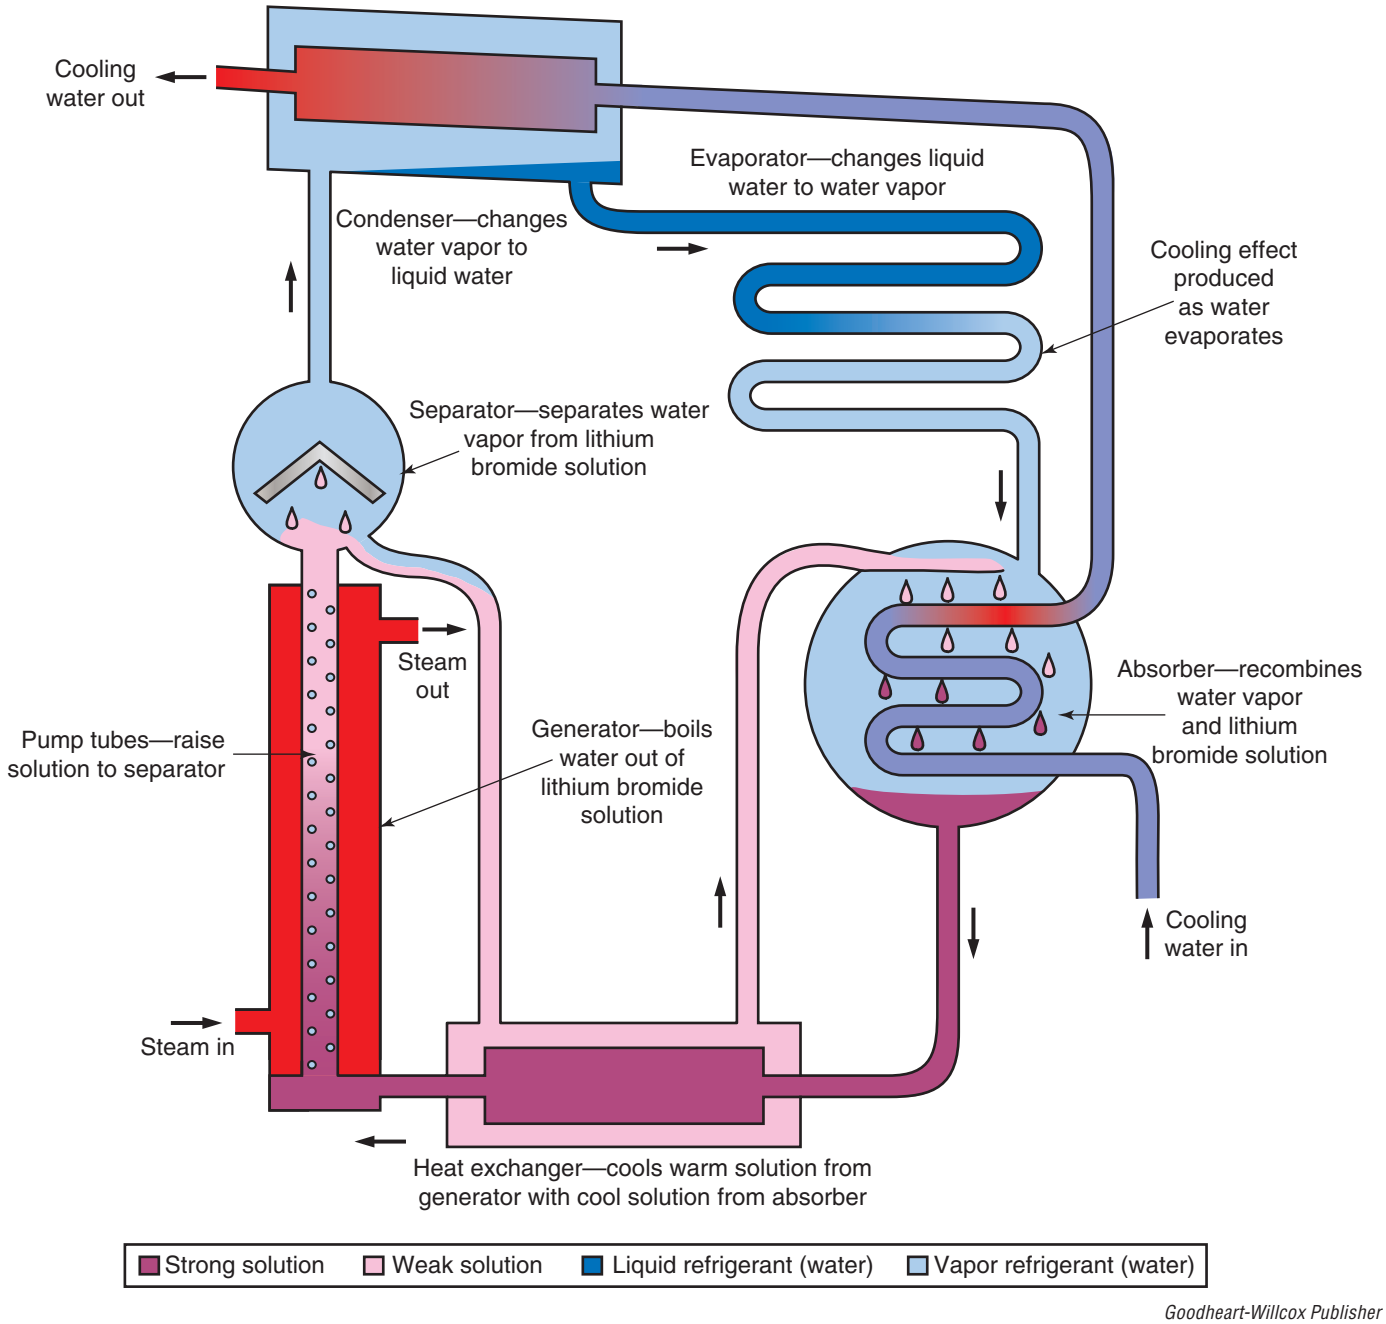
When the waste or by-product energy from one process is used as the primary source of energy for another process, the overall energy efficiency of a building is increased. The use of energy by-products from one process as the primary energy source for another process is referred to as ***cogeneration***. For example, a building using steam to run a generator turbine could use the waste heat from that process to operate an absorption chiller. See **Figure 34-14**.

Pro Tip

Trigeneration

A power plant that produces electricity and useful steam is referred to as a cogeneration plant, or ***combined heat and power (CHP) plant***. If some of that steam is used for heating and some is used to power an absorption chiller, the process is referred to as a ***trigeneration*** or *polygeneration*.

Copyright Goodheart-Willcox Co., Inc. 2017



Goodheart-Willcox Publisher

Figure 34-13. Absorption cycle that uses water as refrigerant and lithium bromide as the absorbant. This system relies on gravity to circulate the fluids through the system.

Absorption units provide very high efficiency when they are used in conjunction with solar energy systems. With the right equipment setup, the heat generated by solar energy can be used to heat water, which can then either be used to heat the building or to operate an absorption cooling system that will cool the building.

An advantage of using a gas-fired absorption chiller is seasonal energy costs. Gas usage is traditionally lower during the summer months. Therefore, gas prices are usually lower during these months. Absorption chillers take advantage of this price reduction and provide chilled cooling water at an economical cost during peak cooling load seasons.

34.3 Absorption System Service

Most residential absorption systems are serviceable. They are typically equipped with service valves.

Goodheart-Willcox Publisher

Figure 34-14. Cogeneration example. A gas turbine powers a generator to produce electricity. Exhaust from the gas turbine heats a boiler. Steam from the boiler is used to power an absorption chiller.

However, the technician should be trained by the manufacturer before attempting to service these systems.

Safety Note

Working with Ammonia-Based Absorption Systems

Ammonia is toxic and flammable when mixed at certain ratios with air. Wear a face shield or safety goggles when working with ammonia. Because ammonia reacts with some metals, you should use only steel or aluminum tubing, gauges, fittings, and manifolds when servicing ammonia systems.

34.3.1 Servicing Ammonia-Based Absorption Systems

An ammonia-based absorption chiller is charged with a solution of ammonia, distilled water (pH 6.0 +), and a corrosion inhibitor. A solution cylinder is used to charge the system with the solution. This cylinder usually has about a 45-lb (20-kg) capacity. The solution charge is about 35 lbs (16 kg) of distilled water. It also contains corrosion inhibitor and 10 lbs (4.5 kg) of ***anhydrous ammonia*** (ammonia that is free of water).

The solution cylinder is filled with distilled water and corrosion inhibitor (yellow in color). It is put in through the fill plug. If a white precipitate forms in the solution, the solution should be discarded and a new batch made.

The solution cylinder is then charged with anhydrous ammonia. Anhydrous ammonia is available in 25-lb (11-kg) cylinders. The cylinder has both a vapor and a liquid valve. **Figure 31-15** shows the charging arrangement.

Note that the charging line is connected to the liquid valve of the anhydrous ammonia cylinder. The pail is partly filled with water. It is connected to the vapor valve of the solution cylinder. Vapor is purged from the solution cylinder if necessary to lower the pressure. (This will enable anhydrous ammonia to flow into the solution cylinder.) The water in the pail will absorb the small amount of ammonia purged.

The system must have the correct pressures and the correct amount of anhydrous ammonia. It must also have the correct amount of distilled water and corrosion inhibitor. To check pressures, install a 100% steel gauge manifold, steel lines, and steel fittings. Do not use any equipment containing copper or brass. The steel gauge manifold must have standard steel fittings and steel valves. The manifold will operate exactly like the gauge manifolds described in earlier chapters, **Figure 34-16**.

Leaks in ammonia absorption systems can often be detected by smell. If a leak is too small to produce a noticeable odor, a wet litmus paper test strip can be moved around the suspected leak site. The litmus paper will turn red if it is exposed to ammonia.

Caution

No Bubble Leaks with Ammonia

Bubble leak tests cannot be used for ammonia absorption systems. The leaking ammonia would be absorbed by the soapy water without producing bubbles.

34.3.2 Servicing Lithium Bromide–Based Absorption Systems

Lithium bromide is a nontoxic, nonflammable, nonexplosive, and chemically stable salt used in some absorption systems. In a lithium bromide absorption system, water is the refrigerant. Lithium bromide is mixed with the water as an absorbing solution. The resulting mixture is a liquid. It can be handled in open containers but becomes corrosive when exposed to air. Octyl alcohol is sometimes added to reduce the surface tension of the lithium bromide solution. It acts as a wetting agent.

A solution containing 65% lithium bromide by weight will start to crystallize at 110°F (43°C). The solution must not be allowed to reach lithium bromide concentrations high enough or temperatures low enough to allow crystallization.

Copyright Goodheart-Willcox Co., Inc. 2017

A typical charge is made up of the following ingredients:

- Lithium bromide solution 120 gal (454 liters).
- Corrosion inhibitor 1 pt (473 ml).
- Refrigerant (water) 35 gal (132 liters).
- Octyl alcohol (2-ethylhexanol) 1 gal (3.7 liters).

The solution becomes thicker if the amount of lithium bromide in the solution increases. A greater concentration of lithium bromide will cause a greater temperature difference between the evaporator and the chilled water. If solution concentration gets too high, the refrigerant will turn solid and must be dissolved. If the absorber becomes too cold (below 85°F or 29°C), solidification can also occur.

Safety Note

Working with Lithium Bromide

Lithium bromide solution may irritate skin, eyes, and mucous membranes. Always use protective gloves, face mask, and eye protection when working with lithium bromide.

Maintenance of a lithium bromide absorption system should include the following tests:

- Specific gravity.
- Alkalinity and pH.
- Copper content.
- Suspended solids.
- Corrosion inhibitor concentration.

To check the system for leaks, it is charged with nitrogen or helium in accordance with the manufacturer's instructions. Soapy water is applied to potential leak points, such as welded joints, sight glasses, and diaphragm valves. If bubbles form, a leak is indicated. After the leak test, the nitrogen or helium is removed, any necessary repairs are made, and the system is purged. Proper purging is necessary to remove any noncondensibles from the refrigerant-absorber solution.

Pro Tip

Maintenance of Lithium Bromide Absorption Chillers

Once air enters a lithium bromide system, the lithium bromide solution becomes highly corrosive. The damage caused by corrosive solution can make it very difficult to recondition a failing system. Every effort should be made to prevent air from entering the system and to keep the lithium bromide solution properly balanced and free of contaminants. The manufacturer's maintenance recommendations must be closely followed.

34.4 Evaporative Cooling

As you have already learned, if warm, dry air is moved rapidly over water at the same temperature, some of the water will evaporate. When those water molecules evaporate, they absorb heat energy from the surrounding molecules, causing the temperature of the remaining liquid water to drop. When this natural cooling process is used to cool a space or objects, it is referred to as ***evaporative cooling***. In dry climates, evaporative cooling is both effective and practical.

For example, if air that is 105°F (41°C) with 20% relative humidity is blown over a reservoir of water, some of the water will evaporate. The remaining water can cool to as low as 55°F (13°C). Normally, the water will cool down to a range of about 65°F (18°C) to 70°F (21°C). As air is forced around the water container, the air is cooled to approximately 75°F (24°C) or 80°F (27°C) with about 40% relative humidity. The cooled air can then be distributed into the space to be cooled. The conditioned room would be quite comfortable. **Figure 34-17** illustrates such a system.

34.4.1 Indoor Applications

Evaporative cooling is often used in climates with bright sunshine and low relative humidity. For example, evaporative cooling can maintain a safe temperature for plants growing in greenhouses. The typical evaporative cooling system used in greenhouses is shown in **Figure 34-18**.

At one end of the greenhouse is an opening covered by a tight lattice of fibers such as ***excelsior*** (fine curled wood shavings). At the top of the lattice are water pipes with small holes. Water leaks out of the small holes and flows downward, wetting the fibers. A fan at the other end of the greenhouse draws in outside air through the lattice. The air entering the greenhouse is cooled by the evaporation of the water on the lattice surfaces. Plants do best under conditions of high relative humidity. Therefore, this type of cooling is ideal. It provides a high relative humidity as well as a lower temperature inside the greenhouse.

Foundries sometimes use this system in situations where a few degrees of cooling are desirable. In such installations, the evaporation takes place in a structure on the roof of the building. The cooled air is brought down into the work area.

34.4.2 Wet Roof Cooling

Wet roof cooling is a method of cooling indoor temperature by the evaporation of water on a

Goodheart-Willcox Publisher

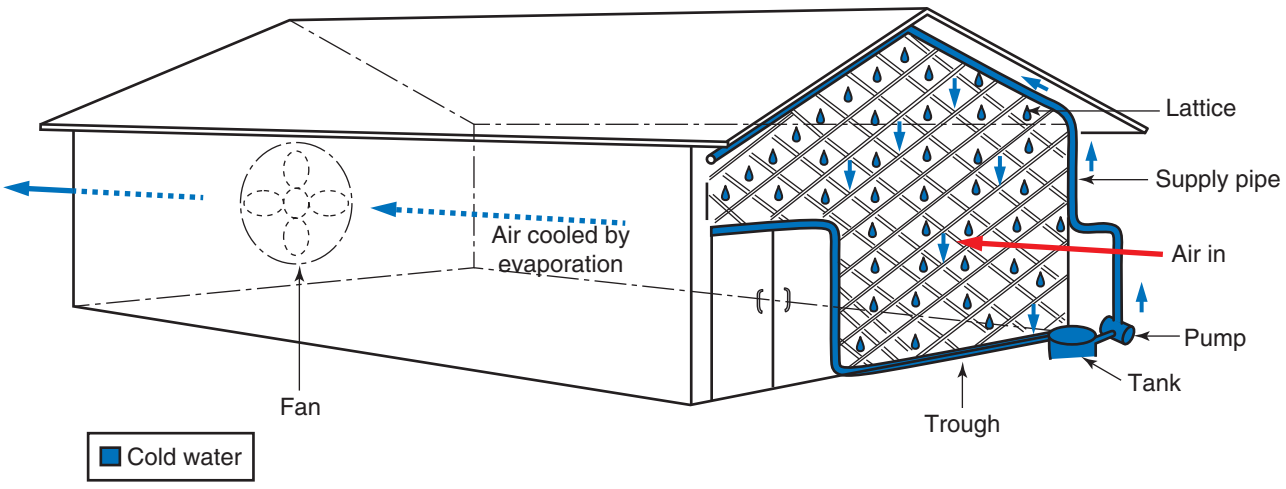
Figure 34-17. Evaporative cooling process. Outside air filters through a water-saturated evaporative medium, is cooled by evaporation, and is circulated by a blower.

building's roof. Like other applications of evaporative cooling, it is used primarily in climates where ambient air temperatures are high and relative humidity is low. There are numerous methods of wet roof cooling. Some systems are designed so that the roof is a trough or pond.

With a ***roof pond cooling,*** the entire surface of the roof remains wet and the water is replaced as it evaporates. Roof ponds are typically 2″–3″ (50 mm–75 mm) deep. Where there is bright sunshine much of the day, the building heat load may be high. If the relative humidity is low, a roof pond can maintain a comfortable indoor temperature.

Roof misting systems are another type of wet roof cooling system. A ***roof mist cooling system*** periodically mists small amounts of water onto the roof of a building. The water droplets evaporate when they hit the hot roof. In doing so, the water absorbs a relatively large amount of heat from the roof's surface. Roof mist cooling is designed to prevent heat from entering a structure. It is a simple method of cooling. The cost of a roof misting system may be less than the cost of other types of mechanical air-conditioning equipment.

Roof mist cooling systems operate only during the summer and primarily during daylight hours. However, the systems may be operated into the night for additional cooling. One type of system cools the water at night and stores it in an insulated container. The water cooled at night is then used for evaporative cooling during the day. A roof mist cooling system can reduce the



Goodheart-Willcox Publisher

Figure 34-18. A typical evaporative cooling system used in a greenhouse.

Copyright Goodheart-Willcox Co., Inc. 2017

flow of solar heat from the roof into the building's interior by more than 90% during daylight hours.

A roof mist cooling system includes a network of water pipes on the roof. The network is a supply line that branches into "fields." Depending on water pressure available, fields are generally 5000 ft² (465 m²) or larger. Spray heads are distributed throughout the network of piping and are turned on and off by solenoid valves, **Figure 34-19**.

An electronic control designed specifically for roof misting turns the solenoid valves on and off as needed. The solenoid valves open and close the water supply to the sprinkler heads. The electronic control receives data from temperature sensors on the roof and uses that data to calculate the amount of water that can be evaporated at any given time. Only that amount of water is sprayed onto the roof. This prevents water runoff, waste of water, and water stagnation.

Evaporation continues as long as the roof's surface temperature is greater than the wet-bulb temperature of the ambient air. Roof temperatures of 150°F–165°F (65°C–74°C) can be reduced by 60°F–75°F (33°C–42°C), thus reducing the heat gain into the building through the roof.

As the water mist evaporates, the roof is cooled. This reduces the amount of solar radiation (heat) transferred through the roof to the interior of the building. It should be noted that solar radiation transferred through the roof is generally the largest contributor of unwanted heat inside a building. A roof misting system virtually eliminates the roof as a contributor to the internal heat load. See **Figure 34-20**.

The higher the temperature of air, the more water vapor it can hold. Evaporation will continue even when the surrounding air's relative humidity is 100%, as long as the temperature of the roof is higher than the wet-bulb temperature of the air/vapor combination adjacent to the surface. The roof cooling system should maintain a roof surface temperature close to the wet-bulb temperature of the air surrounding it, thereby minimizing the transfer of heat from the roof into the building.

In circumstances where the interior of a building is very hot due to generation of heat within the building, cooling the roof can transfer the internal heat to the outside of the roof. The cooler the roof is, the greater the amount of internal heat that will be transferred to the roof, where it is dissipated.

Evaporative roof cooling can be used as a stand-alone system or in conjunction with a mechanical air-conditioning system or energy management program.

Chapter Review

Summary

- An absorption refrigeration system uses heat energy to drive the refrigeration process. Both compression and absorption refrigeration systems use evaporators and condensers, but instead of using a compressor, absorption systems use a generator.
- The two classifications of absorption refrigeration systems are intermittent and continuous-cycle. Intermittent systems do not have a constant power source; therefore, they run on a single charge for a given amount of time. Continuous-cycle systems have a constant power source; therefore, they run as long and often as needed.
- Absorption systems can use ammonia as the refrigerant and water as the absorbant, or water as the refrigerant and lithium bromide as the absorbant. The heat needed to run an absorption system can come from many sources, including natural gas, LP gas, kerosene, steam, solar energy, and electricity.
- In a typical absorption chiller, heat supplied to the generator boils refrigerant out of a refrigerant-absorber solution. The solution, which contains very little refrigerant (weak solution), then travels to the absorber. The refrigerant vapor passes to the condenser, where it is changed to a liquid. The liquid refrigerant passes through a restriction, into the evaporator where it turns into refrigerant vapor again. As it evaporates, it absorbs heat from the water in the cooling coil. The refrigerant vapor travels into the absorber, where it is reabsorbed by the solution, returned to the generator, and begins the cycle again.
- Residential absorption chillers are typically installed outside on a slab. The cooling coil is installed in the plenum of the air handler. Controls for such systems can include gas valves, ignition system, flame detectors, chilled water switches, and time delays for heating and cooling.
- The capacity of an absorption chiller system is dependent on ambient air temperature and the temperature of the chilled water. The capacity is directly proportional to the temperature of the chilled water leaving the system and inversely proportional to ambient air temperature.
- Commercial absorption systems may be direct-fired or indirect-fired. Direct-fired systems use a burner or other heat source inside the system to directly heat the solution in the generator. Indirect-fired systems use piped-in steam, hot water, or hot gas to heat the solution in the generator.
- Absorption systems can be further classified as single-effect or double-effect systems. In single-effect systems, all of the heat absorbed during the condensation of the refrigerant is rejected from the system through a cooling tower. In a double-effect system, some of the heat from the high-temperature generator is used to create additional vapor in the low-temperature generator.
- Some commercial absorption systems use ammonia as the refrigerant and water as the absorbant. Other systems use water as the refrigerant and lithium bromide as the absorbant.
- Some simple evaporative cooling systems, like those used in some greenhouses, draw air through a wetted medium into the space to be cooled. This cools the air being drawn in and increases its humidity.
- Evaporative cooling can be used to cool roofs in order to prevent the transfer of heat from the roof to the interior of the building or to transfer heat from inside a building to outside. Roof cooling systems are usually ponds or mists.
- A roof pond is a shallow pool of water that continuously evaporates and is replenished, cooling the roof. A roof mist cooling system sprays a precise amount of water onto the roof. The water evaporates quickly, cooling the roof in the process.

Review Questions

Answer the following questions using the information in this chapter.

1. While compression systems use mechanical energy to power refrigeration, absorption systems use _____ energy to do the same.
   A. heat
   B. magnetic
   C. mechanical
   D. nuclear

Copyright Goodheart-Willcox Co., Inc. 2017

2. In an absorption system, a substance that soaks up the refrigerant returning from the evaporator is called the _____.
   A. absorbant
   B. affinity
   C. precooler
   D. restrictor
3. Which of the following is the process in which a solid attracts and holds a substance on its outer surfaces?
   A. Absorption.
   B. Adsorption.
   C. Subcooling.
   D. Superheating.
4. Which of the following is the process in which a substance attracts and combines with another substance to form a uniform solution?
   A. Absorption.
   B. Adsorption.
   C. Subcooling.
   D. Superheating.
5. When an absorption system is operating, high pressure is maintained in the _____.
   A. absorber and generator
   B. condenser and evaporator
   C. condenser and generator
   D. evaporator and generator
6. When a solution in an absorption system is saturated with refrigerant, it is a(n) _____ solution.
   A. affinity
   B. cogeneration
   C. strong
   D. weak
7. In an absorption system, refrigerant is boiled out of the refrigerant-absorber solution in the _____.
   A. absorber
   B. condenser
   C. evaporator
   D. generator
8. Which of the following may be used for a heat source in absorption chillers?
   A. Natural gas.
   B. Steam.
   C. Electricity.
   D. All of the above.
9. In a residential absorption chiller, the _____ is installed in the air handler plenum.
   A. absorber
   B. evaporator
   C. generator
   D. water-type cooling coil
10. When an absorption heat pump is in heating mode, _____.
    A. the evaporator acts like a condenser
    B. the condenser acts like an evaporator
    C. the generator acts like an absorber
    D. All of the above.
11. Which of the following statements regarding an indirect-fired absorption system is true?
    A. Indirect-fired absorption systems do not have a generator.
    B. Indirect-fired absorption systems must have a secondary (low-temperature) generator.
    C. Steam, hot water, or hot gas is produced away from the system and delivered through pipes.
    D. All of the above.
12. Which of the following best explains the difference between a double-effect absorption system and single-effect absorption system?
    A. A double-effect system has a lower operating efficiency than a single-effect system.
    B. A double-effect absorption system has both a primary and secondary generator.
    C. A double-effect absorption system requires less heat input to operate than a single-effect system.
    D. In a double-effect absorption system, the function of the absorber and condenser are combined in a single chamber.
13. Which of the following is *not* true when an absorption system changes from cooling to heating mode?
    A. Cooling water is shut off.
    B. The generator produces no heat.
    C. One or more valves change position.
    D. Water sent to the conditioned space is warmed.
14. Which of the following statements regarding ammonia absorption systems is *not* true?
    A. Ammonia acts as the refrigerant.
    B. Water boils out of the solution in the generator and condenses in the condenser.
    C. Water acts as the absorbant.
    D. All of the above.

Copyright Goodheart-Willcox Co., Inc. 2017

15. Which of the following statements regarding lithium bromide absorption systems is *not* true?
    A. Lithium bromide acts as the refrigerant.
    B. Water acts as the absorbant.
    C. Lithium bromide is reabsorbed by the weak solution in the absorber.
    D. All of the above.
16. Using waste heat from one process to power another process is referred to as _____.
    A. coadaptation
    B. cogeneration
    C. polyreabsorption
    D. power derivation
17. For servicing ammonia absorption systems, it is important that the gauge manifold, valves, lines, and fittings used should *never* be made of _____.
    A. aluminum
    B. cast iron
    C. copper
    D. steel
18. A water and lithium bromide solution should *not* be exposed to air to prevent the solution from becoming _____.
    A. bitter
    B. corrosive
    C. explosive
    D. nuclear
19. Roof misting and roof ponds are examples of _____ cooling systems.
    A. absorption
    B. evaporative
    C. excelsior
    D. trigeneration
20. Wet roof cooling is most effective in _____ climates.
    A. cool, dry
    B. cool, humid
    C. hot, dry
    D. hot, humid

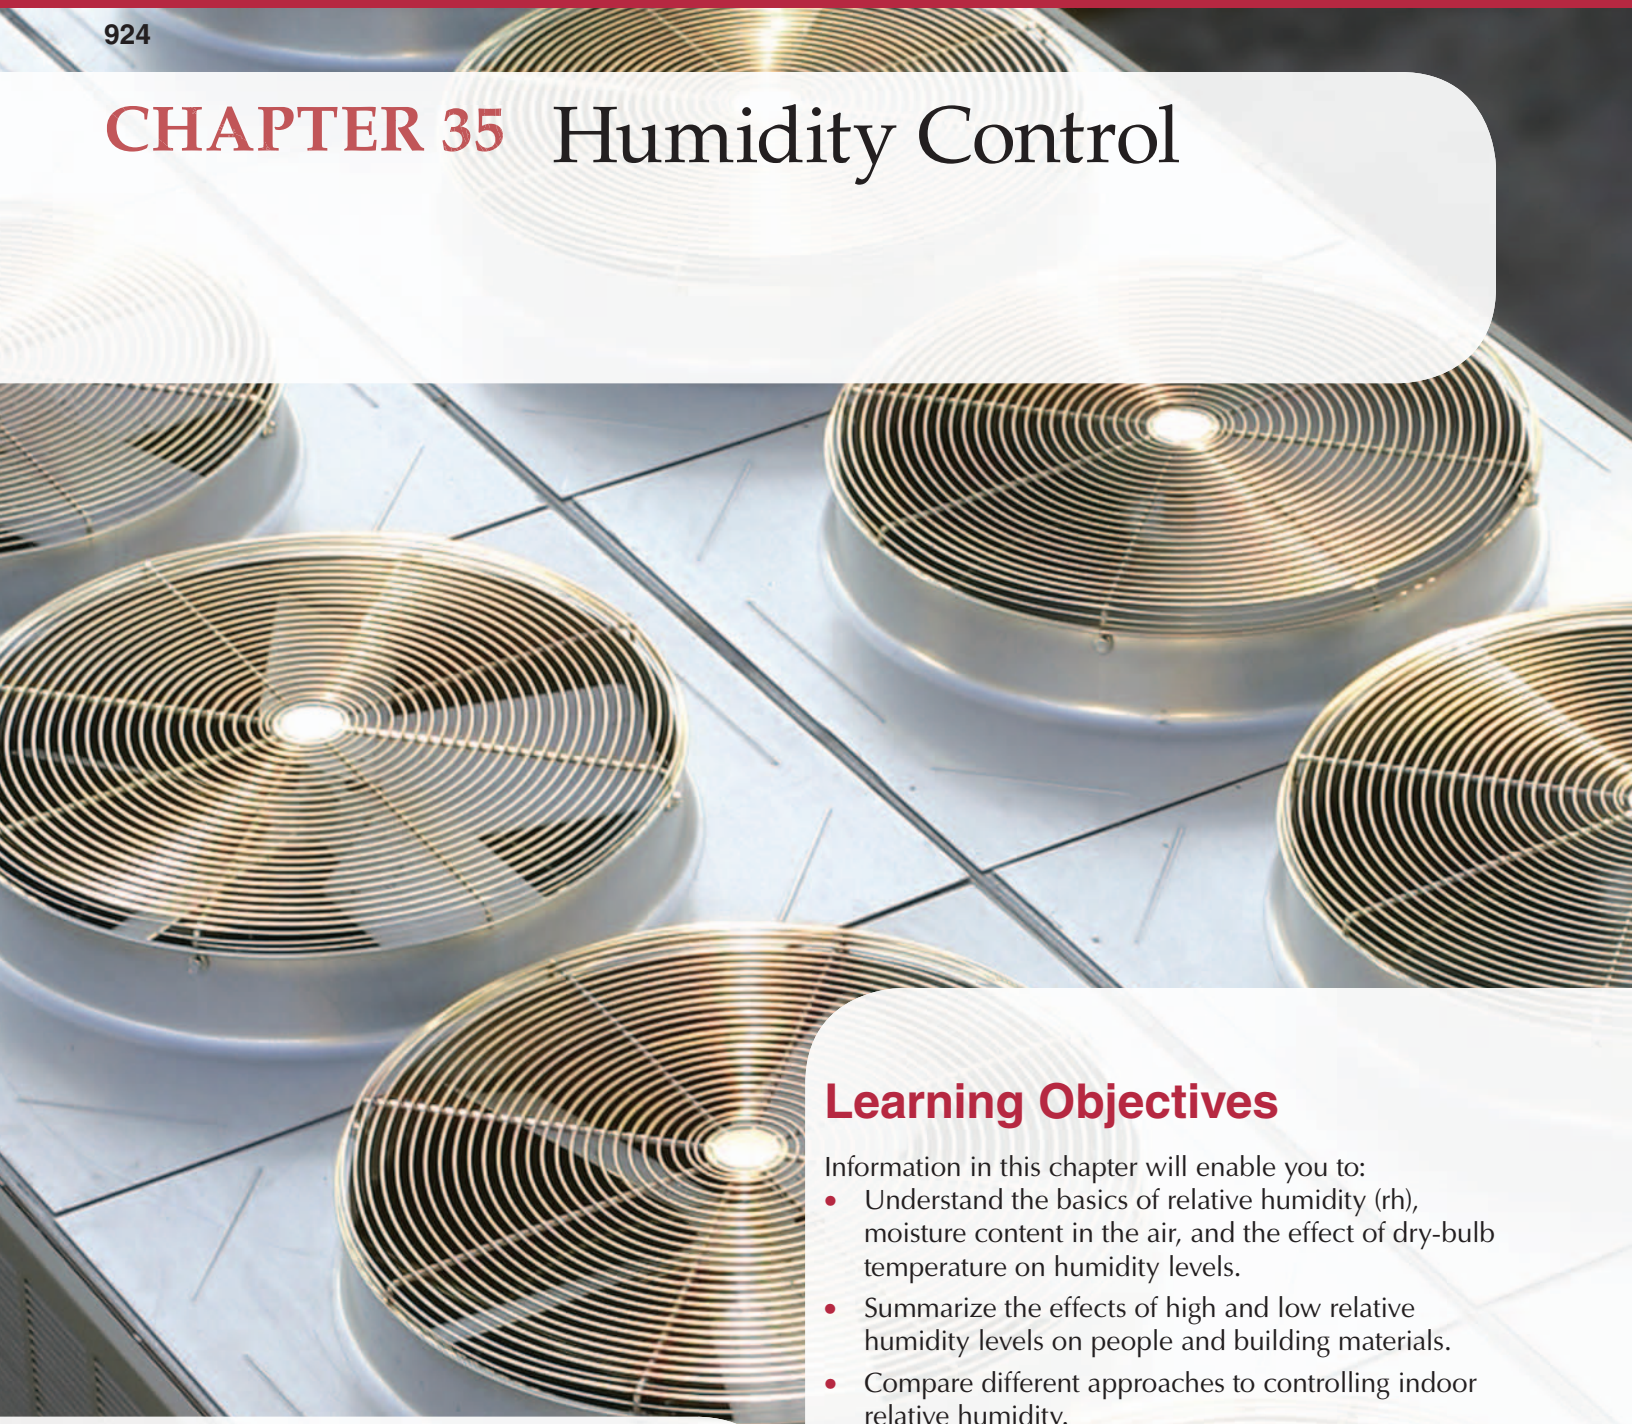
CHAPTER 35 Humidity Control



Chapter Outline

35.1 Humidity Levels and Comfort
35.1.1 Humidifier Basics
35.1.2 Humidistats
35.2 Types of Humidifiers
35.2.1 Central Humidifier Designs
35.2.2 Portable Humidifiers
35.3 Dehumidifying Equipment
35.3.1 Dehumidifiers
35.3.2 Use of Desiccants
35.4 Servicing and Installing Humidifiers

Learning Objectives

Information in this chapter will enable you to:

- Understand the basics of relative humidity (rh), moisture content in the air, and the effect of dry-bulb temperature on humidity levels.
- Summarize the effects of high and low relative humidity levels on people and building materials.
- Compare different approaches to controlling indoor relative humidity.
- Understand how humidistats control humidifiers and dehumidifiers.
- Compare the design and operation of evaporative humidifiers, atomizing humidifiers, and vaporizing humidifiers.
- Explain the different ways water is supplied to humidifiers and compare the different type of water that can be used (hard, naturally soft, softened, demineralized, and distilled).
- Summarize the design and operation of a typical dehumidifier.
- Understand the steps involved in humidifier installation and service.

Review of Key Concepts

Reviewing these concepts from earlier chapters will help you understand new concepts presented in this chapter:

- Latent heat is heat that changes the physical state of a substance, such as ice melting or water evaporating. (Chapter 4)
- Since the evaporation of a substance, such as water into vapor, requires it to absorb heat, there is a cooling effect around the substance from where the heat is drawn into the substance. (Chapter 4)
- Since the condensing of a substance, such as vapor into water, requires it to expel heat, there is a warming effect around the substance. (Chapter 4)
- Humidity is the presence of moisture or water vapor in the air. Humidity is moisture in vapor form, and it is invisible. (Chapter 27)
- The amount of moisture that air will hold depends on the air temperature. Warm air holds more moisture than cold air. (Chapter 27)
- Relative humidity (rh) is a term used to express the amount of moisture in an air sample compared to the total amount of moisture the same sample would hold if it were completely saturated at the same temperature. (Chapter 27)
- Relative humidity is stated as a percentage. Air with a relative humidity of 25% contains only one-fourth of the moisture it is capable of holding. (Chapter 27)
- Dew point is the temperature below which water vapor in the air will start to condense. It is the temperature at which air will have 100% relative humidity. (Chapter 27)

Introduction

Good, complete air-conditioning systems must provide heat, remove heat, and clean and circulate the air. Most systems accomplish all of these tasks. However, many systems do not completely control the relative humidity of the air. To control relative humidity, there must be two devices in the system ready to be used at any time, winter or summer:

- A device to add water vapor to the air (humidifier).
- A device to remove water vapor from the air (dehumidifier).

In some central air-conditioning systems, a humidistat causes the system to operate if the air is too moist. The evaporator is located in the plenum chamber of the central air-conditioning system. When the air-conditioning system is operating, the cold surfaces of the evaporator will condense out moisture, drying the air. This method provides fairly effective humidity control during the cooling season.

Another method of controlling humidity is to bring in and mix cool air and warm air to achieve the desired temperature and relative humidity. Both cool and warm air should have a normal (50%) relative humidity. By mixing these air volumes in different proportions, the needed temperature and relative humidity conditions can be produced.

10

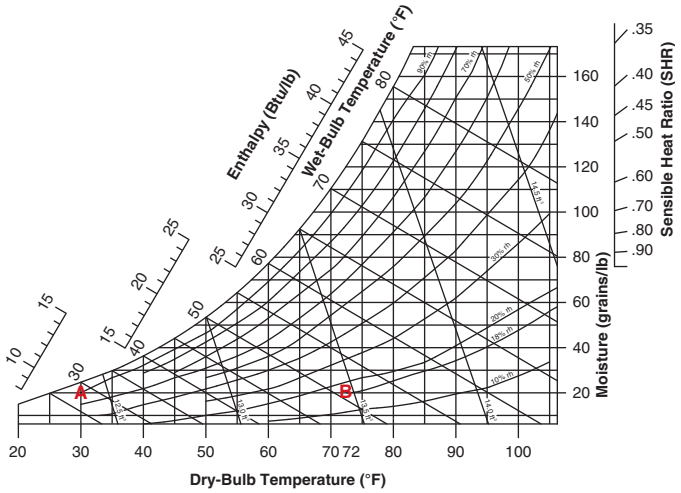
35.1 Humidity Levels and Comfort

Relative humidity (rh) is a ratio of the moisture content in the air compared to the maximum amount of moisture that the air can hold at its current temperature. As air is heated, it is able to hold more moisture, so its relative humidity decreases (unless additional moisture is added). For example, when outside air at 30°F (–1°C) and 90% rh is heated to 72°F (22°C), its rh drops to about 18%. The amount of moisture in the air is the same, but humidity has dropped. The psychrometric chart in **Figure 35-1** shows this relationship.

Human comfort requires a relative humidity between 30% and 50%. A lower relative humidity results in dry skin, mouth, nose, and throat. A low relative humidity also causes hygroscopic materials to lose moisture. Examples of common hygroscopic materials include natural wood fibers (wood furniture and woodwork) and most foods. Low relative humidity can cause wood to crack and furniture joints to get loose. Dry air also promotes the generation of static electricity. To increase relative humidity, moisture must be added to the air.

Typical indoor moisture sources are plumbing devices, cooking, and perspiration. In fact, all water-based activities in a building increase the relative humidity. Perspiration and respiration of humans and animals increase relative humidity. In addition, moisture in the air can be increased and controlled with humidifiers.



Goodheart-Willcox Publisher

Figure 35-1. This graph shows that an increase in dry-bulb temperature results in a decrease in relative humidity but a constant moisture content (grain/lb). A—Starting point. The air is at 30°F (–1°C) with a 90% rh. B—The air sample is heated from 30°F (–1°C) to 72°F (22°C) without adding any water vapor. As a result, the relative humidity decreases from 90% to 18%.

Too much humidity may cause swelling of hygroscopic materials (such as wood products). It may cause condensation on cold surfaces, such as windows, window frames, and doors. Water vapor may also condense on the inner surface of outside walls. Wood frames can rot from water dripping off cold glass window panes. Mold can grow and rot can occur if a home's relative humidity level is maintained above 50%. At a relative humidity of 70%, mold thrives.

During the heating season, the windows and exterior walls of a building can often be much colder than the indoor air temperature. If the temperature of the walls or window panes falls below the dew point of the indoor air, condensation will form. This condensation can drip onto wood and drywall surfaces where it will support mold growth, mildew, and rot. For this reason, it is sometimes necessary to lower the humidity indoors when the temperature outside is extremely cold. Although drier air might not be as comfortable in the short term, it will help prevent condensation from forming and the damage and health problems that can result from it.

The chart shown in **Figure 35-2** identifies the recommended indoor relative humidity levels for various outdoor temperatures. The recommended indoor relative humidity is 40% when the indoor temperature is 72°F (22°C) and the outdoor temperature is 30°F (–1°C). If the temperature outside drops to 0°F (–18°C), the recommended indoor relative humidity level would be 25%. A higher relative humidity level would increase the risk of condensation forming. If the indoor temperature is cooler than 72°F (22°C), the recommended indoor relative humidity levels would be slightly higher than those listed. If the indoor temperature is above 72°F (22°C), the recommended relative humidity levels would be slightly lower.

Recommended Indoor Relative Humidity Based on Outdoor Temperatures

Outside Temperature	Recommended Inside RH (at 72°F)
–10°F	20%
0°F	25%
10°F	30%
20°F	35%
30°F	40%

Goodheart-Willcox Publisher

Figure 35-2. This chart shows the recommended inside relative humidity based on outside air temperature when inside temperature is kept at 72°F (22°C).

Copyright Goodheart-Willcox Co., Inc. 2017

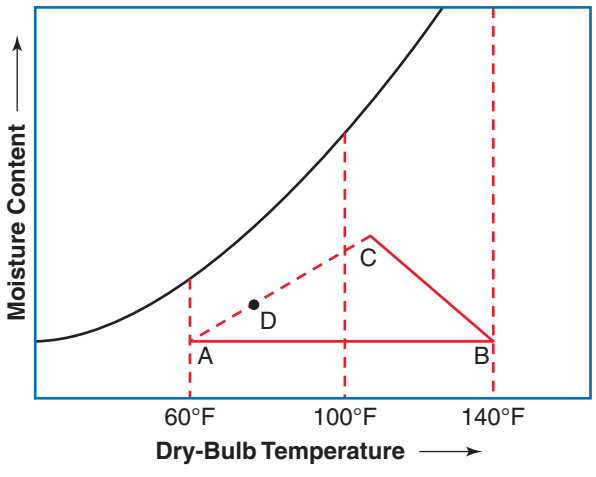
35.1.1 Humidifier Basics

The term ***humidifier*** refers to equipment that adds water vapor to the air. For example, imagine a system where the air returning to a warm air furnace is 60°F (16°C) with 25% rh. The furnace heats the air to 140°F (60°C), and a humidifier adds moisture to the warmed air. This heated air is then mixed with the air in the room.

The graph in **Figure 35-3** shows the effects of the heating and humidifying process. The line from A to B represents the air being heated. The line from B to C represents the warm air passing over the humidifier. The temperature of the air decreases, but the latent heat in the air increases, so the total heat remains constant. Remember, it requires about 1000 Btu to vaporize each pound of water. The dotted line between C and A represents all of the possible temperature and relative humidity combinations that can be created by mixing various ratios of the heated and humidified air with untreated air. D indicates the final condition of the air as it is delivered to the conditioned space.

The ideal relative humidity for a room depends on personal preference. Some people like more humidity than others. As a general rule, relative humidity should be maintained at about 30%. During extremely cold weather, a home loses humidity. Cold air inside a home being heated to 73°F can have a relative humidity as low as 6%. As a comparison, the humidity in the Sahara Desert is approximately 25%.

Too much moisture in the air may result in the formation of bacteria and fungus, and too little moisture can dry out building materials and skin. The amount of moisture required to maintain a relative humidity of 30% can be significant. For example, it may require the addition of up to 25 gallons of water to the air of a 3,000 square foot home to maintain 30% relative humidity at 72°F (22°C).



Goodheart-Willcox Publisher

Figure 35-3. This psychrometric chart depicts a warm air recirculating heating cycle. A—Cold air return. A to B—Heating in furnace. B to C—Humidifying air. C to A—Range of conditions available by mixing warmed and humidified air with room air. D—Final condition after mixing.

Humidifiers are used to add needed moisture (water vapor) to room air. A ranch home that is 25′ × 60′ with 8′ ceilings has a volume of 12,000 ft^3. Up to 16 gallons of water may need to be added to the air per day. The amount of water needed would be impacted by the relative humidity of the intake air entering the building. If air entering the space has a high moisture or humidity level, less water would need to be added.

Air changes per hour (ACH) is a measure of how many times the entire volume of air within a defined space is replaced in one hour. It is used to measure the ventilation rate. The following formula can be used to calculate the number of air changes necessary in a building:

$$\text{Air changes per hour} = \frac{\text{airflow (in cfm)} \times 60 \text{ min}}{\text{volume of room (cubic feet)}}$$

35.1.2 Humidistats

A ***humidistat*** is a control device that responds to changes in humidity and activates and deactivates parts of the humidity control system, such as humidifiers, dehumidifiers, or air mixers as needed. It is usually located in the same room as the temperature controls. In humidifiers, the humidistat closes the circuit when humidity decreases (drops). On a dehumidifier, the humidistat closes the circuit when the humidity increases (rises). See **Figure 35-4**.

Humidistats are typically adjustable to maintain relative humidity between 20% and 90%. Most humidistat sensing elements should be mounted on a return air duct at a minimum of 6″ upstream of the bypass duct or humidifier. A humidifier's solenoid valve opens only when the furnace and blower are running. If the water is still flowing when the furnace is not running, there is a bad connection or valve that is not seated properly. **Figure 35-5** shows two humidistats.

The sensing element of a traditional electromechanical humidistat is called a ***hygroscopic element***. Such an element stretches as the moisture content of the air increases and shrinks as humidity decreases. Commonly used hygroscopic elements include human hair, wood, nylon ribbon, and membranes.

Electronic humidistats are equipped with solid-state sensors in place of a hygroscopic element. In an electronic humidistat, the sensor resistance changes as the moisture content of the air changes. Some materials used in solid-state sensors include:

Goodheart-Willcox Publisher

Figure 35-4. This diagram shows the role of a humidistat in a humidifier and in a dehumidifier. A—In a humidifier, the humidistat energizes the solenoid water valve and humidifier motor when humidity drops below a set level. B—In a dehumidifier, the humidistat activates the dehumidifier compressor when the relative humidity rises above a set level.

General Filters, Inc.

Figure 35-5. Humidistats are available with analog dial adjustments or incremental digital adjustments for controlling relative humidity.

- Hygroscopic salt (for example, lithium chloride).
- Carbon particles embedded in a hygroscopic material.

In these substances, the resistance decreases as the humidity increases. An electronic humidistat recognizes the changes in resistance in these materials and generates a corresponding output signal.

The change in size, shape, or electrical resistance of the sensing element is used to operate a switch that activates or deactivates a humidity control system, like a humidifier or dehumidifier, or triggers a damper actuator. An electronic humidistat varies its output current based on an internal resistance that changes with humidity.

35.2 Types of Humidifiers

Humidifiers can be attached into ductwork, in which case they add moisture to the air before it leaves the supply ducts and enters the conditioned space. These types of humidifiers are referred to as *central humidifiers*. Humidifiers can also be standalone units that are placed in the spaces where the humidity level is to be maintained. These types of humidifiers are referred to as *portable humidifiers*.

35.2.1 Central Humidifier Designs

Central humidifiers are humidifying units that are incorporated into an HVAC system through bypass

Copyright Goodheart-Willcox Co., Inc. 2017

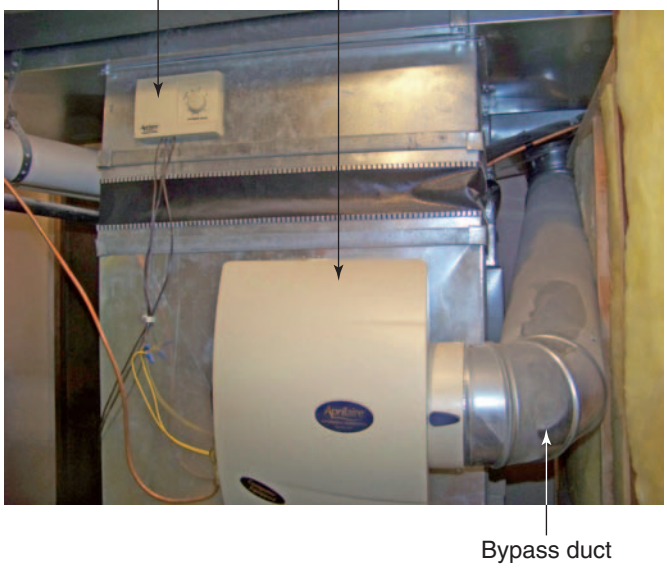
ductwork or by installing directly into the return or supply ductwork. These installations may vary by manufacturer.

A ***bypass humidifier*** humidifies bypassed air that flows from the supply air plenum into the return air plenum. A certain amount of conditioned air in the supply plenum flows through a bypass duct, into the humidifier, and back into the return plenum. Not all of the conditioned air follows this bypass route. The air that is bypassed is humidified, **Figure 35-6**.

The pressure difference between the lower pressure return plenum and the higher pressure supply plenum forces some air from the supply plenum through the bypass humidifier and into the return plenum just ahead of the furnace. During the cooling season, a damper in the bypass duct is closed to prevent air from passing through the humidifier, **Figure 35-7**.

For central humidifiers that are not the bypass type, there are two ways to install it into ductwork. A ***plenum-mounted humidifier*** is installed through the side of a return or supply ductwork. An ***under-duct humidifier*** is installed through the bottom of a return or supply ductwork.

Humidifiers can be further classified based on the way they add moisture to the air. There are three main categories of humidifiers: evaporative humidifiers, atomizing humidifiers, and vaporizing (steam) humidifiers.



Goodheart-Willcox Publisher

Figure 35-6. This bypass humidifier is mounted on the return supply plenum. A bypass duct from the supply plenum connects to the humidifier.

General Filters, Inc.

Figure 35-7. Air flows through this bypass humidifier by entering from behind and exiting out the side. In summer, when a humidifier will not be used, the bypass passage may be closed by the seasonal damper.

Evaporative Humidifiers

Evaporative humidifiers add moisture to the air through evaporation. In general, these humidifiers contain an element that is kept damp. As air is forced through the humidifier, some of the moisture in the element evaporates, increasing the humidity of the air. There are four main types of evaporative humidifiers:

- Plate humidifiers (low-capacity).
- Fixed filter humidifiers.
- Rotating drum humidifiers (for restricted spaces).
- Rotating disk humidifiers.

Plate Humidifiers

Plate humidifiers consist of a series of porous plates and a water pan. The pan is typically equipped with a float valve, which regulates the water level. The porous plates are arranged so their bottom portions are submerged in the water pan. The porous material acts like a wick, drawing water up through the plate. As air passes through and around the plates, some of the water in the plates evaporates, increasing the humidity of the air. As the water evaporates out of the plates, additional water is drawn up through the plates by capillary action. Plate humidifiers generally have a lower capacity than other types of humidifiers. Also, their effectiveness decreases as the evaporating water leaves behind mineral buildup that clogs the porous material.

Fixed Filter Humidifiers

In a ***fixed filter humidifier,*** a pad consisting of numerous layers of a tight metallic mesh is wetted by water metered through a solenoid valve. Evaporation takes place as heated air passes through the evaporator pad. Water that has not evaporated flows to the bottom of the humidifier and is drained out. Humidified air is then returned to the heating system and enters the living area.

This type of humidifier is equipped with a solenoid water valve to regulate water flow, and can be a bypass or plenum-mounted type. **Figure 35-8** shows an under-duct humidifier that uses a fixed filter.

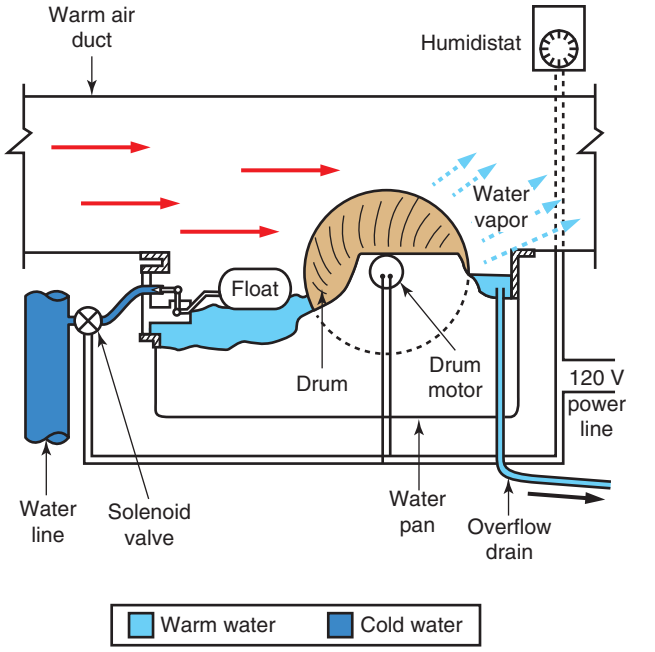
Rotating Drum Humidifiers

The main components of a ***rotating drum humidifier*** are a water pan and a rotating drum. The drum is covered in an absorbent filter sleeve and the bottom portion of it is submerged in the water pan. As the drum rotates, it soaks up water from the water pan. Moisture in drum filter sleeve material then evaporates as the moistened section of the filter sleeve is rotated into the airstream, **Figure 35-9**.

Figure 35-10 shows a typical under-duct rotating drum humidifier. A float in the water pan opens and closes a water supply valve to maintain a constant water level in the pan. The water for the humidifier is typically supplied by the building's potable water lines.

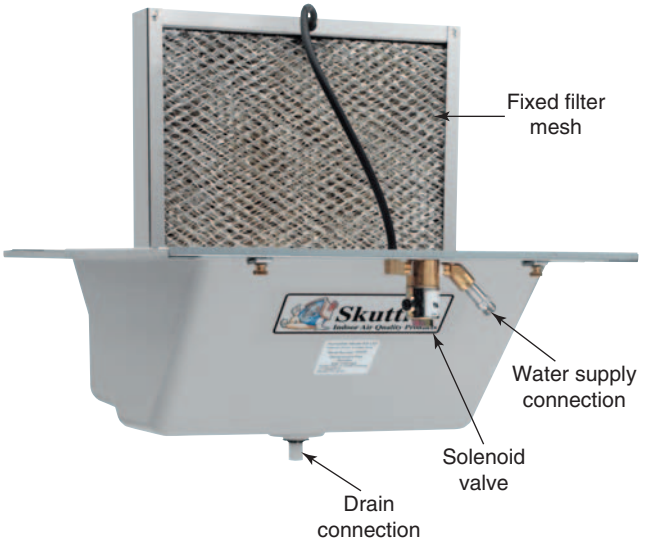
Drum humidifiers may be wired to run when the furnace operates or when the air handler blower operates. Two types of installation are common: bypass and under-duct. For a bypass installation, a standalone drum humidifier may be installed with a bypass duct running from the furnace plenum to the humidifier. An under-duct drum humidifier is installed into the bottom of a duct. In both cases, heated air passes over the wet, rotating drum and absorbs moisture. The humidified air is then reheated in the furnace and distributed throughout the house.

Drum humidifiers should be inspected annually. Their sleeves should be checked for wear and cleaned



Goodheart-Willcox Publisher

Figure 35-9. Illustration of an under-duct humidifier using a rotating drum to add moisture to the plenum air.



Skuttle IAQ Products

Figure 35-8. When a fixed filter humidifier's solenoid valve opens, water flows down across the mesh medium. Heated air circulating through the ductwork evaporates the dropping water.

Copyright Goodheart-Willcox Co., Inc. 2017

or replaced as needed. Float mechanisms should be checked for calcium buildup and cleaned. Always replace the sleeve with the correct replacement part.

Rotating Disk Humidifiers

Rotating disk humidifiers are similar to rotating drum humidifiers, but instead of having a single rotating drum covered by an absorbent sleeve, they have a series of plastic disks covered with shallow grooves. Like the drum in a rotating drum humidifier, the disks in a rotating disk humidifier are partially submerged in a water pan. Water clings to the grooves as the disks are rotated. As air passes around the disks, the residual water on the disks evaporates, adding moisture to the air.

Pro Tip

Rotating Disk Humidifier Applications

Because the disks do not deteriorate the way an absorbent drum sleeve deteriorates, less maintenance is required. Because there is no porous material to clog or deteriorate, this type of humidifier is often recommended for situations where only hard water is available.

Atomizing Humidifiers

An ***atomizing humidifier*** sprays small water droplets into the air, either by mechanically flinging water against a diffuser or by forcing it through a nozzle, atomizing the water. The atomized moisture evaporates easily in dry, warm environments.

There are three main types of atomizing humidifiers:

- Nozzle-type humidifiers.
- Impeller-type humidifiers.
- Piezoelectric (ultrasonic) humidifiers.

Nozzle-Type Humidifiers

In a ***nozzle-type humidifier***, water is forced through a restrictive nozzle, which creates a very fine mist. That fine mist is injected directly into the supply airflow, where it evaporates, raising relative humidity. Since this type of humidifier does not have a water reservoir, there is no risk of problems associated with stagnant water.

Pro Tip

Nozzle Clogging

The nozzle on nozzle-type humidifiers can easily become clogged with minerals from the water. If possible, filter the supply water. If not possible, then regularly clean the nozzle.

Impeller Humidifiers

Impeller humidifiers have a spinning disk that flings water against a diffuser, which atomizes the water on impact. The water droplets then enter the airstream, where they evaporate, raising the relative humidity of the air.

Piezoelectric (Ultrasonic) Humidifiers

Piezoelectric (ultrasonic) humidifiers use a vibrating element to atomize water (break it up into tiny droplets). Often, the vibrating element is a ***piezoelectric crystal***. A piezoelectric crystal is an electronic device that vibrates when electric current is run through it. The crystal operates at a high frequency of about 100 kHz (100,000 cycles per second). See **Figure 35-11**.

A piezoelectric humidifier produces moist air that feels cool when it comes in contact with the body. This is because the tiny droplets of water in the air quickly vaporize when they contact a warmer object. A piezoelectric humidifier is shown in **Figure 35-12**.

10

Figure 35-12. A—Piezoelectric humidifier. B—Diagram of a piezoelectric humidifier installed in a fan coil unit.

Vaporizing (Steam) Humidifiers

Evaporative and atomizing humidifiers rely on heat in the airstream to evaporate water. These systems work well when the air in the supply ducts is very warm. However, the cooler the supply air is, the less effective the humidifiers operate. Evaporative and atomizing humidifiers may not provide adequate humidification when used with certain warm-air heating systems, like low-temperature heat pumps.

Unlike evaporative and atomizing humidifiers, ***vaporizing humidifiers*** use their own heat source (electric heating coils) to create steam. This steam is then added to the air to increase its humidity. Rather than relying on the heat of the warm air, vaporizing humidifiers can accurately control their steam production using their own heat source.

An adjustable humidistat controls the electric heating coil. When the humidistat turns on a vaporizing humidifier, its water supply solenoid valve opens to fill the water reservoir. When the water level touches the water level probe, the solenoid valve closes, and the electric heater begins heating the water. Steam rises from the water reservoir and travels through tubing to enter the airstream leaving the furnace, increasing the humidity, **Figure 35-13**.

Vaporizing humidifiers are relatively easy to install. They may be designed to be installed in a duct or plenum chamber or installed remotely with a small duct connecting its steam chamber to the ductwork. Vaporizing humidifiers may be used in buildings using steam, hydronic, or warm-air heating systems.

Central Humidifier Water Supply

In most central humidifiers, water is supplied to the humidifier through potable (suitable for drinking) water lines. Typically, a saddle valve is used to tap into one of the home's water lines. Then, compression fittings are used to connect tubing between the saddle valve and the humidifier's water supply valve, **Figure 35-14**.

Code Alert

Accessing Domestic Water

When dealing with water, be aware of local building and plumbing codes. Some jurisdictions require that access to a water line include a T-fitting and a permanent shut-off valve instead of a saddle valve. Codes may also place restrictions on the use of compression fittings. Check with local building authorities before beginning work on such a project. Note that this often applies to water accessed for central humidifiers and also ice makers and water dispensers for refrigerator-freezers.

Water from city water mains or from wells contains various types of foreign matter. If the water is to be used in a humidifier, this foreign matter should be treated or removed. The quality of water varies with its source:

- ***Soft water*** is natural, untreated water with a low mineral content of less than 5 grains of hardness per gallon and no chlorides. The natural source is rainwater.
- ***Softened water*** is water in which minerals have been removed by the ion exchange process (as with a water softener). When water is softened, unwanted mineral ions are replaced with water-soluble sodium salts.
- ***Demineralized water*** is water that has been treated to remove minerals.
- ***Medium hard water*** (well water) is untreated water with 5 to 15 grains/gal. of mineral content.
- ***Very hard water*** (well water) is untreated water with over 15 grains/gal. of mineral content.

Hard water is tested by using a water hardness test kit. These kits include two strips that are dipped into the water source. The resulting color change indicates the hardness of the water. Consult a reference chart for recommendations for water filtration.

Ideally, distilled water would be used in humidifiers because it does not put any foreign matter into the air. In addition, it leaves no deposits in the humidifier or in the duct system. Although distilled water would be the best type of water for a humidifier, it is not available in sufficient quantity for use in central humidifiers. City water is often used and results in minimal calcium buildup and corrosion of metal parts. Annual cleaning of a humidifier will help prevent failures. In areas that have hard or very hard well water, a water softener is often used to remove minerals from the home's water supply. Humidifiers that operate with well water and softened well water may require more frequent maintenance.

35.2.2 Portable Humidifiers

Central humidifiers can be easily added to forced-air heating systems. However, central humidifiers cannot always be added to heating systems that use hydronics, steam, or electric heat. Also, some buildings may not need humidification in every room. In such cases, occupants may decide to use a portable humidifier.

A ***portable humidifier*** is a stand-alone unit placed where a specific humidity level needs to be maintained. These are used for room humidity control, not building humidity control. **Figure 35-15** shows a typical portable humidifier.

Goodheart-Willcox Publisher

Figure 35-14. A self-tapping water valve that can be used to access potable water for humidifiers in jurisdictions where allowed.

Goodheart-Willcox Publisher

Figure 35-15. Portable humidifiers often have a water tank that needs to be removed and refilled after a cycle.

10

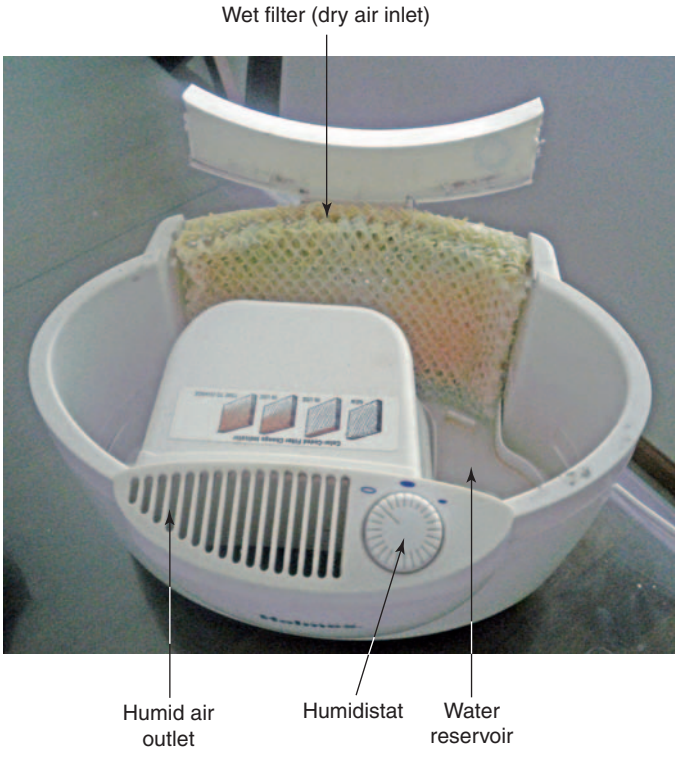
Copyright Goodheart-Willcox Co., Inc. 2017

Like a central humidifier, a portable humidifier is used to maintain the relative humidity in a given space. The components of a portable humidifier are housed in a single cabinet, which is located in the room or space in which humidity is to be increased. Many portable humidifiers add moisture by circulating air across a wet filter, though some units use ultrasonic humidification.

The cabinet has air intake and outlet openings. Often, a fan circulates air through the cabinet. The wet filter is partially submerged in a reservoir filled with water. Water wicks up the filter and is exposed to the airstream. With its water tank removed, a portable humidifier's wet filter is accessed for inspection or replacement, as shown in **Figure 35-16**.

An electric heating element is sometimes installed in the water pan to warm the water for greater evaporation. The controls on a typical cabinet humidifier consist of an on-off switch and a humidistat, which controls the fan motor and other components, depending on the type of humidifier.

Some portable humidifiers use a float-operated switch that turns on an indicator light when the water level in the water pan gets too low. Most units must be refilled manually. However, some can be connected to building water supply and refilled by means of a valve controlled by an automatic float mechanism.



Goodheart-Willcox Publisher

Figure 35-16. With its water tank removed, a portable humidifier's wet filter is revealed. A fan draws in dry air through the wet filter.

Portable humidifiers are easily maintained. The water tank and the wet filter can be removed and cleaned or replaced. Maintenance should be performed in strict accordance with the manufacturer's schedule to keep the humidifier working properly.

35.3 Dehumidifying Equipment

Excessive humidity is a common problem that can cause discomfort to occupants, cause wood to swell, and promote the growth of mold and mildew. If a conditioned space's relative humidity is too high, some type of dehumidifying equipment may be needed. For example, buildings using electric heat frequently have high relative humidity. If a building envelope is very tight, humidity can build up as a result of normal activity. Common sources of humidity include:

- Cooking.
- Wash basins.
- Lavatories.
- Respiration.
- Perspiration.
- Laundry.
- Showers and bathing.
- Houseplants.
- Pets.

35.3.1 Dehumidifiers

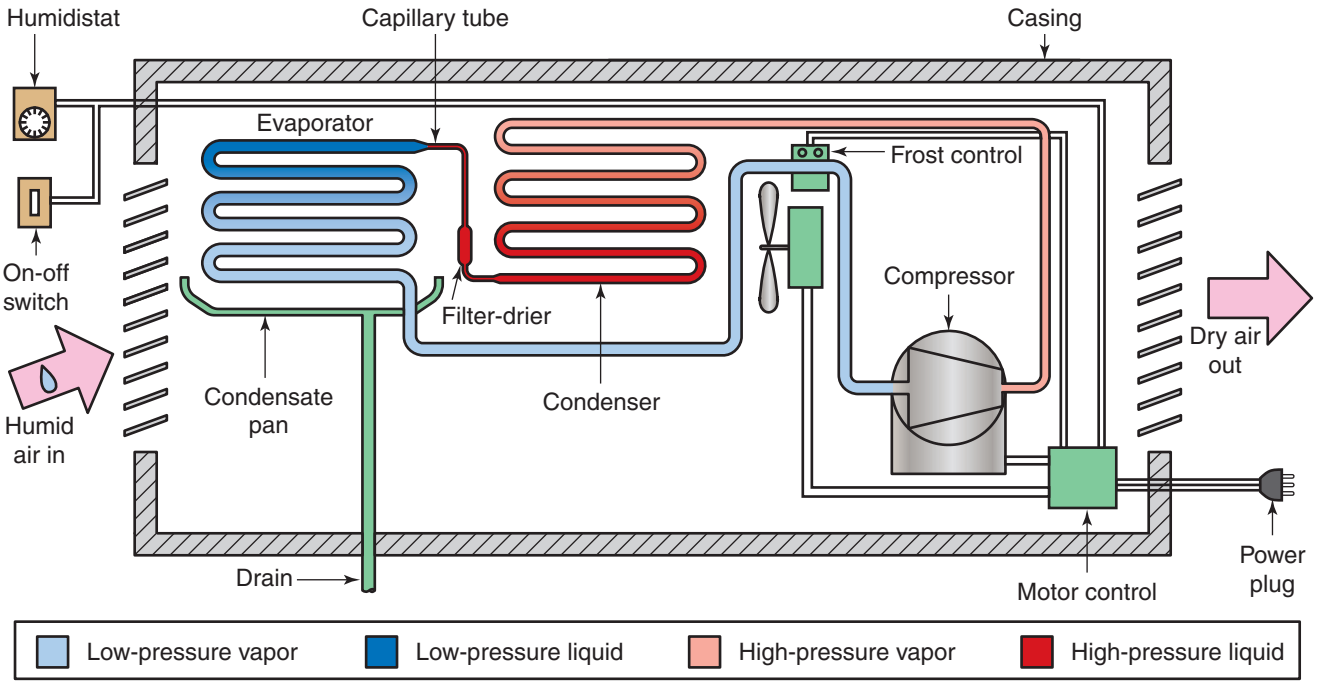
A ***dehumidifier*** is a device that decreases relative humidity by condensing moisture out of the air. Dehumidifiers have a cooling coil over which air is blown. By keeping the coil temperature below the dew point of the air, moisture condenses out of the air when the air comes into contact with the cold surface.

Typically, a dehumidifier consists of a hermetic compressor, condenser, and evaporator with a capillary tube refrigerant control in a single packaged unit. A motor-driven fan forces air through the evaporator. Due to the low evaporator temperature, moisture carried in the air condenses on the evaporator surfaces. The moisture drips to the bottom of the evaporator and into the condensate trough, **Figure 35-17**.

Air flowing through a dehumidifier's evaporator coil is both cooled and dehumidified. The air then flows through the condenser coil. Heat from the condenser is transferred to the air flowing through it. Therefore, the air leaving a dehumidifier is about the same temperature as it was when it entered. However, air discharged from a dehumidifier has a lower relative humidity than its intake air.

Dehumidifiers may be standalone, portable units for spot dehumidification or units incorporated into

Copyright Goodheart-Willcox Co., Inc. 2017



Goodheart-Willcox Publisher

Figure 35-17. The components and operation of a room dehumidifier are similar to those of a window air conditioner.

a central HVAC system for building dehumidification. Often, a house may have acceptable humidity on the ground floor and upstairs but high humidity in its basement or crawlspace. In such a case, a portable dehumidifier is the solution, **Figure 35-18**.

Goodheart-Willcox Publisher

Figure 35-18. This portable dehumidifier is located in a basement mechanical room.

A whole house dehumidifier is ducted into the airstream of a forced-air furnace. Air that is drawn from all the rooms of a building through the return air duct passes over the dehumidifier's evaporator coil to remove moisture. This dehumidified air then returns to the rest of the ductwork, **Figure 35-19**.

Ducting arrangements can vary by application. Some ducting arrangements require the dehumidifier to run simultaneously with the HVAC system, and others require the dehumidifier to run during the Off cycle. A dehumidifier can work with the air conditioner to balance humidity levels, or it can work independently of the air conditioner. This arrangement will affect how controls are wired.

General Filters, Inc.

Figure 35-19. A typical whole house dehumidifier. Ducts divert air through the dehumidifier and return it into the airstream dehumidified.

Copyright Goodheart-Willcox Co., Inc. 2017

Some duct arrangements used with dehumidifiers may incorporate automatic dampers to regulate airflow to dehumidify two different zones to different levels. Some ducts may include dampers be used for fresh air inlet from outside.

A dehumidifier is usually controlled by a humidistat. However, some electronic thermostats have a built-in humidistat function. These can be used to control heating, cooling, humidity, and fresh air intake for indoor air quality control. In addition to an on-off switch and a humidistat, a dehumidifier usually has other controls for safety and optimal operation.

One such control is a float switch. If the condensate drain line becomes clogged or restricted, moisture condensed in the dehumidifier could spill out. Before spilling occurs, a float switch responds by turning off the dehumidifier's compressor, which stops the condensing and accumulation of moisture.

A dehumidifier's evaporator coil surface temperature must be kept above freezing, otherwise frost or ice could form on the coil. This could happen when a dehumidifier operates for a long time or conditioned space air is already very cool. If frost builds up enough, it could block airflow and stop dehumidifying the air. To prevent this from happening, a frost control element monitors temperature. If temperature drops too low, the frost control will turn off the dehumidifier's compressor. However, the fan will continue to operate to bring as much heat as possible to melt any frost quickly. Once the temperature rises, the frost control element will turn on the compressor to begin dehumidification again.

35.3.2 Use of Desiccants

Sometimes, dehumidification of air is accomplished with special chemicals called ***desiccants***. The chemicals are usually circulated so they are exposed to the air. Moisture from the air is adsorbed by the chemicals. The chemicals are then circulated to a different chamber where they are heated. Any moisture adsorbed by the chemicals is released as water vapor when the chemicals are heated. The moisture driven out of the chemicals is exhausted to an area outside the conditioned space. The heated, dry chemicals are then ready to repeat the process.

35.4 Servicing and Installing Humidifiers

Humidifier capacity should be based on the size of the space being conditioned and the design conditions in that space. The humidifier must be able to deliver adequate moisture to the air under all operational conditions. Once selected, humidifiers must be carefully installed. If the unit has a water reservoir, mount it so it is level in all directions. Use a spirit level to check the angle.

The water feed line should be tapped into a cold water line. This is often done in the same manner as an ice cube maker line, using a piercing or saddle valve. See **Figure 35-20**. Check with local authorities to see if this is acceptable. After water lines are connected, check for leaks.

The overflow drain tube (bleeder tube) should slant down all the way to the outlet. The outlet should be at least 1" above the open drain to prevent siphoning of waste water back into the potable water supply.

The humidifier may be controlled by a low-voltage humidistat and a relay or by a 120 V humidistat. Electrical installation should be done according to the local electrical codes. The humidifier must be plugged into a grounded receptacle.

After installation, the unit should be turned on (electricity and water) and checked for proper operation. After each month of operation, check for bacterial growth and scale buildup inside the humidifier. If evidence of bacterial growth, algae, or scale is found in the humidifier, clean the unit thoroughly and treat the water in the reservoir on a regular schedule to prevent future problems. Water treatment compounds are available at hardware stores and HVAC supply dealers.

Chapter Review

Summary

- Relative humidity is the ratio of the moisture content of air compared to the maximum amount of moisture that the air can hold at its current temperature. The warmer air is, the more moisture it can hold. People are generally comfortable at a relative humidity between 30% and 50%.
- Low relative humidity can shrink wood and dry out skin. High humidity causes wood to swell and allows mold and mildew to grow. During the heating season, if indoor relative humidity levels are not adjusted to correspond with outdoor temperatures, condensation can form inside on walls and windows. During extremely cold weather, indoor relative humidity should be kept lower than normal.
- Humidity can be controlled in different ways. Air-conditioning systems can remove excess humidity. Humidifiers can add moisture to the air, and dehumidifiers can remove moisture from the air.
- Humidistats measure the moisture content of the air and turn on or off humidity control equipment.
- Humidifiers can be part of a central HVAC system or standalone, portable units. Central humidifiers may be installed outside the plenum using bypass ductwork or directly into the plenum.
- Humidifiers can be classified by the way they introduce moisture into the air. There are three main categories of humidifiers: evaporative humidifiers, atomizing humidifiers, and vaporizing humidifiers.
- As air passes through an evaporative humidifier, moisture from a dampened element evaporates and increases the humidity of the air. Common types of evaporative humidifiers include plate, fixed filter, rotating drum, and rotating disk.
- Atomizing humidifiers add a mist of fine water particles to the air by either flinging water or by forcing the water through a nozzle. Common types of atomizing humidifiers include nozzle-type, impeller, and piezoelectric (ultrasonic).
- Vaporizing humidifiers use a concentrated heat source to produce steam, which enters the airstream and increases humidity.
- In most central humidifier installations, water is supplied to the humidifier through the building's potable water lines. Water often contains minerals that leave a residue as the water is evaporated. The most common mineral removal process is ion exchange water softening.
- If hard water or softened hard water is used in a humidifier, it will require more frequent maintenance than a humidifier that uses natural soft water or city water.
- Portable humidifiers are standalone units that are placed in the space that requires humidity control. In most portable humidifiers, the water supply must be replenished manually.
- A dehumidifier is a device that removes excess humidity from the air. The most common type of dehumidifier is very similar to a window air conditioner in design and operation. Air drawn into the dehumidifier passes over the cold evaporator, which causes moisture to condense out of the air. The air then passes over the warm condenser and is reheated before it exits the dehumidifier.
- Other methods of dehumidification use a desiccant to remove unwanted moisture from the air. In these systems, a chemical is exposed to the air and adsorbs moisture. The chemical is then circulated to a different part of the system where it is heated. As the chemical is heated, the moisture it has adsorbed is vaporized and vented to an area outside the conditioned space.
- Humidifiers must be properly sized to provide adequate moisture under all operational conditions. The water supply line should be tapped into a cold water line. The humidifier's drain line should end at least 1" above a drain to prevent siphoning. Electrical hookup of the humidifier must be in accordance with local electrical codes, and water connections must be done according to local plumbing and building codes.

Review Questions

Answer the following questions using the information in this chapter.

1. The ratio of the moisture content in the air compared to the maximum amount of moisture that the air can hold at its current temperature is called _____.
   A. hygroscopic level
   B. piezoelectric pressure
   C. relative humidity
   D. vapor saturation level
2. When humidity is too high in a building, the following events may occur, *except* _____.
   A. frequent generation of static electricity
   B. growth of mold, bacteria, and fungus
   C. formation of condensation on cold surfaces
   D. swelling of hygroscopic materials
3. When a humidifier adds moisture to air already heated by a furnace, the temperature of the air _____.
   A. decreases somewhat
   B. increases somewhat
   C. increases a lot
   D. remains steady
4. Being a measure of ventilation rate, _____ refers to the replacing of the entire volume of air in one hour.
   A. air changes per hour (ACH)
   B. available static pressure (ASP)
   C. external static pressure (ESP)
   D. total air balance (TAB)
5. A humidistat is a control device that responds to changes in conditioned space humidity by doing the following tasks, *except* _____.
   A. cycle on and off the attic exhaust fan
   B. modulate dampers and air mixers
   C. turn on or off a dehumidifier
   D. turn on or off a humidifier
6. A traditional electromechanical humidistat senses humidity using a(n) _____.
   A. desiccant
   B. hygroscopic element
   C. piezoelectric crystal
   D. solid-state sensor
7. Humidifying an entire building's conditioned space, central humidifiers are categorized by the following installation types, *except* a(n) _____ humidifier.
   A. bypass
   B. portable
   C. plenum-mounted
   D. under-duct
8. The following humidifiers are categorized as atomizing, *except* _____.
   A. hygroscopic
   B. impeller-type
   C. nozzle-type
   D. piezoelectric (ultrasonic)
9. Using their own heat source (electric heaters), _____ humidifiers add moisture to air by creating steam.
   A. piezoelectric (ultrasonic)
   B. plate
   C. rotating drum
   D. vaporizing
10. Central humidifiers are typically supplied with water from _____.
    A. a building's tapped water lines
    B. bottled water
    C. rain
    D. sewer piping
11. Moisture from air passing through a dehumidifier condenses on its _____.
    A. compressor
    B. condenser
    C. evaporator
    D. humidistat
12. Before condensation spills out of a dehumidifier, its _____ shuts off the compressor, stopping the production and accumulation of moisture.
    A. float switch
    B. frost control element
    C. humidistat
    D. hygroscopic element
13. To prevent or undo the blocking of airflow through a dehumidifier, the _____ shuts off the compressor.
    A. float switch
    B. frost control element
    C. humidistat
    D. hygroscopic element

Copyright Goodheart-Willcox Co., Inc. 2017

14. Special chemicals exposed to conditioned air to adsorb moisture and release it outside of the conditioned space are called _____.
    A. bioaerosols
    B. desiccants
    C. hygroscopic elements
    D. piezoelectric crystals

15. Why must the overflow outlet of a whole house humidifier be installed at least 1″ above an open drain?
    A. The gap allows gasses to escape from the condensate before it enters the sewer system.
    B. The gap prevents drain water from being siphoned back into the potable water supply.
    C. The gap prevents humidifier vibration from stressing the drainpipe.
    D. The gap provides an air break that allows the condensate to drain properly.

- 36.8.3 Multistage HVAC Systems
- 36.8.4 Low-Voltage Measurements
- 36.8.5 Closing a Troubleshooting Service Call
- 36.8.6 Line-Voltage Thermostats
- 36.8.7 Domestic and Commercial Refrigeration Systems

36.9 Zoned Systems
- 36.9.1 Zoned System Operational Sequence for Heating
- 36.9.2 Zoned System Operational Sequence for Cooling
- 36.9.3 Troubleshooting Zoned Systems

Learning Objectives

Information in this chapter will enable you to:

- Describe how a thermostat can function in different roles in HVACR systems.
- Explain the operating principles of different temperature-reactive components and the switching components used in thermostats.
- List the features and options available in modern thermostats.
- Understand the differences among heating, cooling, combination, and multistage thermostats.
- Understand the purpose and operation of anticipators in thermostats.
- Summarize the operations and applications of line-voltage, low-voltage, and millivolt thermostats.
- Identify and explain the operation of line-voltage thermostats.
- Explain the operation of low-voltage thermostats.
- Understand the use and operation of millivolt thermostats in standing-pilot heating systems.
- Explain the use and operation of wireless and power-stealing thermostats.
- Program and set up a programmable thermostat.
- Identify thermostat wiring terminals by their letters.
- Arrange free cooling through the use of an air-side economizer in a forced-air HVAC system.
- Evaluate a building to determine suitable locations for thermostats and remote sensing devices.
- Diagnose an HVAC system that is not operating properly by using its thermostat.
- Diagnose a high current draw on a step-down transformer used with a low-voltage thermostat.
- Understand the operation and purpose of the various components used in a forced-air zoned system.
- Troubleshoot a forced-air zoned system that is not operating properly.

Review of Key Concepts

Reviewing these concepts from earlier chapters will help you understand new concepts presented in this chapter:

- Series circuits provide current with a single path to follow, whereas parallel circuits allow current to flow along two or more electrical paths. Therefore, in a series circuit, the voltage drop across each electrical load is added together to calculate the total circuit voltage drop. In a parallel circuit, amperage through each electrical load is added to calculate the total circuit current. (Chapter 12)
- According to Ohm's law, voltage equals current times resistance ($V = I \times R$). According to Watt's law, electrical power (watts) equals current times voltage ($P = I \times E$). (Chapter 12)
- Sensing devices, such as bimetal devices, thermistors, and fluid-filled sensing bulbs, react to temperature change and can be incorporated in various control devices. (Chapter 17)
- Solid-state (semiconductor) electronic components are incorporated into many sensing and switching devices in HVACR systems. (Chapter 14)
- Wiring diagrams for HVACR systems can be ladder diagrams, which show sequence of operation, or pictorial diagrams, which show the location and wiring interconnection of devices. (Chapter 16)
- A control system relies on processing feedback based on its set point, control point, and offset. (Chapter 16)
- Airflow through ductwork can be managed manually or automatically using dampers. (Chapter 29)

Introduction

10

One of the most common control devices in HVACR systems is the thermostat. A ***thermostat*** is a sensing device that reacts to temperature change. Often, a thermostat reacts in order to control a system's starting and stopping when preset temperature conditions are reached. Conditioned space temperature is usually the primary variable that must be measured, but many other temperatures can be measured to monitor system operation and efficiency.

Copyright Goodheart-Willcox Co., Inc. 2017

36.1 What Is a Thermostat?

Over time, specific industries, such as HVACR, develop their own jargon. As a result, miscommunication can result when an industry person and a non-industry person speak together. For example, the word *thermostat* does not mean the same thing to everyone. To most non-HVACR people, a thermostat is just the device they operate to change the temperature in their building. To HVACR people, a thermostat may be any kind of switch that automatically responds to a change in temperature, such as a bimetal disc. Many HVACR parts manufacturers list bimetal switches as thermostats. These thermostats are often used as safety devices, such as some roll-out switches in gas furnaces. Be mindful of the word *thermostat* and what that term may mean to customers, clerks, and any person using that word. This chapter will focus on the thermostat as it is understood by the average non-HVACR person: as the control device running a building's heating and cooling system.

Thermostats were traditionally a simple set of contacts that closed or opened on a temperature rise or fall. They required the occupant to manually adjust the set point to maintain a room at the desired temperature.

Modern thermostats can be much more responsive and intuitive. Wi-Fi enabled thermostats, for example, can be operated from anywhere in the world using a smartphone. ***Learning thermostats*** can remember an occupant's desired set point and adapt the HVAC system operation to automatically program On and Off cycles and temperature set points. Some thermostats can ***modulate*** system operation (increase or decrease intensity), in addition to starting and stopping a system. This can result in a significant reduction in energy usage over the life of the thermostat. This chapter describes the basic components of thermostats and reviews specific thermostats in depth.

36.1.1 Thermostat Sensing and Operation

An important part of a thermostat is its sensing element. This component reacts to temperature change. There are several different types:

- Thermistor.
- Bimetal strip.
- Rod and tube.
- Bellows or diaphragm.
- Thermocouple.
- Hydraulic.
- Digital sensor.

Figure 36-1 shows various sensing elements used in different types of thermostats. A bimetal strip reacts to changes in temperature by bending. It is usually wound into a coil, which allows a longer strip to be used in a smaller space. The longer the strip, the greater the movement it will produce.

Contacts and Magnets

Having a long bimetal coil that can produce more movement for each degree of temperature change is designed to reduce ***contact point bounce***, which causes arcing. Using magnets to hold contacts closed also reduces arcing and contact point bounce. Longer bimetal strips also reduce contact "walking" (sliding over each other). Contact walking can also cause arcing.

Some three-wire thermostats have two sets of contacts. One set is for "pull-in" and the other is for "hold-in." Pull-in contacts are energized first. They are usually larger and draw more current than hold-in contacts. The hold-in contacts are then energized to maintain the contacts in a closed position. These contacts maintain stable connections.

Reed Switch

Bimetal strips in thermostats are not always designed to work with a pair of contacts. A bimetal strip can also work in conjunction with a reed switch or a mercury switch. A ***reed switch*** consists of a pair of electrical contacts in a glass tube that are opened and closed by an outside magnet. A magnet connected to the movable end of a bimetal coil opens and closes a reed switch's contacts based on how close it is to the reed switch, **Figure 36-2**.

Mercury Switch

The movable end of a coiled bimetal strip may hold a mercury switch. A ***mercury switch*** consists of a sealed tube containing a small puddle of mercury and two to four contacts made of the ends of wires that run outside the tube, **Figure 36-3**.

Since a mercury switch opens and closes based on how far it is turned or tilted, it may also be called a *tilt switch*. Since the tube is enclosed and the mercury moves quickly from end to end when tilted, electrical arcing does not occur.

Thinking Green

Proper Mercury Thermostat Disposal

Older thermostats used mercury as a switching element. Mercury is a toxic substance. Prolonged exposure may cause severe health effects. It is also harmful to the environment. Due to its health risk and harm to the environment, the use of mercury thermostats is being phased out and banned in some nations. Mercury

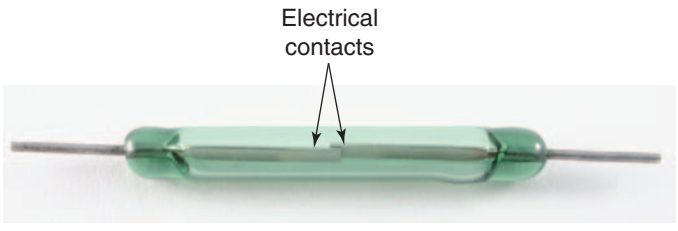
Goodheart-Willcox Publisher

Figure 36-1. Basic types of thermostat sensing elements.

is a hazardous waste. Proper disposal of mercury thermostats is required by law. Mercury should only be sent to an authorized recycler, **Figure 36-4**. The Thermostat Recycling Corporation is an industry-funded, nonprofit organization that offers recycling services to HVACR contractors. Many states and municipalities hold mercury and hazardous material recycling and collection programs. Check with your local town hall for additional information on local programs. Additional information about proper mercury handling and disposal procedures can be found at the Environmental Protection Agency website.



Goodheart-Willcox Publisher

Figure 36-2. A reed switch may be used in a thermostat with a bimetal coil and magnet.

A mercury switch's sealed glass tube prevents dust, lint, and oxygen from wearing and corroding the contacts. As the bimetal coil warms, it expands, which tilts the mercury tube. Once it turns far enough, mercury slides from one end of the tube to the other end. At one or both ends, the mercury puddle flows to complete the circuit between

Figure 36-4. Take old mercury thermostats to an authorized recycler to ensure they are properly handled.

the wires. Mercury switches were used extensively until the 1990s. They are still found in many older thermostats in residential and commercial buildings.

Caution

Mercury Exposure

Mercury is an extremely hazardous material and must be disposed of properly in accordance with local and federal guidelines. If a mercury spill occurs, do not touch it. Call local hazardous material (HAZMAT) disposal authority. Persons exposed to mercury should seek medical help immediately.

As a coiled bimetal strip reacts to heat by expanding or contracting, it tilts the mercury switch. The puddle of mercury always flows to the lowest point in the glass tube. If the mercury puddle is touching any two or more contacts, it will allow current to flow through the wires. When a bimetal coil expands or contracts in the other direction, it will tilt the glass tube, and the mercury puddle will flow away from those contacts, opening the circuit and stopping the current, **Figure 36-5**.

Pro Tip

Leveling a Thermostat with a Mercury Switch

Be aware of how important angle and tilt is to mercury switch operation. If a thermostat with a mercury switch is mounted at an angle, its set point calibration can be off. On every service call, a technician should make sure to check that a thermostat is mounted level, as this will affect the temperature at which the mercury flows from one end of the tube to the other.

Figure 36-6 shows a mercury switch thermostat wiring diagram for a hot water heating zone valve. When connections #5 and #4 are closed, the motorized zone valve opens. When the thermostat's bimetallic strip tilts the mercury tube the other direction, connections #5 and #6 close. This closes the motorized zone valve.

Due to the hazardous nature of mercury, many thermostats use other sensing elements to monitor temperature. Electronic thermostats use a small thermistor to sense room air temperature. There are no moving parts in an electronic thermostat. A thermistor changes its electrical resistance in response to temperature change.

Safety Note

Handling Mercury Spills

In the event of a mercury spill, immediately evacuate the area. Mercury spills may release mercury vapor into the surrounding area. Stay out of the exposed area for at least 15 minutes. Ventilate the area and shut off HVAC equipment and open windows. Follow these guidelines:

- Never touch mercury.
- Never vacuum up mercury. Doing so would spread it through the air.
- Never wash mercury down the drain.
- If you get any mercury on your clothing or skin, immediately remove contaminated clothing and wash all contaminated skin areas with soap and cold water. Seek medical attention.
- Contact a local hazardous material disposal agency for cleanup and disposal instructions.

36.1.2 Thermostat Features and Options

When selecting a thermostat for a given application, be aware of all the available features and options. Several to review include the following:

Power source:

- Low-voltage: 24 Vac.
- Power-stealing.
- Battery.
- Millivolt—from heat applied to a thermocouple device.
- Line voltage: hardwired into the building service at 120 V, 120/240 V, 208 V, or 240 V.

Temperature-sensing device:

- Thermistor.
- Thermocouple.
- Bimetal coil.

Switching:

- Solid-state.
- Reed (magnetic) switch.
- Diaphragm switch.
- Mercury switch.
- Bellows switch.
- Contacts with magnets.

Contact points:

- SPST (single-pole, single-throw) two-wire.
- SPDT (single-pole, double-throw) three-wire.

Changeover (how the system switches between heating and cooling modes):

- Manual—usually has a three-position selector switch: Heat, Off, and Cool.
- Automatic—occurs whenever the set point temperatures are sensed.

Programming options:

- Learning.
- Nonprogrammable.
- Weekdays and weekend.
- 7-day.
- Vacation/away settings.

Display:

- Touchscreen.
- Smartphone.
- LCD.

Service reminders:

- None.
- Air filter change.
- Air cleaner.
- Humidifier water pad change.
- UV lightbulb change.

Communication interface:

- Wi-Fi.
- Ethernet (hard-wired).
- Internet accessible.
- Home automation system interface.

10

Copyright Goodheart-Willcox Co., Inc. 2017

Special features:

- Talking thermostat.
- Easy-to-read display.

Temperature display:

- Indoor.
- Outdoor.
- Multiple (in different set point zones).

36.2 Types of Thermostats

There are many types of thermostats that control heating and cooling systems. The two basic ones are heating thermostats and cooling thermostats. Often these are combined into one unit called a ***heating-cooling thermostat*** or a *combination thermostat*. Some heating-cooling thermostats change from one mode of operation to another automatically, while others must be switched manually.

36.2.1 Heating Thermostats

This section introduces the basic operation of a heating thermostat. A residential heating thermostat typically controls a 24 Vac or 120 Vac circuit. However, there are also some heating thermostats that control millivolt circuits.

Heating thermostats usually operate on a 0.5°F to 2°F (0.3°C to 1°C) differential or smaller. This allows close temperature control. Older thermostats use a bimetal strip as the temperature-sensing element instead of a thermistor. A small magnet connected on or near the contacts is often used to produce snap action between the contact points. The differential is usually established by moving this small magnet closer to or farther from the bimetal strip. Moving the magnet closer reduces the differential. Moving the magnet farther away increases the differential. A range adjustment is usually a direct force on the bimetal. Thermistors use an electric resistance element for temperature control. It is possible to obtain differentials of 0.01°F using thermistors for more accurate control.

Some thermostats are hydraulically operated. **Figure 36-7** shows a diaphragm mechanism. The diaphragm moves as a liquid expands and contracts. The dial adjusts the setting and the small magnet produces snap action in the thermostat. Hydraulic thermostats are primarily used in industrial applications where having wiring in an enclosed area may be a safety issue due to explosive fumes, such as in manufacturing processes.

Thermostats are rated by the voltage they carry. They are also rated by the controls to which they are electrically connected. These controls open the circuit when the temperature rises. They complete the circuit when the temperature falls.

One type of 24 V thermostat is a two-wire 24 V thermostat. It controls the 24 V furnace devices directly. **Figure 36-8** shows a wiring circuit for a control using a mercury switch. The circuit is designed for forced-air heating.

Another type of low-voltage thermostat has three wires connected to it. The wires are connected when the thermostat's sensing element reacts to a temperature drop. Once these wires are connected, they close a holding circuit. The wires will open the circuit when the thermostat's sensing element reacts to a rise of temperature. This type of thermostat must be used with a relay. The relay opens and closes the 120 V circuit for an oil burner, gas burner, or electric heater.

A holding circuit is used in larger applications where a 24 V relay does not have enough strength to hold down the gas relay. The 24 V circuit signals a 120 V circuit, which is capable of providing sufficient current to hold down a large burner relay.

Another type of 24 V thermostat has separate on and off controls. One of these opens the contacts on a rise in temperature to cycle off the heat. The other closes contacts on a drop in temperature to cycle on the heat. This type of thermostat is used on gas burners, oil burners, or electric heaters.

Pro Tip

Open Thermostat Contacts

If contact points remain open when they should be closed, there may be lint or some other substance between the points, resulting in an open circuit. To clean contact points, first shut off power to the thermostat. Then use a piece of clean paper to rub between the contacts. If the contacts are pitted, a fine emery cloth may also be used to clean the terminals.

If a mercury switch remains open when it should be closed, the open circuit may be caused by a mercury tube that is not level. Use a plumb line or level to carefully level the tube.

Heating systems are equipped with safety controls known as ***temperature limit switches***. Most furnaces contain a bonnet temperature limit, which ensures that the furnace plenum does not exceed recommended temperatures. A bonnet temperature limit is also known as a *high-limit*. Large-capacity heating systems use a relay along with low-voltage thermostats to control high-wattage loads. Some technicians prefer low-voltage thermostats with a relay on all electric heating systems. This reduces system overshoot.

System overshoot (heat lag) occurs when a furnace shuts down and the amount of residual heat that has built up is sent through the ductwork and into the conditioned space, raising the temperature above the set point. Some thermostats compensate for heat lag and are programmed to shut down the furnace and blower before the thermostat reaches the set point.

Temperature Swing

Some line-voltage thermostats produce a wide swing of temperatures. Conditioned space temperature will vary too much. ***Temperature swing*** is the total difference of the high and low temperature in a room. This includes values below the cut-in temperature and above the cut-off temperature.

For example, a thermostat is set for 75°F (24°C) with a 6°F (3.3°C) differential. However, the room cools to 70°F (21°C) before any heat is delivered to the room, and then the room warms to 80°F (27°C) before heat flow is stopped. The 10°F (5.6°C) temperature swing may be too large for comfort.

Pro Tip

Thermostat Setting Adjustment

When adjusting a thermostat, avoid heating it with your hands or breathing on the sensing element. If the thermostat is warmed above the room temperature, incorrect thermostat settings may result.

When a thermostat's points close at the beginning of a heating cycle, it takes a certain amount of time for the furnace to heat up and to move this heat to the conditioned space. During this start-up period, the conditioned space temperature may continue to drop, even as much as a few degrees. This temperature drop between the time the heating system turns on and the time heat is delivered to the conditioned space is called ***system lag***. To avoid the discomfort of lower temperatures, a system's cut-in temperature may need to be set about 1°F (0.6°C) above the lowest temperature desired.

Copyright Goodheart-Willcox Co., Inc. 2017

The combination of system lag and system overshoot often results in occupant discomfort and frustration, because of the wide range of temperatures in a conditioned area. For example, a system has a set differential of 6°F (3.3°C), and an occupant sets the heating system for 75°F (24°C). This means that the heating system will turn on at 72°F (22°C) and turn off at 78°F (26°C). However, due to system lag, heat only begins reaching the room when the temperature has dropped to 70°F (21°C). Also, heat only stops warming the room by the time it reaches 80°F (27°C). In one cycle of operation, the temperature swings from 70°F to 80°F (21°C to 27°C), **Figure 36-9**.

This wide temperature swing can be reduced but not completely eliminated. To stop system overshoot, a thermostat would need to shut off the system before the set temperature is reached in the conditioned space. In order to do this, additional heat above room temperature must be produced for the temperature-sensing device to detect in order to switch off the heater early.

Heat Anticipators

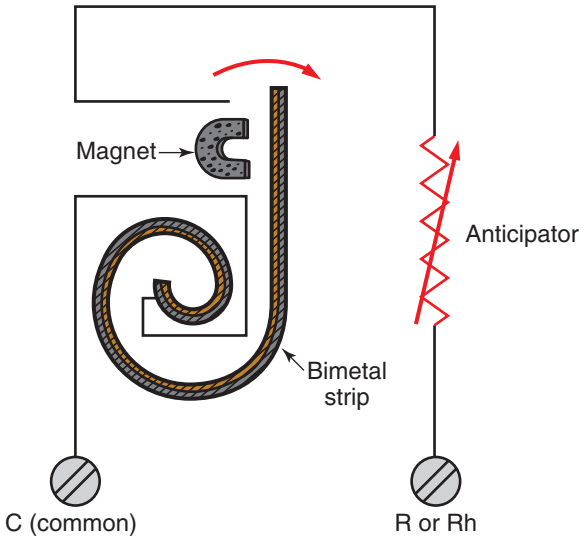
Electronic thermostats using a thermistor as the sensing element are simply programmed to provide control as standard heating and cooling anticipators. The system may also have an algorithm or program that learns how long it takes the system to reach the set point temperature and automatically shuts down the unit prior to reaching the set point.

Mechanical thermostats generate heat in the thermostat's electrical circuitry. Often, it is not enough to keep the thermostat temperature higher than the conditioned space temperature. To produce this higher temperature, many thermostats contain a small heating coil. When the thermostat closes its contacts to call for heat, current flows through the coil to produce enough heat to keep the thermostat warmer than the ambient air temperature. These small resistance coils are usually called ***heat anticipators***. **Figure 36-10** shows a heating thermostat wiring schematic diagram with a heat anticipator.

During the heating cycle, a thermostat with a heat anticipator remains about 1°F (0.6°C) warmer than the conditioned space. If the thermostat is set for 74°F (23.3°C), the thermostat will turn off the heater while the room temperature is actually 73°F (22.8°C). Then residual heat from the furnace will continue to flow into the conditioned space, and room temperature will rise to 74°F (23.3°C). By turning off the heating system before this occurs, system overshoot is reduced.

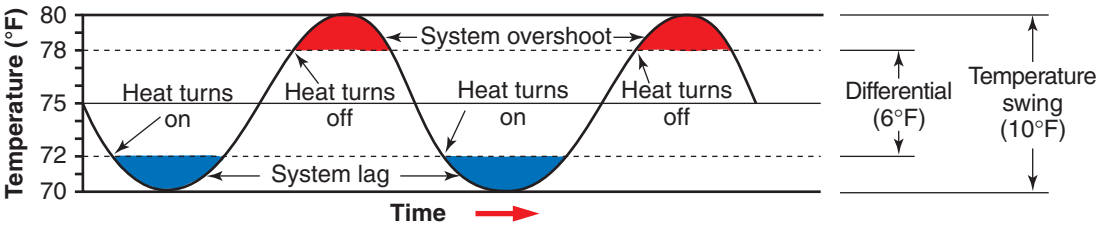
Heat anticipators can be either fixed or adjustable. They are most often used on low-voltage and millivolt thermostats (24 Vac and 750 mV). The anticipator size (current capacity) is related to the current flowing through the thermostat contacts. Current level depends on the electrical loads connected to the thermostat for both millivolt and 24 Vac thermostats, such as a gas valve or relay coil. The current varies between 0.15 A and 1.0 A.

With a fixed anticipator, current through the anticipator equals the control circuit current. An adjustable anticipator is regulated to match the control circuit current. Manufacturer's installation



Goodheart-Willcox Publisher

Figure 36-10. This diagram shows a heat anticipator wired in series with the bimetal coil. In this design, the heat anticipator warms the coil when current flows through it, which is only when the heating system is producing heat for the conditioned space.



Goodheart-Willcox Publisher

Figure 36-9. Chart showing temperature swing.

Copyright Goodheart-Willcox Co., Inc. 2017

instructions indicate the setting and adjustment process for heat anticipators.

An anticipator with a higher rating than the control circuit current will warm the thermostat more slowly. This higher rated anticipator will produce less heat, because it is designed for a higher current than the control circuit provides. An anticipator with a lower rating than the control circuit will warm the thermostat more quickly. The more residual heat in the heating system, the larger the capacity of the anticipator.

36.2.2 Cooling Thermostats

Comfort cooling thermostats are similar in design to heating thermostats, but they react in the opposite manner. The control contacts open as the room cools and close as the room warms.

Pro Tip

Function on a Rise

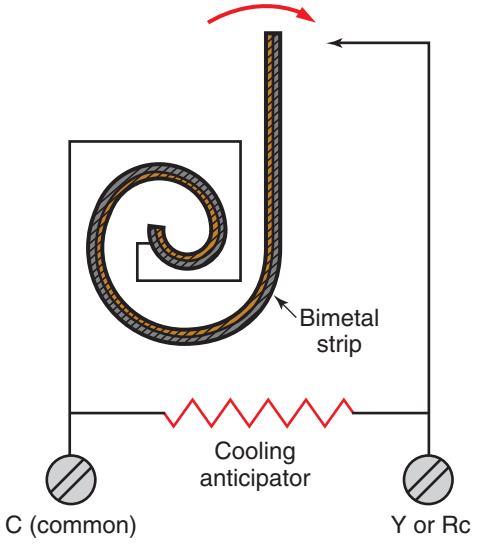
In the HVAC industry, the function that a control performs is normally the function that occurs during a rise in the system variables. For instance, a heating system *opens* on a rise in temperature. In other words, a heating control opens its circuit to stop the heater when it senses a rise above the thermostat set point. The opposite happens in a cooling system, which *closes* its circuit on a rise in temperature. Many safety and limit switches open on a rise to stop operation and prevent damage to components.

As with heating thermostats, the most commonly used cooling thermostats are electronic, which use a thermistor to sense room temperature. Although cooling thermostats are available as either 24 Vac or 120 Vac controls, the 24 Vac thermostat is most widely used. Bimetal thermostats usually have a 1°F (0.6°C) differential and have cooling anticipators. These small electric resistance elements are in parallel with the contact points. Cooling anticipators close the bimetal-controlled points just before the room reaches the cut-in temperature, as they are energized when the thermostat has not yet turned on the cooling cycle.

Cooling Anticipators

System lag and system overshoot problems are not limited to heating systems but are also often present in comfort cooling systems. To compensate for system lag, cooling thermostats often include cooling anticipators. A ***cooling anticipator*** is a high-value resistor wired in parallel with the bimetal coil. Both are connected to the common (C) and cooling (Y) terminals in a thermostat, **Figure 36-11**.

A cooling anticipator conducts current during the cooling system's Off cycle to produce heat. This added heat causes the bimetal coil to activate the cooling system when the room temperature is about 1°F (0.6°C) below the cut-in setting. For example, if a thermostat is set to cut in at 78°F (25.6°C), it will actually start the system at 77°F (25.0°C).



Goodheart-Willcox Publisher

Figure 36-11. Schematic wiring diagram of a cooling thermostat equipped with a cooling anticipator.

Often, cooling systems require a few minutes to begin operating at full capacity. If a cooling system were to begin operating when a conditioned space reaches the cut-in temperature, it could still be a short while before any cooling would occur. During this time, the temperature in the conditioned area would continue to rise. A comfort cooling system with a cooling anticipator can start an air-conditioning system in time for cooling to begin when the cut-in temperature is reached.

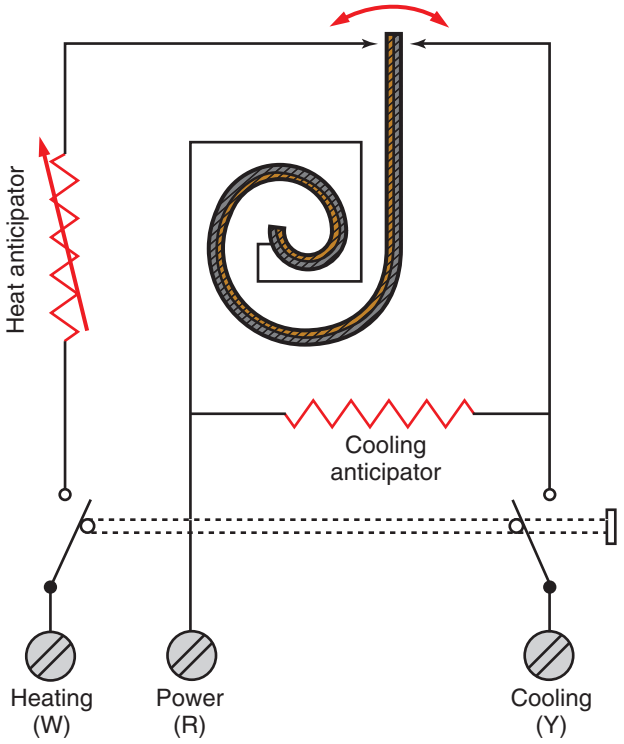
During the On cycle, the bimetal coil closes its contact, and nearly all of the current flows through the contacts rather than through the anticipator. Essentially, the bimetal coil contact bypasses the anticipator. As a result, the cooling anticipator provides no heat during the On cycle.

36.2.3 Combination Thermostats

Today, most thermostats are used for operating both heating and cooling systems. Such thermostats are called ***combination thermostats***. **Figure 36-12** shows a simplified wiring diagram for a combination thermostat that includes a bimetal coil, heat anticipator, and cooling anticipator.

Combination thermostats are available for both line-voltage and low-voltage applications. Many combination thermostats use switches to change from

Copyright Goodheart-Willcox Co., Inc. 2017



Goodheart-Willcox Publisher

Figure 36-12. Schematic of a bimetal heating-cooling thermostat equipped with both a heat anticipator and a cooling anticipator.

heating to cooling and to select fan operation as continuous or automatic. Some use a dial or slide for setting the temperature. On others, these features are accessed through a touch screen or keypad. Combination thermostats can have either a mechanical or digital display, **Figure 36-13**.

Multiple wires connect to a thermostat. The number of wires depends on the heating and cooling stages and other features that the thermostat is designed to control. A schematic diagram including a combination thermostat is shown in **Figure 36-14**.

Some thermostats include advanced controls, such as controls designed to monitor and regulate humidity, indicate when to replace an air filter, or operate other functions. These controls usually operate on a 24 V circuit.

36.2.4 Multistage Thermostats

A ***multistage thermostat*** is a thermostat that can control a system's heating and cooling capacity through various means, such as modulating compressor and fan operation or varying fuel combustion or electrical power. For electric heat, this may involve energizing more or fewer electric heating elements. For gas or oil heat, this could mean regulating fuel to a burner. For a

Siebe Environmental Controls, Invensys Climate Controls Americas

Figure 36-14. Electrical wiring diagram for a 24 Vac combination thermostat.

10

heat pump or air conditioner, this could mean governing fan and compressor operation. Multistage thermostats are usually designed for low-voltage operation.

In single-family residences, a multistage thermostat may control different parts of a building's HVAC system. In a gas furnace, a multistage thermostat will often control a two-stage or modulating gas valve that will vary the amount of gas burned and the amount of heat produced. A multistage thermostat will also often vary the speed of the indoor blower based on temperature readings and settings.

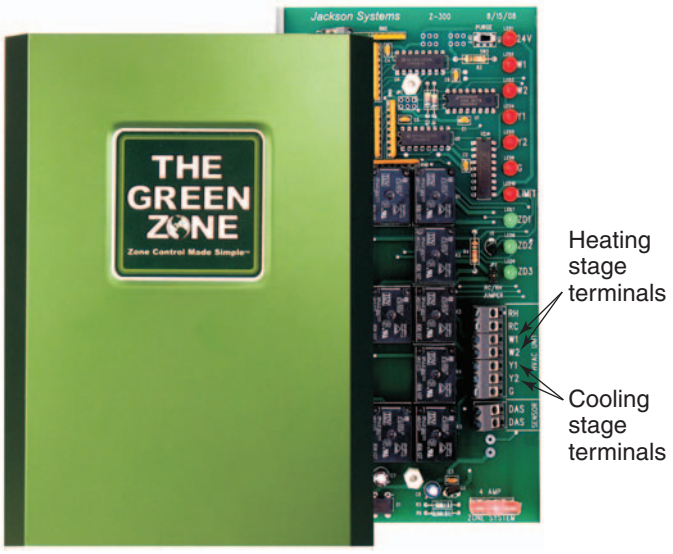
In an electric furnace, more or fewer sets of electric heating coils may be energized to produce more or less heat. These operations are used to reduce energy consumption, prolong furnace operation, and maintain a stable average temperature in the conditioned space.

For cooling in a single-family residence, a multistage thermostat may control blower speed and compressor capacity. Some scroll compressors can bypass a small amount of discharge vapor into the suction line to reduce cooling capacity. Other compressors may be able to run at different speeds, which a multistage thermostat would determine.

In large residential or commercial buildings, a single multistage thermostat uses multiple sets of contacts to control multiple condensing units, furnaces, and blowers. This allows sequenced operation for heating or cooling capacity control. Most multistage mechanical thermostats are replaced with electronic thermostats, which offer the advantage of programming different set points and cycles for each unit.

Copyright Goodheart-Willcox Co., Inc. 2017

Many multistage thermostats are recognizable by their terminals used for multiple stages of operation. Standard heating and cooling systems only have one stage of operation. Terminal W controls heating operation, and terminal Y controls cooling operation. When a thermostat has more than one W terminal (W1, W2, etc.), it can control multiple stages of heating operation. If a thermostat has more than one Y terminal (Y1, Y2, etc.), it can control multiple stages of cooling operation, **Figure 36-15**.



Jackson Systems, LLC

Figure 36-15. This zone control panel is capable of communicating with multistage thermostats for heating and cooling operation.

36.3 Line-Voltage Thermostats

In industry, ***line voltage*** is typically considered either 120 Vac or 240 Vac. A ***line-voltage thermostat*** is a thermostat that typically operates using either 120 Vac or 240 Vac. It may be designed to control current as high as 22 A.

Line-voltage thermostats are primarily used for electric baseboard resistance heaters and do not require the use of a step-down transformer to a low-voltage thermostat. They offer the advantage of being wired directly to the heater. Line-voltage thermostats are also used in commercial applications to control infrared heaters that operate on 240 V.

A line-voltage thermostat may be wall-mount or mounted directly to an electric heating unit, **Figure 36-16**. Thermostats mounted on baseboard heaters are usually encased in attractive covers. They may have a calibrated dial mounted on an adjustment knob or digital controls, **Figure 36-17**.

Cadet Manufacturing Co.

Figure 36-16. This analog line-voltage thermostat uses a bimetal switch to turn on and off electric resistance heating units.

36.4 Low-Voltage Thermostats

A ***low-voltage thermostat*** is a thermostat that typically operates at 24 Vac supplied by a step-down transformer. A heating and cooling system uses a 120 Vac to 24 Vac step-down transformer to power a low-voltage thermostat's control circuit board. This includes the display showing a variety of relevant information to occupants, **Figure 36-18**.

Low-voltage thermostats often control relays and contactors. These relays and contactors are often used to switch line-voltage circuits on and off. Low-voltage thermostats carry only a small amount of electrical power. This is an advantage, as these lower current levels are safer, having lower shock potential than line voltage, **Figure 36-19**.

Transformers are usually rated by their primary and secondary voltages, as well as the volt-ampere (VA) rating of their design. For example, a step-down transformer may come with a rating of 120 V to 24 V and a VA rating of 40. This means that the primary side

Figure 36-19. Low-voltage thermostat wiring going to an air conditioner's condensing unit uses relays to switch the higher current loads of the compressor and condenser fan.

10

Copyright Goodheart-Willcox Co., Inc. 2017

input voltage is 120 V, the secondary side output voltage is 24 V, and the current rating on the secondary side of the transformer is 1.67 A (40 VA ÷ 24 V = 1.67 A).

Be aware of the current load of a circuit in which a transformer is being placed. Drawing too much current on its secondary can cause a transformer to fail. When possible, include a properly sized fuse on the secondary side of a transformer circuit. The fuse should be rated high enough that all loads can operate without a problem. However, the fuse should be rated low enough to protect the transformer from a high current draw that could burn out the windings, **Figure 36-20**.

Pro Tip

Overloading 24 V Transformers

Most 24 V transformers will produce between 27 V and 28 V when properly placed into a circuit. If the technician measures a voltage of 24 V or lower, it is time to check the transformer and the loads on the circuit for excessive current draw or failure.

Caution

Low-Voltage and Line-Voltage Devices

Low-voltage thermostats will be damaged if connected to line-voltage (120 V or 240 V) circuits. Be careful to check an electrical device's voltage and current before installing it and energizing the circuit.

Low-voltage thermostats normally use 18 AWG wire for distances up to 50′ (15 m). For distances over 50′, 16 AWG wire is typical. Thermostats require multiple wire connections. Always review system and thermostat specifications before buying thermostat cable for installation to ensure it has enough conductors.

Pro Tip

Thermostat Wiring Diagrams

Because of the variety of systems and optional controls, not all manufacturers follow the same wiring color code or lettering system. Be sure to connect wires as indicated in the wiring diagrams provided by the manufacturer. When installing a replacement thermostat, always mark the existing thermostat's wires according to their terminal connection before disconnecting any wires.

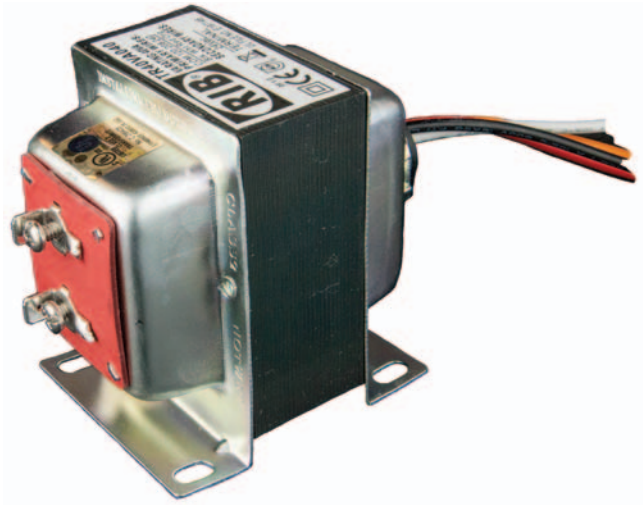
Code Alert

Class 2 Circuits

Low-voltage thermostats control the power to low-voltage controls of Class 2 (power) circuits as defined by the National Electrical Code (NEC). Class 2 circuits are generally used for remote control or signaling circuits. These are power-limited circuits, which means there is less chance of electric shock or fire initiation. Some municipalities require that a licensed electrician complete the wiring for these circuits. For more information on Class 2 circuits, see Article 725 of the NEC.

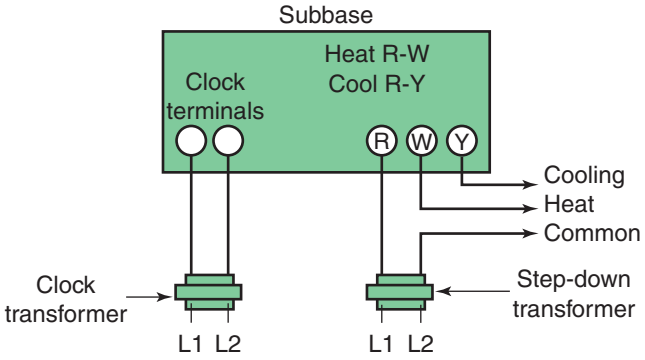
The thermostat mounting usually requires other parts. The subbase—the part to which the thermostat is attached—contains the wiring terminals. Sometimes it holds other parts, such as switches, indicator lamps, and batteries. Beneath the subbase may be a wall plate. This is the part attached to an outlet box or wall. **Figure 36-21** shows a simple wiring diagram for a low-voltage thermostat.

Most low-voltage thermostats sense temperature using a thermistor. A thermistor is a device that changes its electrical resistance based on temperature.



Jackson Systems, LLC

Figure 36-20. Many step-down transformers used with HVAC systems are rated 40 VA. These can safely provide 1.67 A at 24 Vac.



Honeywell Inc.

Figure 36-21. Low-voltage thermostat wiring diagram. Note that not all thermostats have clock terminals, and not all require a clock transformer.

Copyright Goodheart-Willcox Co., Inc. 2017

These thermostats have numerous advantages over older bimetal coil and mercury switch thermostats:

- Environmentally friendly—a thermistor replaces a hazardous mercury switch.
- Programmable—digital input allows easy programming by the homeowners.
- Durable—few or no moving parts or contacts to sustain wear.
- Expandable—programming may allow additional stages of operation and sensors.
- User friendly—touch screen models allow easy operation and access to information.
- Remote access—wireless interface via the web and smart device applications.
- Easily serviced—trouble codes may be accessed from user screen or USB port.

White-Rodgers Division, Emerson Climate Technologies

Figure 36-22. This thermocouple senses the heat of a pilot light and generates enough electrical power to operate a solenoid valve controlled by a millivolt thermostat.

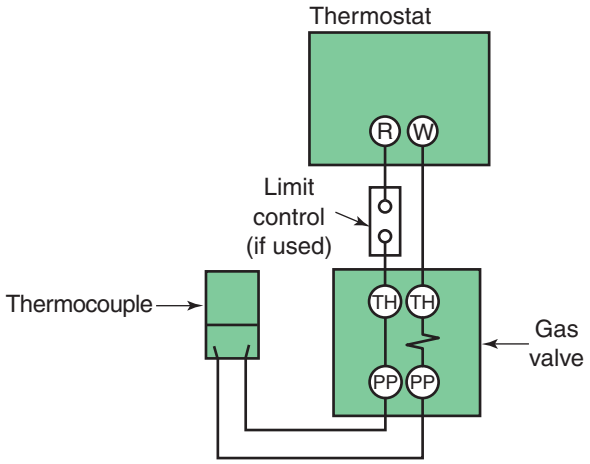
36.5 Millivolt Thermostats

A ***millivolt thermostat*** is a heating thermostat that operates a small solenoid valve powered by a very small direct current (dc) voltage produced by a thermocouple device. Millivolt thermostats require no external power source. The thermocouple is located near a gas pilot light, which provides the heat required to generate enough electrical power for operation, **Figure 36-22**.

Millivolt thermostats were common for many years but have generally been phased out. These thermostats depend on a standing pilot light, but many gas furnaces and other gas-fired appliances no longer have a standing pilot light. Therefore, millivolt thermostats cannot be used to control such systems. For safety and environmental reasons, many areas no longer permit the use of a standing pilot light. Many low-voltage electronic thermostats are capable of operating millivolt systems and can be used as replacements.

Millivolt thermostats cannot be used to operate cooling systems. They are only used on systems with a standing-pilot ignition. These are mainly found on older heating systems, stoves, fireplaces, and water heaters. Millivolt thermostat systems are series circuits that usually have only two wires. Two wires originate from the thermocouple device. The circuit loops in series through a bimetal coil-operated mercury switch, a solenoid valve, and back to the thermocouple device, **Figure 36-23**.

When a millivolt thermostat's switch closes, current from the thermocouple passes through the solenoid valve. The solenoid valve then opens to supply fuel to the burner. When the desired temperature is reached, the thermostat's switch opens. This stops current to the solenoid, which closes the valve and stops the main gas supply. After the main burner is turned off, the small pilot gas supply continues to keep the pilot lit, which keeps voltage ready for the next On cycle.



Honeywell Inc.

Figure 36-23. Millivolt thermostat wiring diagram.

36.6 Digital and Programmable Thermostats

Advances in electronic circuitry and controls have revolutionized the thermostat and its capabilities. Electronic thermostats use the same basic operating principles as earlier models. However, the various

Copyright Goodheart-Willcox Co., Inc. 2017

functions are all accomplished with electronic components, such as transistors, solid-state relays, integrated circuit chips, and microprocessors. The versatility of electronics allows a thermostat to control and monitor numerous circuits through its ability to communicate with compatible transducers and sensors. These functions include sensing, switching, timing, and staging.

36.6.1 Wireless Thermostats

Wireless thermostats electronically activate a responder on the furnace or air conditioner. This can be done up to a distance of about 120′ (36.5 m). Wireless thermostats may also include remote wireless sensors, such as outside temperature sensors, air filter sensors, and humidity sensors. Each sensor sends a signal to the thermostat that is programmed to operate the heating and cooling unit and various zone valves or dampers throughout a building.

A wireless thermostat may be moved from room to room. It responds to the temperature of whatever room it is in. Since it is an electronic battery-powered unit, the thermostat has no moving parts. It can have an accurate adjustable differential from 0°F to about 5°F (0°C to about 3°C). Many have a range of 45°F to 90°F (7°C to 32°C).

An advantage of a wireless thermostat is that it may interface via Wi-Fi to mobile devices, such as a tablet PC, smartphone, or laptop. This provides the homeowner with the ability to change the set temperature from anywhere. Remote control also allows the user the ability to precondition the home. For example, the user may raise or lower the home's temperature while still at work so that the home is heated or cooled prior to the owner's arrival. Many HVAC manufacturers offer a mobile application that may be downloaded to a smartphone or mobile device to control the HVAC system remotely, **Figure 36-24**.

Courtesy of Nest Labs, Inc. Copyright © 2012 Dwight Eschliman

Figure 36-24. Wireless thermostats allow for easy adjustment and monitoring. A—Controlling a thermostat remotely through a laptop. B—Reviewing HVAC system energy usage over time using a smartphone.

36.6.2 Power-Stealing Thermostats

Power-stealing thermostats are electronic thermostats that draw a small amount of power from the low-voltage side of the HVAC system control to operate the thermostat electronics. The current draw is in the milliamps (mA) range. Power-stealing thermostats are very efficient and do not require a separate power source to operate. **Figure 36-25** shows one type of power-stealing thermostat display.

A power-stealing thermostat "steals" power for the control board by tapping into the fan, cooling, or heating terminals. When the heating or cooling is operating, a small amount of current flows into the thermostat to recharge its internal battery.

Control4 Corporation

Figure 36-25. A power-stealing thermostat with a touch screen interface. Note this unit is a whole home management system.

Copyright Goodheart-Willcox Co., Inc. 2017

Caution

Power-Stealing Thermostat Compatibility

Power-stealing thermostats may not be compatible with some HVAC system circuit boards. The small voltage draws required by the thermostat may result in activation of the relay from which the thermostat is attempting to draw power. This may result in HVAC control board failures or relay issues. To prevent this condition, it may be necessary to install a small bypass resistor. The bypass resistor is placed between the power-stealing thermostat leg and common. The resistor prevents overcurrent conditions to the control board. **Figure 36-26** illustrates a power-stealing thermostat wiring diagram with a bypass (bleed) resistor installed. Also, some zone valves used in hot water heating systems require a small bleed resistor to be installed across two pins on the zone valve.

36.6.3 Programmable Thermostats

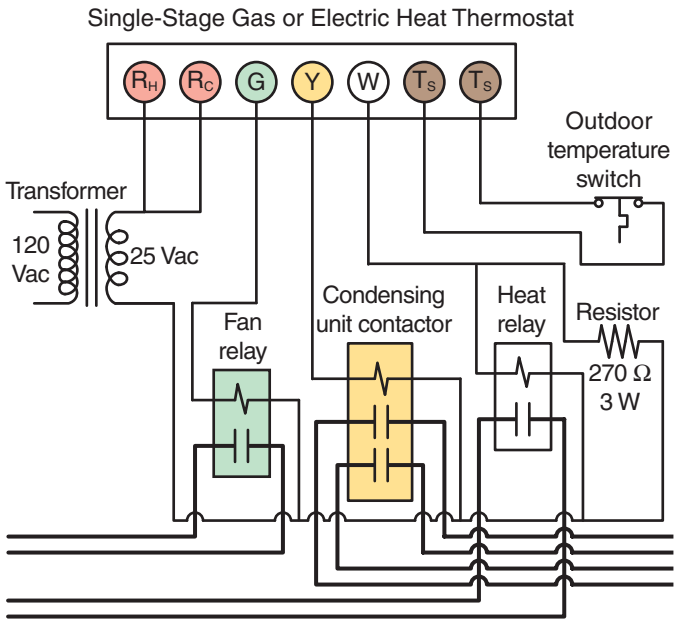
A ***programmable thermostat*** contains a microprocessor that functions as a clock and allows users to select different indoor climate conditions for different blocks of time. The precision and responsiveness of solid-state controls result in the best operation for high-efficiency operation. These same controls are often used to detect, monitor, and display for the user the system conditions. The conditions are indicated by instruments, lights, and recorders. Electronic components of a solid-state thermostat usually include a thermistor (temperature sensor) and an integrated circuit board.

Many heating-cooling systems use a programmable thermostat governed by a clock. It changes the temperature range during the night and returns the range to normal during the day. Many also provide seven-day settings, which enable different temperature settings for weekdays and weekends. This type of control can provide a lower operational cost by operating an HVAC system only when needed and operating less when occupants are away. **Figure 36-27** shows a single day's schedule as governed by a thermostat's clock.

Unlike line-voltage or mercury switch thermostats, many electronic thermostats do not have heat anticipators, because they often use remote sensing units. A remote sensing unit includes a temperature sensor that is at the end of a cable run from the thermostat to within a few feet from a supply register, so it will more accurately sense the actual room temperature.

Through the use of electronic circuitry rather than mechanical controls, a greater variety of control options and features are available in a thermostat of the same size as an older mechanical thermostat. A typical electronic thermostat can perform the following functions:

- Fully programmable temperature settings. Various temperatures can be programmed to achieve maximum comfort throughout the day. These settings can also be varied for each day of the week depending on occupancy, allowing high levels of efficiency.



Goodheart-Willcox Publisher

Figure 36-26. Single-stage combination thermostat wiring diagram with 270 Ω 3 W bypass resistor in the circuit for power-stealing setup.

Venstar

Figure 36-27. This programmable thermostat's display is showing the time and temperatures for system operation for Fridays.

Copyright Goodheart-Willcox Co., Inc. 2017

- Multistage and combination control. A single device can control various stages of heating and cooling. For heat pump applications, programmable thermostats designed specifically for heat pumps should be used, **Figure 36-28**.
- Override control. This feature overrides the thermostat's normal programming in order to maintain a preset temperature condition. An example would be a vacation setting. A single temperature might be desired for those periods of time when no one is home.
- Digital display using a back-lit LCD screen. Room temperature, desired temperature, time, and date are displayed at the push of a button.
- Battery backup. Most electronic thermostats are low-voltage thermostats, and most models have a battery backup. The battery backup prevents loss of an entire program in case of a power failure.
- USB or wireless interface. Some thermostats can be programmed and monitored using a USB cable or wireless connection from a laptop or handheld device.

Additional features that can be found on some models include the following:

- Maintenance alerting. The unit can automatically keep track of the number of days that the air filters, humidifiers, and other components are in use. Then, it will automatically signal with a light or tone when maintenance is required, **Figure 36-29**.
- Outside temperature anticipator. Some electronic thermostats sense outside temperature and include this value in calculations to determine the length of a heating and cooling system warm-up or cool-down time. They adjust the operating cycles accordingly. Outside temperature can often be digitally displayed.
- Security protection. The thermostat requires a security code before allowing the user to modify settings. This feature is sometimes used in commercial settings in which the thermostat is in a public location.

Venstar

Figure 36-28. A programmer must input how many stages of cooling and heating operation will be used with the system connected to a thermostat.

Venstar

Figure 36-29. This thermostat allows its user to select the frequency of equipment service reminders.

Programmable thermostats vary somewhat with each manufacturer. Some are available as a control unit with one or more separate temperature sensing units. The sensors can be mounted in a conditioned space, and the control unit can be mounted elsewhere, such as a manager's office, **Figure 36-30**.

Programmable thermostats, due to their precision components, offer exact temperature control. Usually, temperature can be controlled within 1°F (0.6°C) of the set temperature. Programmable thermostats offer significant energy savings without reducing overall comfort. This is accomplished through simple preprogrammed temperature settings. Once the unit has been programmed, very little effort is required from the owner.

36.6.4 Programming a Thermostat

A programmable thermostat allows an occupant to tailor indoor comfort to suit individual preference and schedule. Often, they are used to change the temperature settings for night and reset them for different periods through the day. Most units include preset programs, but allow the operator to modify the program to desired temperatures for different times and days of the week.

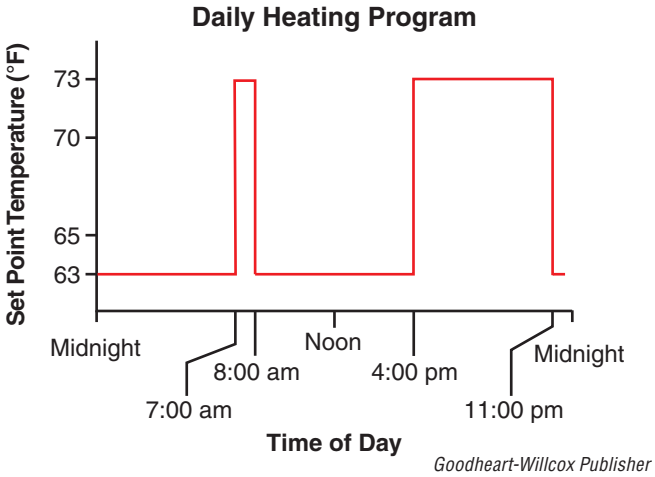
Figure 36-30. An electronic thermostat with a separate control and sensing unit.



Goodheart-Willcox Publisher

Figure 36-31. A typical programmable thermostat control program for a heating day. When occupants are present and awake in the morning and evening, the thermostat maintains a 73°F (22.7°C) set point. When the occupants are away during the day or asleep at night, the thermostat maintains a 63°F (17.2°C) set point.

Most thermostats permit programming on three basic levels:

- Time of day.
- Day of the week.
- Heating or cooling.

Programming a thermostat involves adjusting the on-off schedule and temperature of a building to meet the occupant's desired comfort while maximizing the efficiency of the HVAC system. Programs allow the temperature in a room to rise and fall based on occupancy levels.

Depending on the season and weather, systems may be programmed to allow the temperature set point to raise or drop at night when the occupants are sleeping or the building is vacant. Systems can then either raise or lower the set point to a more comfortable temperature in the morning just prior to wake-up or occupancy. If a building is left vacant all day, the set point may be set lower or higher for the entire day, depending on the season.

Figure 36-31 illustrates a typical program for a heating day. The thermostat is set at 63°F (17.2°C) during the night. Prior to the occupants waking up at 7:00 am, the thermostat calls for heating. The home warms up to the set point of 73°F (22.7°C) for the hour that the occupants spend getting ready for work or school and eating breakfast. The set point then falls back to 63°F (17.2°C) when the occupants are away, **Figure 36-32**.

From 8:00 am until 4:00 pm, the house is vacant, and the building is allowed to cool down to 63°F (17.2°C). Prior to 4:00 pm, the thermostat calls for heat and begins warming the building. By 4:00 pm, building temperature has risen to the set point of 73°F (22.7°C). The house remains this warm until bedtime at 11:00 pm.

Figure 36-32. Thermostat in automatic away mode.

Figure 36-33 illustrates a cooling program. In the morning, prior to the peak power rate hours and a reduced thermal load from the sun and outdoor temperature, the air conditioning cools the building to 70°F (21°C). During the day, when occupants are away, the building temperature is allowed to rise up to a 73°F (22.7°C) set point. Before occupants return home, the thermostat turns on the air conditioning to cool the building back down to

Goodheart-Willcox Publisher

Figure 36-33. Daily cooling program.

70°F (21°C) by 4:00 pm. In the later evening, with lower solar load, the set point is allowed to rise back up to 73°F (22.7°C). It is important to not allow the building to heat up during the day. The air-conditioning system would then have to remove the large amount of heat accumulated throughout the day.

The advantage of using a programmable thermostat is that it can provide energy savings when a building is not required to maintain a high or low set point, such as when occupants are away. Many electric utilities charge higher rates for "peak times," when energy consumption is at its highest. During daylight working hours, energy usage is at its peak. By programming the heating and cooling system to a more moderate set point during peak periods, daily energy consumed is reduced, which results in a smaller power bill. Home energy monitoring systems can display the cost of kilowatt per hour and energy usage data. This can serve as a reminder to conserve energy as much as possible, **Figure 36-34**.

Manufacturers are developing new technologies and thermostat features that allow increased self-monitoring of energy usage over time. These thermostats can show occupants hours of system run time, electrical energy used, and other useful information, **Figure 36-35**.

Thinking Green

Programming a Thermostat

A properly programmed thermostat can significantly reduce a customer's utility bill without sacrificing comfort. The thermostat should be programmed to adjust temperature to save energy during periods that the occupants are typically asleep or away. However, the system must maintain the energy-saving temperature for an extended period (several hours) or the energy used to restore the normal temperature will offset any savings.

Insteon

Figure 36-34. This home energy monitor displays the cost of kilowatts per hour next to indoor temperature.

Venstar

Figure 36-35. This thermostat shows hours of heating system operation over the course of several days. By knowing our habits and temperature preferences, we can program thermostats to run only when and as much as needed to prevent wasting energy.

36.7 Thermostat Installation

Thermostat wiring varies by manufacturer. Each thermostat should come with installation instructions, which must be followed to ensure proper operation. When replacing a thermostat, it is common practice to use the existing thermostat wiring from the furnace, boiler, or heat pump. It is always a good practice to note which wires were connected to the old thermostat terminals and label these accordingly.

Copyright Goodheart-Willcox Co., Inc. 2017

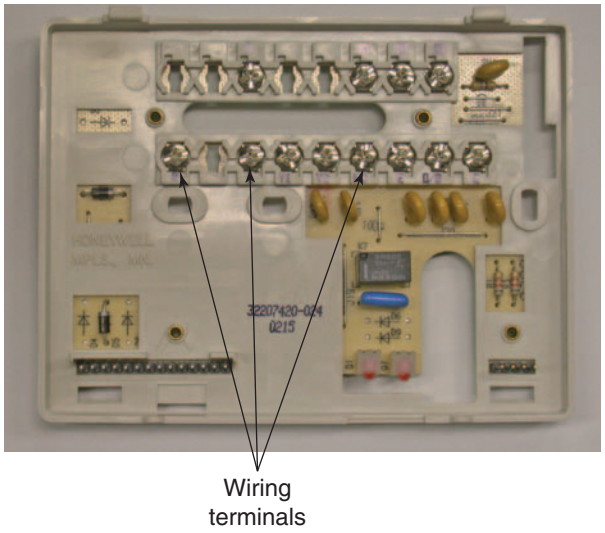
36.7.1 Thermostat Wiring

Although thermostats and units may be wired differently, there are some basic conventions and terminal designations used when wiring a thermostat:

- Rc—cooling power.
- Rh—heating power.
- R—power.
- Y—condensing unit (compressor) contactor.
- Y2—compressor contactor (stage 2).
- C—24 V common connection.
- W—heat relay (stage 1).
- W2—heat relay (stage 2).
- G—fan relay (cooling only).
- CR—cooling relay.
- O/B—heat pump reversing valve.
- Aux/E—heat pump auxiliary heat.
- HMD—humidification.
- DHD—dehumidification.
- Ts—outdoor temperature switch.
- Out, Temp, OD, OAS, or ODT—outdoor air temperature sensor.
- In or IDT—indoor temperature sensor.
- M1 or DMP—air duct damper control.

Thermostats with auxiliary functions may use different terminal designations than those shown here. Always refer to manufacturer literature to be certain.

Removing an installed thermostat reveals its subbase. Wiring terminals with letters show what parts of a system are controlled by the thermostat, **Figure 36-36**.



York International Corp.

Figure 36-36. Subbase of a low-voltage thermostat.

Look for the corresponding wiring terminals in a system's condensing unit, air handler, and any other system control board, **Figure 36-37**.

The subbase may also contain other components. Of importance to thermostat subbase installation are ***DIP switches***. *DIP* stands for *dual in-line package*. These are small switches grouped together in a single package. They are commonly found on circuit boards and used to manage system settings. Usually, they are positioned once for the commissioning of a system and then left alone. A subbase may have DIP switches used

10

Copyright Goodheart-Willcox Co., Inc. 2017

to indicate the type of heating and cooling system that will be connected to the thermostat, **Figure 36-38**.

After installing a new thermostat, always test it to make sure that it operates as it should. Some thermostats include some self-diagnostic capabilities. To check wiring connections before programming a thermostat, use the test outputs function available on certain thermostat models. This initiates operation immediately by bypassing any time delays, which confirms whether the wiring is correct before programming all days, times, and set points, **Figure 36-39**.

Venstar

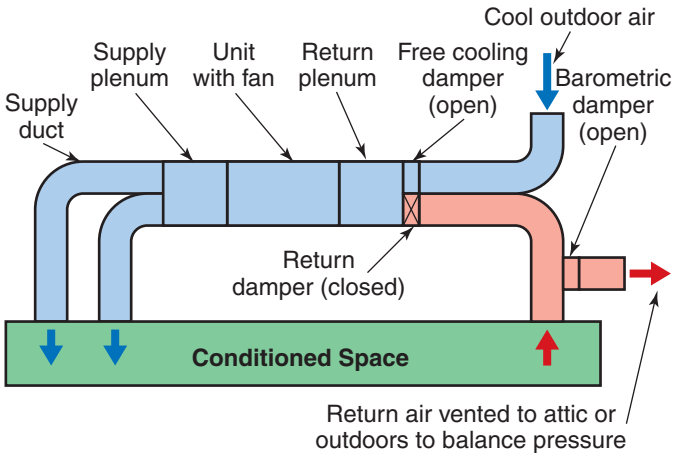
Figure 36-39. The test outputs function bypasses any time delays and initiates operation immediately. This function quickly checks the wiring connections and can be a quick starting point for troubleshooting a system.

36.7.2 Free Cooling

Building owners and system designers continue to look for energy saving methods and technologies. A great way to reduce electrical power consumption is to utilize free cooling. However, this is only available under certain conditions. Indoor air must be warm and in need of cooling. Outdoor air must be low in temperature and preferably also low in humidity.

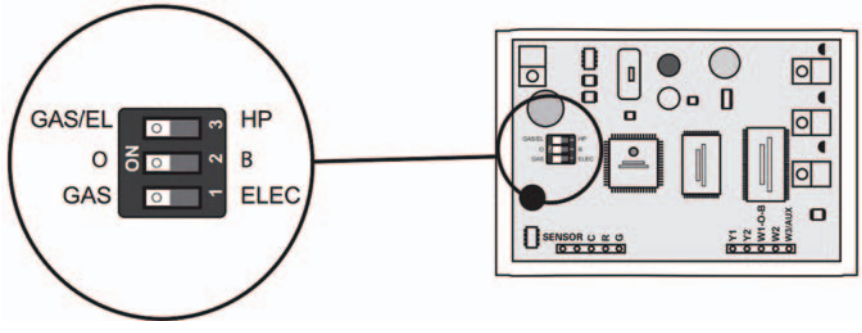
Free cooling is the use of an air-side economizer to draw in cool outdoor air to reduce indoor air temperature. An air-side economizer controls an HVAC system's blower and duct dampers. By opening and closing certain dampers, a system's blower can draw in the cool outdoor air and exhaust warm indoor air. This is considered *free cooling* because only dampers and the blower are using electrical power. The compressor does not run during free cooling. Since a compressor consumes much more electrical power than a fan does, using a few dampers and a blower to draw in cool outdoor air is comparatively, but not actually, "free," **Figure 36-40**.

A thermostat must be equipped to control free cooling. The thermostat will need to have an outdoor air temperature sensor connected. When outdoor air temperature is low enough, free cooling operation can begin. Some systems may also monitor outdoor humidity.



Goodheart-Willcox Publisher

Figure 36-40. A forced-air system diagram using an air-side economizer for free cooling. As indoor pressure rises, a barometric damper opens and releases return air to an unconditioned space or outdoors.



Venstar

Figure 36-38. This thermostat subbase has three DIP switches. The top switch tells the thermostat whether the system is a heat pump or uses gas or electric heat. The middle switch determines whether the heat pump reversing valve is energized for cooling or for heating. The bottom switch tells the thermostat whether the system uses gas or electric heat.

Copyright Goodheart-Willcox Co., Inc. 2017

For these systems, relative humidity must be low enough before operation begins. This is called *enthalpy control*. For more information on enthalpy control, see Chapter 33, *Commercial Air-Conditioning Systems*.

To operate free cooling, a thermostat often must be capable of controlling more than one stage of cooling operation. Stage one cooling (Y1) can be used to operate free cooling. Stage two cooling (Y2) can be used for running the air conditioning. Thermostat terminal Y1 controls the damper positions. The diagram in the example earlier showed two motorized dampers. To control and operate these dampers requires additional step-down transformers and relays. See the wiring diagram for controlling the free cooling damper in **Figure 36-41**.

When the outdoor temperature sensor senses the cut-in temperature (65°F in this example), the thermostat initiates stage one cooling (Y1) for free cooling. The thermostat signals the damper relay, which energizes the free cooling damper. The indoor blower also turns on to begin drawing in the cool outdoor air. When outdoor air temperature rises too high or the thermostat is satisfied with the cooling indoors, the thermostat cycles off the free cooling operation.

36.7.3 Installing Wireless Thermostats

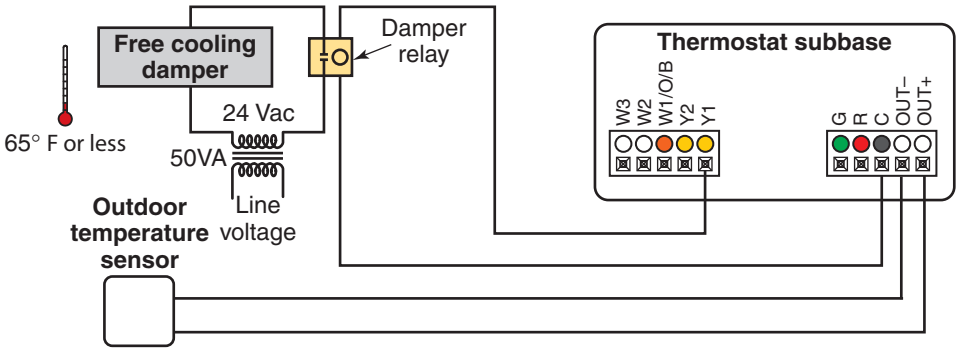
The use of wireless thermostats with remote sensors has made the location of such thermostats less critical. Remote, wireless temperature and humidity sensors allow the control to be placed in a convenient location, while the sensors are located in the best location to measure room conditions. The location of a thermostat sensor is important. Similar to a traditional thermostat, it should be located in an average-temperature location. An example would be an inner wall about 5′ above the floor. It should be out of the way of furniture and beyond the reach of small children. The location of a temperature sensor should be changed if it is affected by any of the following:

- Drafts or dead air spots behind doors and in corners.
- Hot or cold air from ducts.
- Radiant heat from the sun or an appliance.
- Concealed pipes and chimneys.
- Unheated areas behind it, such as an outside wall.

With ***Wi-Fi enabled thermostats***, a user can operate the thermostat while away from the building. Whole home automated systems enable a homeowner to monitor and adjust settings using an Internet-connected device, **Figure 36-42**.

Control4 Corporation

Figure 36-42. Thermostat operation from a tablet and smartphone.



Venstar

Figure 36-41. A forced-air system wiring diagram for free cooling.

Copyright Goodheart-Willcox Co., Inc. 2017

Wi-Fi enabled home automation systems include a controller that is connected to the buildings lighting, window shades, and security system. Whole home automation allows maximum energy conservation. For example, at night the system can automatically reduce the thermostat set point, shut off room lights, and close blinds to conserve energy.

Pro Tip

Setting Up Online Account and Downloading Apps

Learning and Wi-Fi enabled thermostats often require setting up an online account and downloading software to operate the thermostat from a wireless device or the Internet. Following installation, remember to assist the homeowner in setting up their online account and selecting the correct app. This will allow the homeowner to monitor their energy savings and operate their thermostat remotely.

36.8 Thermostat Diagnostics

It is good practice to begin troubleshooting a comfort cooling or heating system using the thermostat. This is a quick way of locating the source of system malfunction. The process usually determines that the cause is one of the following:

- Wiring problem.
- Furnace/air handler problem.
- Thermostat problem.

The diagnostic sequence for a heating thermostat and a cooling thermostat is almost the same with two major differences in operation. A heating thermostat is considered "calling for heat" if the setting on the thermostat is two or more degrees *over* room temperature. A cooling thermostat is considered "calling for cooling" if the set point is two or more degrees *under* room temperature. A technician can check whether a thermostat is operating according to these principles by measuring voltage across its electrical terminals. See **Figure 36-43** for terminal configuration for heating and cooling operation.

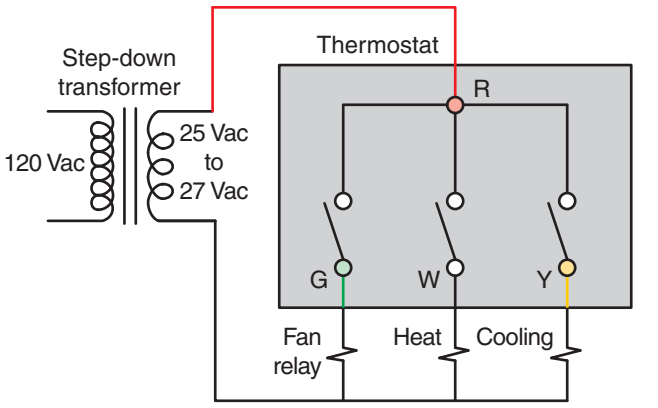
Before checking voltage, make sure the thermostat's fan switch is set to auto. When taking a voltage reading, the meter is sensing a difference in electrical potential. The voltage across an "open" connection is the source voltage. The voltage across a "closed" connection is 0 V. There is no voltage difference between the two sides of a closed switch, **Figure 36-44**.

Before taking measurements, determine what type of thermostat is installed. The two most commonly used thermostats are low-voltage and line-voltage. On a low-voltage thermostat, source voltage will most often be 25 Vac to 28 Vac. On a line-voltage thermostat, source voltage will be 120 Vac or 240 Vac. Always use a meter to identify what the source voltage is before attempting any diagnostics or repairs.

Thermostat Terminal Checking Chart		
Wiring Terminals	HVAC System Mode of Operation	
	Heating On	Cooling On
R and W	Closed	Open
R and Y	Open	Closed
R and G	Open	Closed

Goodheart-Willcox Publisher

Figure 36-43. A thermostat's electrical terminal configurations for a comfort heating and cooling system. This table assumes that the thermostat's fan setting is on auto.



Goodheart-Willcox Publisher

Figure 36-44. A basic low-voltage thermostat wiring diagram.

Pro Tip

Keep a Mercury Switch Level

Before beginning diagnostic steps on a thermostat, check whether it uses a mercury switch. If so, make sure that the thermostat is mounted level. A thermostat that is mounted crooked can tilt a mercury switch so that the system cycles on and off outside of calibration. Do not just "eyeball" the thermostat. Check it with a level.

36.8.1 Heating System Diagnostics

Before diagnosing a heating system using a thermostat, review any available manufacturer literature about the system. Be sure to know what each thermostat terminal controls before measuring. Common terminal designations are listed here:

- Rc—cooling power.
- Rh—heating power.

Copyright Goodheart-Willcox Co., Inc. 2017

- R—power.
- Y—compressor contactor.
- C—24 V common connection.
- W—heat relay.
- G—fan relay.
- O/B—heat pump reversing valve.

Pro Tip

Fan Relay

Frequently, the thermostat's G (fan relay) terminal does not control the auto fan setting in heating mode. Instead, the blower fan may be controlled by a temperature switch or a time-delay switch in the furnace. The furnace switch delays the starting of the blower until the furnace has heated the air in the heat exchanger. If the fan is controlled by the thermostat and starts on the call for heating, the cold air in the ductwork would be blown into the conditioned space.

Troubleshooting a Heating System with a Low-Voltage Thermostat

The following procedure can be used to troubleshoot a low-voltage thermostat for a heating system that is not working:

1. Turn off the power at the furnace.
2. Place a jumper across terminals R and W on the furnace circuit board or control connections.
3. Turn the power back on and wait up to three minutes. Make sure the access door or panel switch is depressed, else it will prevent the furnace from turning on.
4. If the furnace does not turn on, the problem is inside the furnace and troubleshooting should continue inside the furnace. If the furnace does start the heating cycle, the problem is not in the furnace. The problem is in the thermostat or its wiring. Continue the following diagnostic steps.
5. Turn off the power at the furnace and remove the jumper.
6. Turn on the power again and make sure the door switch is depressed.
7. Go to the thermostat, remove the thermostat from the subbase, and use a meter to check the voltage across terminals R and W. The meter should read between 25 Vac and 27 Vac.
8. If the meter does not read between 25 Vac and 27 Vac, there is a problem with the wire between the furnace and the thermostat. This wiring problem will need to be fixed.
9. Examine the thermostat cable. All thermostat cables have multiple wires, and sometimes there may be one or more wires that are not in use. If the cable has an unused wire, use it to replace the wire connected to terminal R or W. Before trying this, take more electrical measurements.
10. To determine which wire to try switching first, measure voltage across terminals R and G and then across terminals R and Y. If the meter does not read source voltage for either measurement, the problem is most likely the wire connected to terminal R. If the meter indicates source voltage, the problem is most likely the wire connected to terminal W.
11. Based on these measurements, switch out the problem wire with the unused wire. Change the wire connections at the terminals on the thermostat and at the furnace to the unused conductor.
12. Measure voltage across terminals R and W on the thermostat. If the meter does not read source voltage across terminal R and any of the other terminals mentioned, it is likely that the entire thermostat cable between the furnace and the thermostat is completely broken. A new thermostat cable will need to be installed and all wire connections redone.
13. If the meter does read 25 Vac to 27 Vac across terminals R and W, the problem is likely the thermostat.
14. For a final check, secure a jumper across terminals R and W on the thermostat subbase. The heating system should cycle on within three minutes. System operation under this condition confirms that the thermostat is faulty. After diagnosing the problem, remember to remove any jumper installed.
15. If the thermostat is an electronic thermostat, check the batteries before recommending a replacement thermostat. Dead batteries will cause a battery-powered thermostat to fail.
16. After determining that the thermostat is the problem, check whether the thermostat uses a mercury switch. If yes, replace the thermostat and the subbase. Work with the customer to locate an acceptable electronic thermostat replacement. Many customers with older, round mercury thermostats prefer a round electronic thermostat, as these have the same appearance and functionality.

Copyright Goodheart-Willcox Co., Inc. 2017

36.8.2 Cooling System Diagnostics

Diagnosing a cooling system problem using a thermostat is similar to diagnosing a heating system problem. The main difference is to check across terminals R and Y and also across terminals R and G, instead of R and W. When a thermostat is calling for cooling, the R to Y terminals will be closed to energize the cooling contactor or relay in the condensing unit. In addition, the R to G terminals will be closed to energize the relay controlling the indoor blower motor.

Pro Tip

Thermostat Vibration

If a building owner notices that a system frequently turns on and then off without running for the entire duration of its scheduled operation, seek out the location of the thermostat. Systems may short-cycle because the thermostat is exposed to vibration. Examples would include stairways or shaky walls. Always mount a thermostat to a firm structure.

36.8.3 Multistage HVAC Systems

Thermostats that have a W2 or Y2 terminal are considered multistage thermostats. A thermostat in heating mode will not close across terminals R and W2 until the temperature drops down below the set point by more than 3°F, in most cases. In cooling mode, terminals R and Y2 will not close until the temperature rises above the set point by more than 3°F. These temperature separations between first and second stages are adjustable in many cases. When troubleshooting second-stage problems, be sure to adjust the thermostat to close the correct terminals.

36.8.4 Low-Voltage Measurements

Voltage readings of 24 Vac and below do occur on low-voltage circuits, but this low value should be seen as a sign of a problem. A 24 Vac measurement means that the transformer is aging or one of the loads on the circuit is pulling more electrical current than can be provided by the transformer. In some cases, this can be caused by the addition of accessories that draw more current into the circuits. Take measurements to find if a high current draw is causing the excessive voltage drop.

Diagnosing a High Current Draw on a Transformer

When looking for voltage drops or high current draws, you apply the principles of Ohm's law. Electrical loads in series drop voltages. Loads in parallel add amperages. For a control circuit that has low voltage, rule out one of these problems and focus on the remaining.

1. Begin by tracing the thermostat circuit from the step-down transformer to the R terminal at the furnace or air handler, then to the thermostat, and then to the heating relay or cooling contactor. Look for any electrical loads that are connected in series with these conductors.
2. If you find a load that should be in the circuit, remove it and retest the voltage to see if the problem is solved.
3. Trace the parallel loads in the circuit. While tracing the circuit, create a ladder diagram schematic that includes all the electrical loads, switches, and other devices. If a manufacturer's schematic is available, use it as a guide but verify that the actual system matches the schematic. The circuit may have been modified after being installed. While tracing through the circuit, look for any add-on devices, such as humidifiers, air cleaners, and zone control panels. All of these devices should have their own transformers, but may be installed incorrectly. Always refer back to manufacturer directions regarding proper installation practices and wiring recommendations.
4. After identifying all the electrical loads in the control circuit from the secondary side of the step-down transformer back to common, add all the current ratings, then multiply this total by the control circuit voltage (typically 24 V) to determine the actual volt-amperes (VA) load. This value should be less than the VA rating of the secondary of the transformer. If the number is not lower, replace the transformer with another transformer that has a VA rating greater than the value calculated.
5. Check the amperage of each load. Start with one branch of the parallel circuit and use a clamp-on ammeter that has a .10 A scale. If that is not available, wrap the wire around the clamp 10 times and then divide the resulting reading by 10. Energize the circuit and record each reading on the ladder diagram.
6. Compare each amperage load measurement with the current rating on the device's label. The current measured should never be greater than the current rating on the label of the electrical load. If it is greater, replace that electrical load. Most low-voltage loads cannot be repaired.

Copyright Goodheart-Willcox Co., Inc. 2017

Note: There are certain electrical loads to look at more closely. These include the following: cooling contactors in the condenser, time delay relays in the condenser, fan relays in the air handler, solenoids in the liquid line, gas valve solenoids, zone dampers, zone control panels, zone valves, gas ignition controls, oil primary controls, and some thermostats themselves.

Pro Tip

More Than Just Measurements

While working through a system and taking amperage readings at each load, listen to the loads in operation. Chattering contactors or relays are a sign that that load is not functioning properly. Be certain to run through all modes of operation (heating, cooling, fan-on, and fan-auto), as each mode energizes different control voltage loads. If the system uses a heat pump, check the reversing valve and run through the defrost sequence.

36.8.5 Closing a Troubleshooting Service Call

After repairing a thermostat wire problem or replacing a thermostat, ask the customer if they want to keep the broken part. If not, remove and properly dispose of any parts and mercury or digital thermostats. In addition, survey the work space and double-check that any jumpers have been removed, covers replaced, and electrical switches returned to their proper position. Show the customer that the repair worked and help them set the thermostat for their comfort. Make sure to leave any manuals or paperwork that came with the thermostat.

If any older thermostats were replaced with a web-enabled Internet thermostat, ensure that the customer knows how to access the thermostat from their computer or smartphone. Taking the time to make sure the customer fully understands the equipment now will increase the customer's satisfaction and may prevent a callback in the future.

36.8.6 Line-Voltage Thermostats

Diagnosing a defective line-voltage thermostat on an electric heating system is somewhat different from diagnosing a low-voltage thermostat. Line-voltage thermostats normally provide power directly to the baseboard or ceiling panel heating units. While line-voltage thermostat operation is less complex, risk of electric shock is higher. Review all electrical safety precautions before dealing with line voltage.

Diagnostics Using a Line-Voltage Thermostat

1. Check that the circuit breakers for the electric heating units are turned on and not open.
2. Carefully remove the thermostat cover and then remove the thermostat from the subbase.
3. Review system literature and wiring in order to anticipate the correct voltage measurement. Set your meter to a higher-than-expected setting and measure the voltage across the two terminals. The measurement should read line voltage across the open circuit. Note that some electric heat systems can use 120 Vac or 240 Vac.
4. If the measurement is not line voltage, there is a problem with the wiring. Depending on the system's location, further repair work may need to be done by a licensed electrician.
5. If line voltage is measured at the subbase, the problem is the thermostat and it will need to be replaced.
6. Select a similar line-voltage thermostat or an electronic thermostat specifically designed for use with line voltage. Never replace a line-voltage thermostat with a low-voltage thermostat.
7. Prior to replacing a thermostat, open the circuit breaker to disconnect the circuit. Use a voltmeter to take measurements to ensure that the electrical circuit is open.
8. Replace the thermostat.
9. Re-energize the circuit once repair work is complete and verify that the problem has been corrected.
10. As with any other repairs, show the customer what was replaced, offer to leave any replacement parts, and show them how to operate the new thermostat.

36.8.7 Domestic and Commercial Refrigeration Systems

Thermostats are also used on domestic and commercial refrigeration systems. Most of these thermostats are line-voltage thermostats and control the evaporator fans, condenser fans, compressors, and liquid line solenoid valves. These thermostats should be diagnosed in the same way as an electric heat line-voltage thermostat. However, remember that a refrigeration thermostat closes on a rise in temperature, rather than a drop in temperature.

Copyright Goodheart-Willcox Co., Inc. 2017

36.9 Zoned Systems

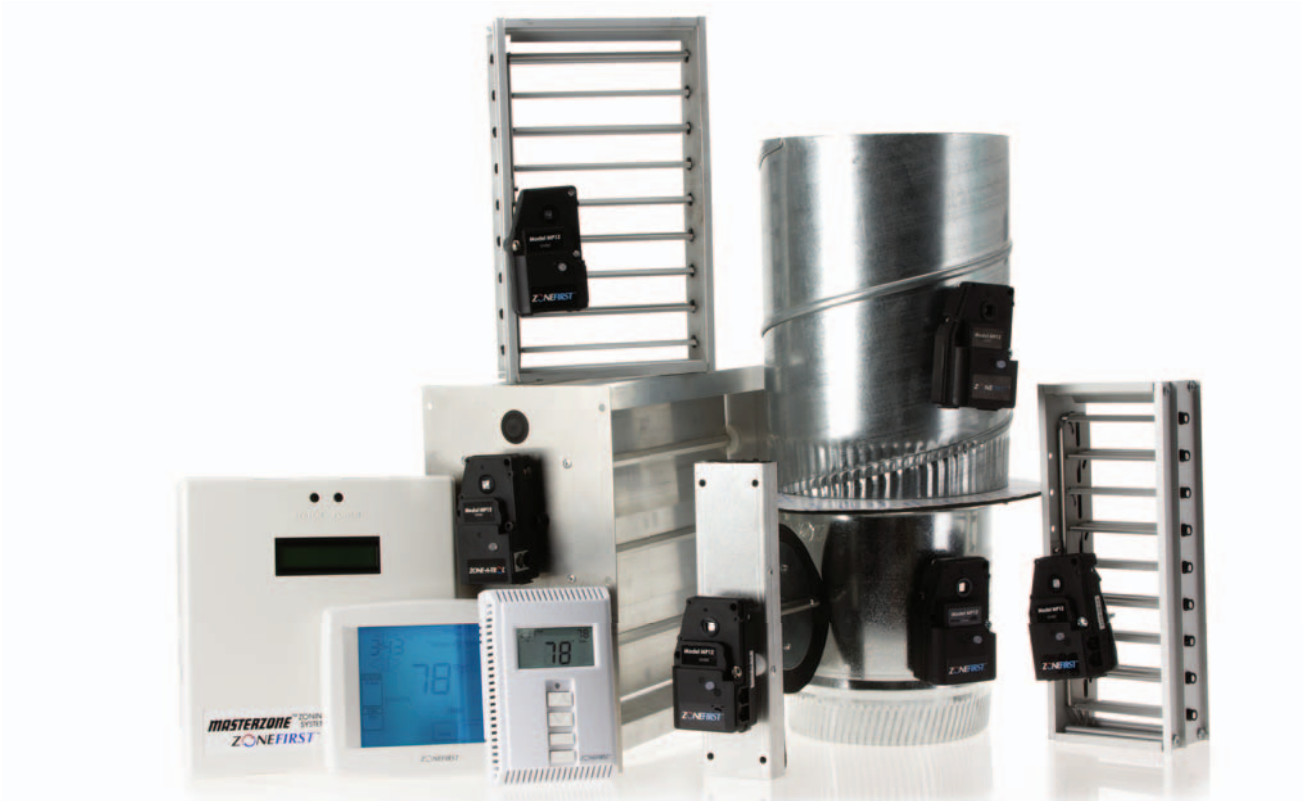
Zoned systems are designed to heat or cool different areas of a building to different comfort, humidity, and ventilation settings. Zoned systems can control water flow, forced air, or electrical supply in different areas of a building's HVAC system. Zoned systems are found in both residential and commercial environments. While the basic operations are identical, the size of these systems varies. The simplest zoned system is electric baseboard heating.

Most electric baseboard heating systems are zoned. Each area of the building has a separate line-voltage thermostat that controls one set or one single baseboard. For example, a house would have a separate thermostat in each bedroom, bathroom, kitchen, and open area. Each thermostat would control the temperature in that specific area of the home by turning its baseboard on and off as the temperature falls and rises. This allows each room to be set for the comfort of the room's occupants.

Another example of zoning is found in residential hydronic heating for baseboards. As with the example of electric heat, a home may have two or three thermostats (zones). Each thermostat controls a valve or a pump coming off of the central boiler. When the thermostat calls for heat, it sends a demand signal to the boiler. The demand signal causes the boiler to start producing heat to supply the operating pump or open zone valve. When the thermostat for the temperature zones calling for heat are all satisfied, the valves will close, the pumps will stop, and the boiler will shut down and wait for the next call for heat.

Another type of zoned system is the forced-air zoned system. These systems use multiple thermostats to control dampers in ductwork that open or close based on the call for heat or cooling in different comfort zones of a building. The zone thermostats are also connected to the air handler or furnace through a zone control board or panel. This central zone control board tells the air handler to heat, cool, dehumidify, or ventilate based on the priority of each zone and what the thermostat's demand signals, **Figure 36-45**.

Forced-air zoning is more complex than the electric baseboard heat or hydronic zoning because of the need to maintain airflow, limit velocity, and limit pressures within the ductwork and across the blower motor in the equipment. To understand this better, take a 4-ton (48,000 Btu/hr) cooling system with three zones in a home as an example. The three zones are the basement, first floor (ground), and second floor (upstairs). For air conditioning, airflow must maintain 400 cfm (cubic



ZONEFIRST

Figure 36-45. Basic components of a forced-air zone system.

Copyright Goodheart-Willcox Co., Inc. 2017

feet per minute) per ton of air conditioning. Therefore, a 4-ton system must maintain an airflow of 1600 cfm (400 cfm × 4 tons).

If airflow drops below this level, the evaporator coil will start to build up ice and freeze. This presents a unique challenge when designing a zoned system. What happens when an air handler designed to supply 1600 cfm of airflow to three zones in a building receives a call to supply airflow to only one zone? Not only does the coil freezing up present problems, but also the remaining zones will have an increased velocity of air causing noise in the ductwork and diffusers. These areas may also experience cooling but without any dehumidifying of air. Additionally, the increased velocity may cause uncomfortable drafts for the occupants of the space being conditioned. Another risk in this scenario is that the increased air pressure at the blower wheel will cause the indoor blower motor to increase its amperage drawn. At a minimum, increased amperage draw will increase a customer's electric bill. At worst, increased amperage draw can begin to overheat and burn out the blower motor. This is assuming that the blower motor is a single-phase motor, which is very common. However, if an HVAC system's blower motor is an ECM (electronically communicated motor), the customer's power bill will rise, and the system will be extremely noisy as the motor attempts to compensate for the restriction in the ductwork.

A zoned system for a three-floor house needs to be able to respond to a single zone's call for cooling without forcing more cold air onto the other two zones. Zone 2 (upstairs) may call for cooling, but the basement and ground floor are already comfortable and would get cold with any more cooling. This means that only 1/3 of the building may need to be heated or cooled at any given time. Thus, the zoned system must be able to maintain sufficient airflow across the evaporator coil, even when automatic zone dampers in the ductwork close to prevent airflow into two of the three zones.

Most systems now overcome this problem by installing a ***bypass damper*** in ductwork between the supply and the return at the air handler. Often the bypass damper is a ***barometric damper***. This is a damper that opens and closes in reaction to static pressure. If the pressure in the ductwork exceeds a certain level, the damper opens and allows the air to flow from the supply to the return to be recycled across the coil and sent out again into the supply plenum, **Figure 36-46**.

A three-zone system would require several components:

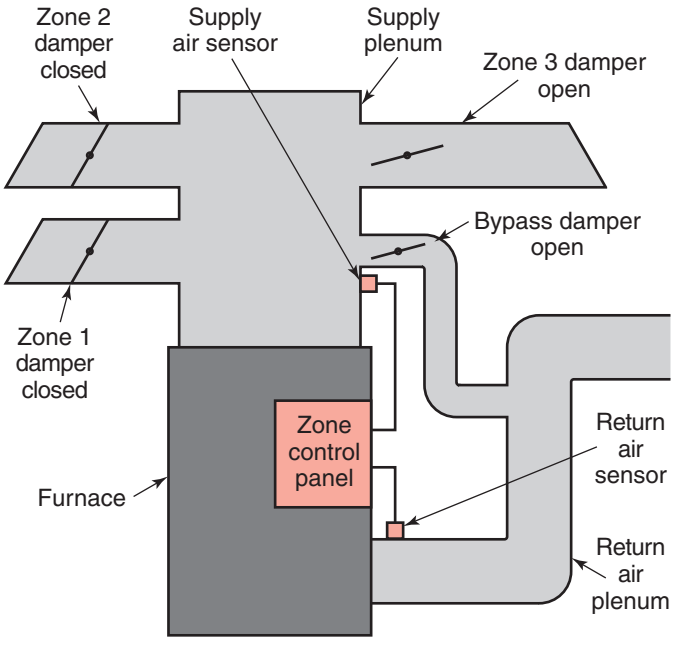
- Three thermostats.
- Three electric dampers (or more based on existing ductwork).
- One zone control panel.
- One static pressure bypass damper.

Optional components could include the following:

- Freezestat on evaporator coil to prevent ice buildup.
- Temperature sensors for supply and return ducts to sense if air is too cold or hot.
- Outdoor temperature sensor for outdoor reset.

The thermostats for most modern zoned systems are the same ones discussed earlier in this chapter. Some of the older zoned systems have what is called a ***master-slave thermostat design***. The ***master thermostat*** sets the mode of the system. For example, it determines whether the system runs in heating or cooling mode. The ***slave thermostat*** monitors the temperature of the zone in which it is located. However, if the slave thermostat calls for cooling while the master thermostat is set for heating, cooling will not cycle on until the master thermostat's mode is changed to cooling. The wiring and design of the slave thermostats are different from the standard thermostat, and the service technician should make sure to replace the thermostat with one recommended by the manufacturer.

In modern systems, the zone control panel regulates the entire system. It takes each thermostat input and determines what area of the conditioned space



Goodheart-Willcox Publisher

Figure 36-46. When a zone control panel receives a call for cooling to only one zone (example is Zone 3), it performs several functions. It opens the zone 3 damper, closes the zone 1 and zone 2 dampers, and opens the bypass damper as needed to maintain proper static pressure and velocity.

Copyright Goodheart-Willcox Co., Inc. 2017

needs to receive airflow. It determines if it is a call for heat, a call for cooling, and in some situations, which zone should have priority. The zone panel then opens the appropriate damper and closes the others. Higher-end zoned systems can tie into a building control system or a home automation system to provide a more integrated level of control.

Caution

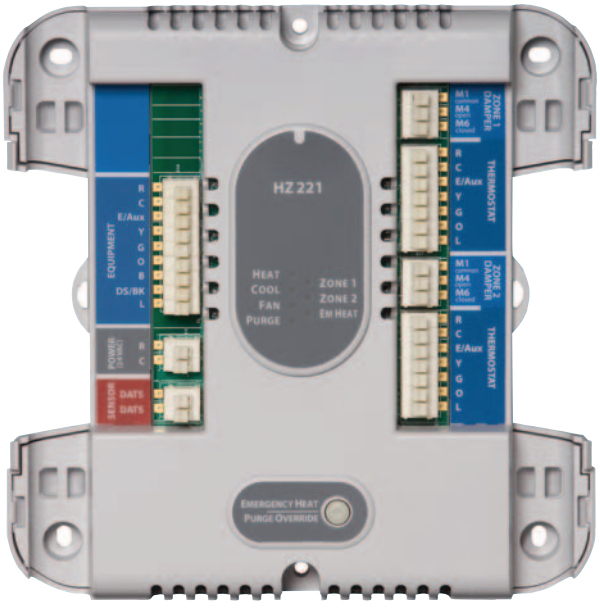
Work in a Zone Control Panel

Zone control panels do not have replaceable parts, so it is extremely important to follow all manufacturer directions when installing and servicing them. Be extremely careful with loose wires and jumpers, as the terminal connections are very small and close together, **Figure 36-47**.

Rectangular zone dampers are typically multiple-blade dampers, **Figure 36-48**. Some are opposing blade dampers, and all dampers must fit tightly inside the main supply trunks to each zone on the system. Many of them use foam tape around their edges to prevent leakage.

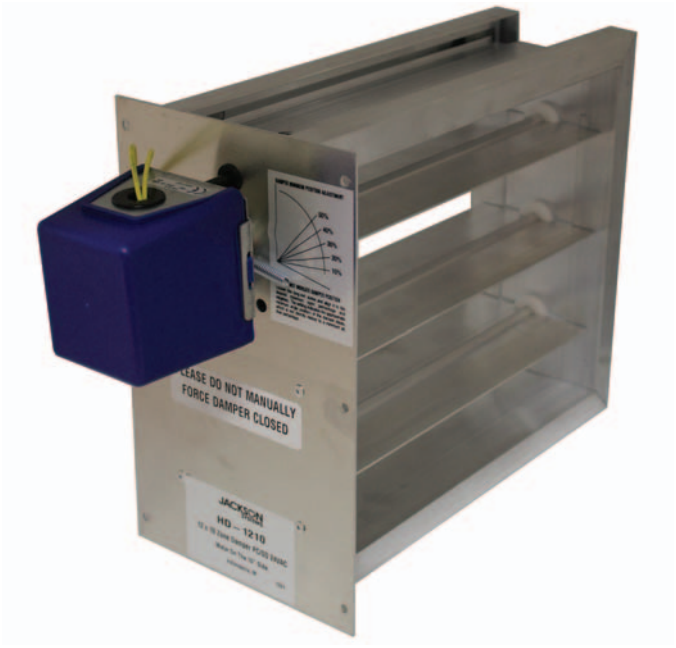
When mounting zone dampers into ductwork, make sure that the blades move freely and do not scrape against the side of the ductwork in any location. Zone dampers should also be installed in a location where they can be easily removed for future service. Make sure that there is enough clearance to completely remove the damper from the ductwork.

For most modern zoned systems, zone damper motors are primarily normally open. A ***normally open damper*** is in the open position when power is not applied to its motor. When power is applied, a small shaded-pole motor drives the damper closed. When the system calls for the damper to open or when the system cycles off, the damper returns to the open state using the force from a small spring mounted on the motor shaft. There are also normally closed dampers that work in the exact opposite manner of normally open dampers. A ***normally closed damper*** is in the closed position when power is not applied to its motor. A spring holds the damper closed when no power is applied. When energized, a motor opens the damper.



Honeywell, Inc.

Figure 36-47. This zone control panel operates with a two-zone heat pump system.



Jackson Systems, LLC

Figure 36-48. Rectangular zone damper.

An example of a normally open damper is a smoke or fire damper used where ductwork penetrates a firewall in a commercial building. The fire damper is held open with the motor. If there is a fire or building power is removed, the damper closes to prevent smoke from migrating through the ductwork.

Some older dampers and those used in some commercial systems are ***power-open/power-closed dampers***. These dampers require power to open and power to close. A technician can easily identify these dampers by looking at the number of wires connected to the damper motor. A normally open damper or normally closed damper will have two wires connected to its motor. A power-open/power-closed damper will have three to five wires connected to its motor, depending on the configuration of the damper.

Power-open/power-closed damper motors require an end switch that comes premounted on the motor that actuates when the damper is in the closed position.

Copyright Goodheart-Willcox Co., Inc. 2017

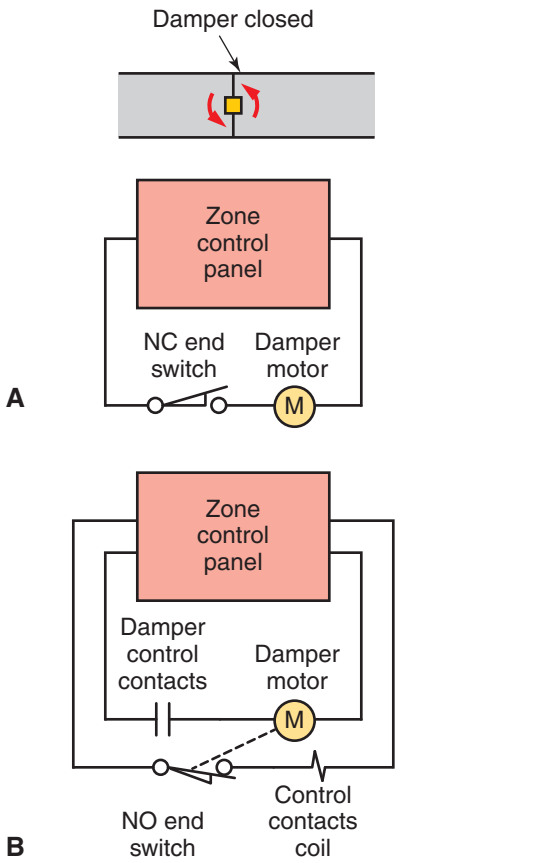
An end switch on a damper can be used in two different ways. An end switch can close when the damper is closed, or it can open when the damper is closed.

Most often, an end switch is wired in series with the damper motor. When the damper reaches its closed position, the end switch opens, which interrupts the current flow to the damper motor. By opening, the end switch stops the electrical signal to the motor from the zone control panel when the damper is in the correct position.

On a few of the higher-end commercial dampers, mainly those tied into building automation systems, a motor shaft–mounted end switch closes when the damper is in the correct position. This closed switch sends a signal to the automation system that is monitoring and controlling the damper positions, **Figure 36-49**.

There are two general types of static pressure bypass dampers. The first and most frequently used type is a barometric damper. This consists of a blade damper with adjustable weights that determine the pressure at which the damper opens. Often, these weights are on a lever on the outside of the ductwork. The adjustable weight is set to keep the damper closed until the pressure in the ductwork exceeds the engineered maximum level. As the pressure in the ductwork pushes open the bypass damper, supply air is allowed to flow directly into the return duct. This bypassing action maintains proper airflow across the evaporator coil, **Figure 36-50**.

The second type of bypass damper uses a motor-driven blade that opens as the pressure in the ductwork rises past a preset level. A zone control panel uses pressure sensors in the supply and return plenums to monitor air pressure and signal when to open the electric dampers, **Figure 36-51**.



Goodheart-Willcox Publisher

Figure 36-49. Damper end switch wiring options example. Check manufacturer diagrams when available. A—A normally closed (NC) end switch opens when the damper reaches the closed position. B—A normally open (NO) end switch closes when the damper reaches the closed position. A NO end switch signals the controller, which opens contacts to stop the damper motor.

ZONEFIRST

Figure 36-51. Static pressure controller for use with an electric bypass damper.

Copyright Goodheart-Willcox Co., Inc. 2017

Even though controls monitor air pressure and bypass airflow to maintain certain operational conditions, some zoned systems use additional safety components. A ***freezestat*** is a thermostat set to open if air temperature above the evaporator coil drops to 33°F. When a freezestat opens, it either directly de-energizes the cooling contactor or sends a signal to the zone control panel. Most freezestats used in residential and light commercial applications close when the temperature rises 5°F. Check the manufacturer documentation for exact temperatures. On some larger commercial applications, especially those where there is a hydrocoil (chilled or heated water) and outside air intakes, freezestats may have manual resets. The manual reset allows a technician to inspect the system for damage before restarting. When a zone control panel senses a freezestat signal, the control either opens an electric bypass damper or de-energizes the cooling contactor to shut off the compressor until the evaporator temperature rises.

Most air-conditioning evaporators operate best at a coil temperature of 34°F to 36°F. Any colder than that risks the chance of developing ice. Lower airflow rates can also cause the coils to freeze. Ice acts as an insulator. Ice buildup will prevent heat from being absorbed from the airstream across the coil into the refrigerant inside the coil. Since heat from the air is not reaching the refrigerant, a frozen coil will worsen over time as the ice builds up across the openings in the fins. More ice means lower airflow, which causes the formation of additional ice.

As an evaporator coil freezes, the boiling of the refrigerant in the evaporator slows and eventually causes liquid refrigerant to flow to the compressor. This can cause ice formation on the compressor and compressor failure.

A frozen evaporator coil reduces airflow to the spaces needing cooling. Conditioned spaces will feel warm and damp. Once a coil is frozen, the only way to defrost it is to cycle off cooling mode (turn off the compressor). Running the blower fan speeds the defrost process.

If a major buildup of ice is on a coil that is installed upstream of a gas, oil, or electric furnace, a technician can turn the blower on, set all zones to heating, and allow the heat to run.

Caution

Frozen Evaporator in a Heat Pump

If a frozen coil is on a heat pump, run the heat pump in heating mode. However, be careful to make sure that electric backup heat does not come on. Do this by either disconnecting the W1 wire or by turning off the circuit breaker or electrical disconnect to the electric heating elements. Airflow is restricted by the ice buildup. If the electric heating elements were to turn on, they could overheat and cause damage.

Caution

Condensate Drain Lines during Defrost

When defrosting a frozen coil, make sure the condensate lines are not plugged. If the drain pans or drain lines overflow, they could cause building damage or wet areas outside the equipment. If water does overflow and spill, be sure to clean up all water to prevent mold growth. It is a good idea to clear condensate lines before starting to defrost an air-conditioning or refrigeration coil.

Forced-air systems that also include heating have evolved even further by the use of a duct temperature sensor that senses the air temperature in the supply plenum. Based on this temperature, the zone control panel can control the furnace's heat production, the cooling contactor, outside air intakes, and bypass dampers to ensure the correct airflow at the correct air temperature is moving into the supply ductwork to the rest of the building, **Figure 36-52**.

Due to more stringent energy codes, recently installed zoned systems require a zone control panel that connects with an outside air temperature sensor. This allows heating and cooling to adjust supply air temperature based on outdoor air. This adjustment allows multistage equipment to be staged based on the true heating and cooling needs of the environment and building envelope. An example of this is how a day with an outside temperature of 50°F requires a lower Btu/hr output from the furnace than a 0°F day. The furnace can change the temperature of its supply air based on outdoor air temperature. This ability to control the output of a system based on outdoor temperature offers large energy cost and footprint savings.

36.9.1 Zoned System Operational Sequence for Heating

The sequence of operation for most zoned systems in heat mode is as follows:

1. A thermostat calls for heating in a single or multiple zones.
2. A switch closes across the R and W contacts on the zone control panel.
3. Zone dampers close for any zones not requiring heating.
4. Once all dampers are in their appropriate positions, the zone control panel closes R to W contacts on the furnace control board.
5. The heat sequence initiates, and the furnace provides heating to the ductwork where open and closed dampers route airflow to the zones required.

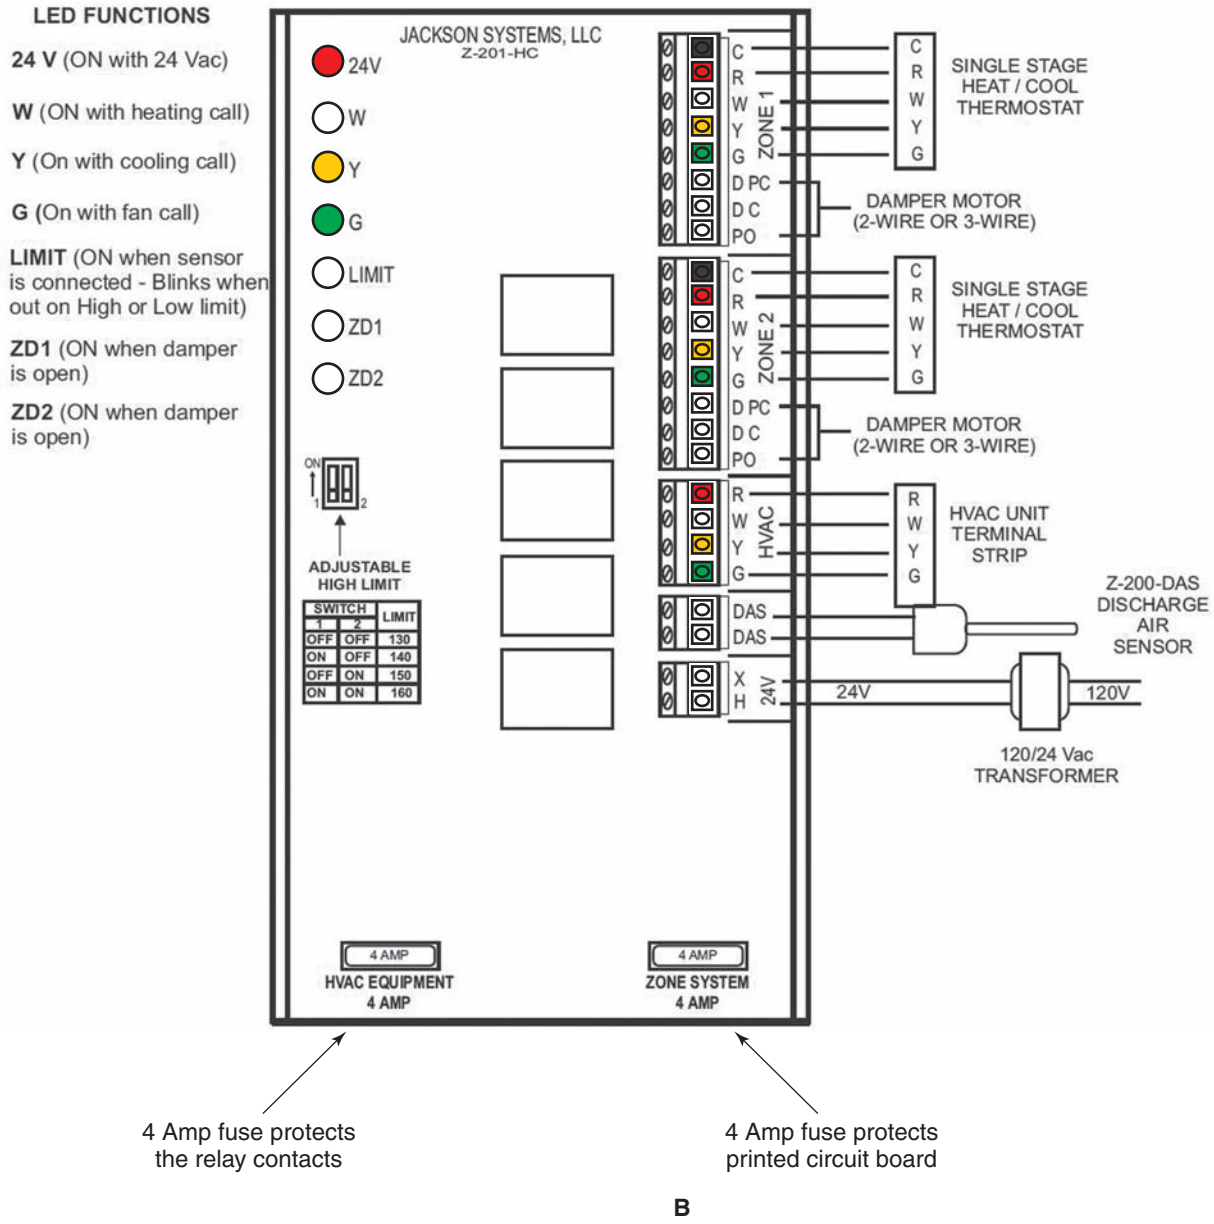
A



B

Jackson Systems, LLC

Figure 36-52. A—Discharge air temperature sensor. B—A two-zone control panel wiring diagram showing a discharge air sensor connection.

10

Copyright Goodheart-Willcox Co., Inc. 2017

6. As temperatures rise in each zone, their thermostats become satisfied and open the appropriate R to W contacts on the zone control panel. As the R to W contacts for a zone open, the zone damper for that zone closes, unless it is the last zone requiring heat.
7. Once the last zone is satisfied, the furnace begins its cool-down sequence, and all zone dampers open to allow airflow to all zones.
8. The furnace shuts off the blower, and the system waits for its next call for heat or cooling with all dampers in the open position.

36.9.2 Zoned System Operational Sequence for Cooling

The operational sequence for cooling is almost identical to heating with the exception of the need to monitor evaporator coil temperature to prevent ice buildup:

1. A thermostat calls for cooling in a single or multiple zones.
2. A switch closes across the R and Y contacts and also across the R and G contacts on the zone control panel.
3. Zone dampers close for any zones not requiring cooling.
4. Once all dampers are in their appropriate positions, the zone control panel closes the R to Y contacts and the R to G contacts on the air handler control board.
5. The cooling sequence initiates, and the air handler provides cooling to the ductwork where open and closed dampers route airflow to the zones required.
6. As the temperatures drop in each zone, their thermostats become satisfied and open the appropriate R to Y contacts and R to G contacts on the zone control panel. As the R to Y and R to G contacts for a zone open, the zone damper for that zone closes, unless it is the last zone requiring cooling.
7. Once the last zone is satisfied, the air handler continues to run for a few minutes after the R to Y contacts have opened. This ensures that the evaporator coil has a chance to defrost and drain properly. All zone dampers open to allow airflow to all zones.
8. The air handler shuts off the blower, and the system waits for its next call for heat or cooling with all dampers in the open position.

While this is the basic process, there are some variations of this depending on how the system is engineered. In commercial buildings and some high-end residential installations, the blower does not completely shut down at the end of the heating or cooling cycle. Rather, all dampers open, and the blower shifts to a low-speed operation to maintain a slight airflow through the ductwork. In commercial buildings, this is especially important to allow outside air to be brought into the building for outside air ventilation requirements and building pressurization.

36.9.3 Troubleshooting Zoned Systems

Troubleshooting zoned systems involves both air and electrical diagnostics. When beginning to troubleshoot a zoned system, find out what is not happening and why it is not happening. The experienced technician does not concentrate on the zone that the customer reports as having a problem, but rather looks at the system as a whole. While the following diagnostic procedure may need to be changed slightly based on a given system, most often this procedure will help in locating the problem, **Figure 36-53**.

Troubleshooting zoned systems is best done by working from big to small. Begin with overall airflow and work down to individual zone dampers and modes. It is important to remember that the problem may not be with the area the customer is complaining about as the entire system needs to work as a whole.

Troubleshooting a Zoned System

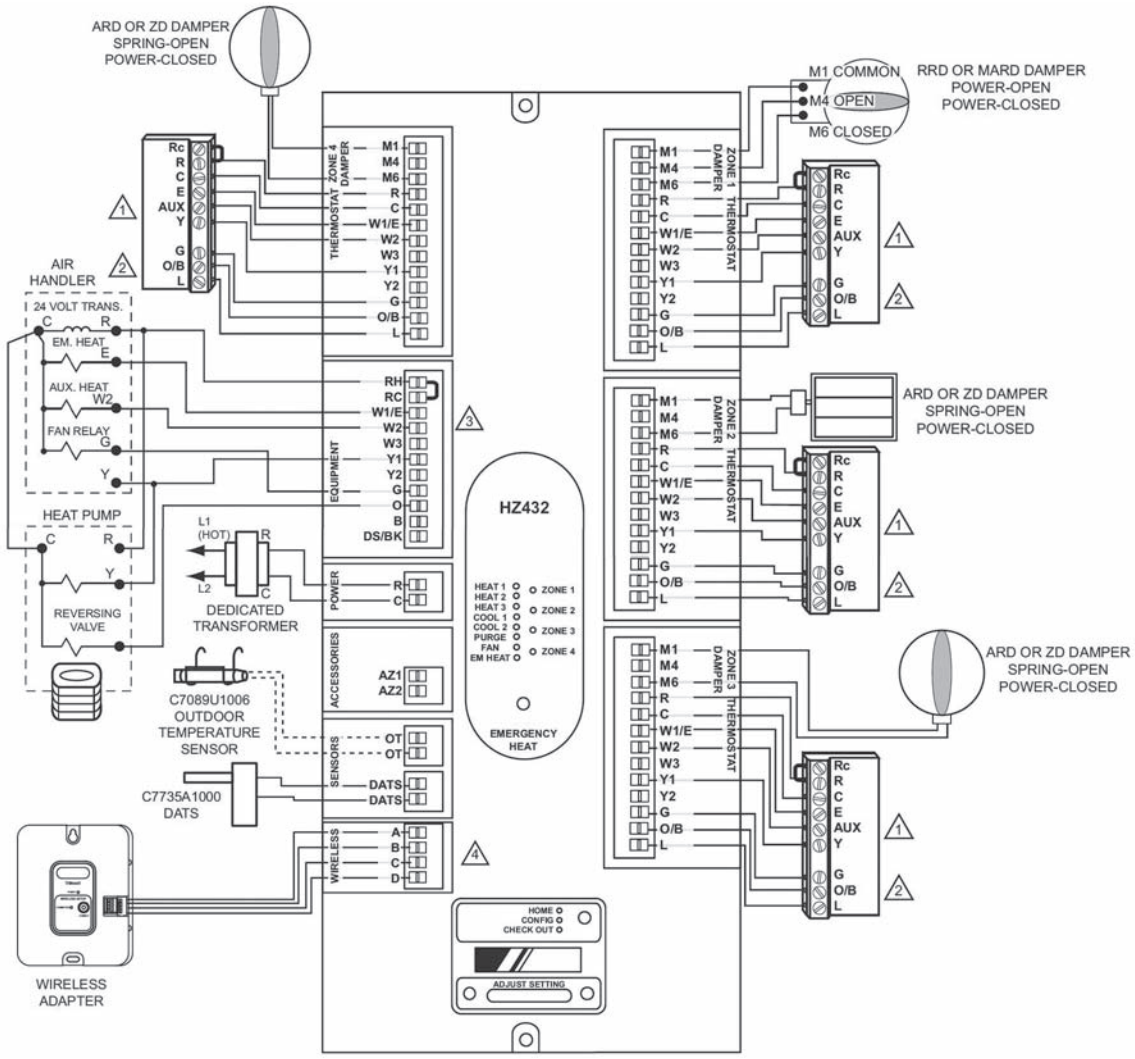
On arrival to the service call, introduce yourself to the customer, get a summary of the problem, and ask the customer to show the locations of all the thermostats on the forced-air system.

Initial Airflow Inspection

1. As the customer identifies each thermostat, adjust its setting. Change it to one of these settings:
   - "Fan-On" (preferred).
   - "Cooling" with the temperature 10°F below set point.
   - "Heat" with the temperature 10°F above set point for heating.

   Of these three options, the "Fan-On" setting is preferable, as it will not lower the temperature of the building, and it provides more time to troubleshoot before needing to change setting due to discomfort. Adjust each of the thermostats on the system to the same setting.
2. Go into each zone and verify that there is airflow from each supply register in the space. This confirms that the system is working and that all zone dampers are open. If airflow is absent or reduced in a zone, check the zone damper as described in the *Damper Inspection*

Copyright Goodheart-Willcox Co., Inc. 2017



Honeywell, Inc.

Figure 36-53. A zone control panel wiring diagram for a four-zone heat pump system.

10

section that follows. Solve any airflow issues before continuing with the system evaluation.

Dampers Closed Inspection

1. Go to one thermostat and turn the thermostat off. If using the "Fan-On" function, switch the thermostat back to "Fan-Auto."
2. Wait a few minutes for the damper to cycle closed.
3. Verify that the airflow has stopped, meaning the zone damper has shut. If airflow continues, the damper has not closed. Check the zone damper as described in the *Damper Inspection* section that follows. Solve the damper issue before continuing to check the other zones.
4. Repeat the three previous steps for each of the remaining zones except the last zone, ensuring that each zone's damper has closed and airflow has stopped.
5. After checking the second-to-last zone, open one of the other zones in order to test the final damper sequence. This will prevent the system from shutting down when the final zone is turned off. System shutdown would return dampers to their "normal" position, which may be open or closed.
6. When testing the final zone, locate the barometric damper. Verify that this damper is opening to allow air to pass from the supply to the return. Verification is done by watching the weighted lever on the side of the damper. It should move as the pressures increase and decrease. If the damper is not opening properly, try manually moving the arm toward the open position.

Copyright Goodheart-Willcox Co., Inc. 2017

With a single zone calling, the damper should move to an almost fully open position. When all the zones are open, the bypass damper should be closed, because maximum airflow is needed to condition all the zones.

Damper Inspection

The following is a general procedure for troubleshooting a damper that is not opening or closing at the proper time. The procedure uses a "stuck-open" damper as an example, but the same concepts would apply to a "stuck-closed" damper. Always refer to manufacturer's product-specific service manual if available.

1. Locate the zone control panel and find the zone number for the zone that is not working properly.
2. Check to make sure the wires are connected to the proper terminals.
3. Check to make sure that the indicator light for that zone shows that the zone is no longer calling for fan, cooling, or heating. If it is still calling for an operation and the thermostat is off, check the wiring or thermostat problems as discussed earlier in this chapter.
4. On the zone control panel, locate the open damper's motor connections. Verify what type of damper it is. If there are two wires, is it normally open or normally closed? Measure the voltage readings on the two terminals.
   - If the damper is normally open and the zone is not calling for operation, there should be more than 24 Vac on the common and control terminals.
   - If the damper is normally closed and the zone is not calling for operation, there should be 0 Vac on the common and control terminals.
   - If the zone has a power-opened/power-closed damper with three wires, take two measurements. Across the common and closed terminals, there should be 24 Vac. Across the common and open terminals, there should be 0 Vac.

   If the readings are incorrect, further diagnose the zone control panel by following manufacturer directions. In most cases, by disconnecting the thermostat wires from the zone panel, the damper should go to its closed position and voltages. If the thermostat terminals do not properly control the voltage output of the zone control panel, most likely it is a bad zone control panel.
5. After verifying that the zone panel is working correctly, check the damper motor in the ductwork. Take a meter reading to make sure that the motor is getting the proper voltage. If it is not, trace the wire between the zone control panel and the motor and check all of its connections.
6. If the motor is getting the proper voltage, locate the lever that is found on the damper motor. Cycle the damper by hand. If it does not move, remove the damper from the ductwork and find out why the linkage is not moving. This could happen because of a broken linkage, the blades are binding, or something that is caught on the blades is interfering with movement.
7. If there is nothing binding the damper, check the motor by measuring the resistance of its winding. Perform the following steps:
   - First, turn off the system.
   - Second, disconnect the wires from the damper motor to isolate the motor from the circuit.
   - Use an ohmmeter to ***ohm out*** the winding (measure its resistance). If the motor shows a small resistance, it should be good. If the motor shows an OL or infinite resistance, the damper's motor is bad. Replace the motor.

Cooling Check

1. After testing all the zones for proper damper operation, adjust all zones to "cooling" mode and turn down the thermostat to 5°F under room temperature. If this is a master-slave system, make sure the system switch is set to cooling mode.
2. Wait about five minutes and check that the condenser contactor has energized and that the system is cooling. If the condenser contactor does not energize, measure whether there is 24 Vac across the Y and C terminals on the zone control panel output. If there is not 24 Vac, troubleshoot the zone control panel and find out if there is a blown fuse. In addition, check whether there is 24 Vac across the Y and C terminals on the thermostat side, 0 Vac across R and Y terminals, and 24 Vac across R and W terminals. Reading these measurements confirms that the zone control panel and attached thermostats are working properly.

Copyright Goodheart-Willcox Co., Inc. 2017

3. If the condenser contactor is not energized, find the condenser and take voltage measurements at the following locations:
   - 24 Vac across the condenser contactor coil.
   - Line voltage (230, 240, or 408 Vac) across the power contacts on the condenser contactor.
   - Line voltage across the disconnect or top of the contactor.
   - 24 Vac across the control terminals in the condensing unit control box (same terminals as were measured in the zone control panel).

Heating Check

1. If the cooling mode of the system is fully operational, check operation in heating mode. Change all thermostats to heating and increase their set point to about 5°F above room temperature. If working on a master-slave system, remember to change the system selector to heating mode.
2. Once again, wait about five minutes and then recheck all dampers. They should all be open and the system should be heating. If the system is not heating, verify that there is 0 Vac across R and W, 24 Vac across R and Y, and 24 Vac across R and C on the thermostat side. On the system side of the zone control panel, measure for 24 Vac across W and C, 0 Vac across Y and C, and 24 Vac across R and C. If any of these are not correct, troubleshoot the zone control panel according to manufacturer's directions.
3. If there is 24 Vac between W and C on the system side of the zone control panel, begin to troubleshoot the furnace. If a gas-fired furnace, check the following:
   - Ignition sequence.
   - Proper gas flow.
   - Any tripped safety devices.
   - Pressure switches.

   Gas furnace troubleshooting is described in Chapter 41, *Gas-Fired Heating Systems*. Oil furnace troubleshooting is described in Chapter 42, *Oil-Fired Heating Systems*.

Service Call Wrap-Up

After verifying proper operation for fan only (airflow), cooling, and heating of the zones, explain all of your findings to your customer. Reset all thermostats to normal operation and set points. Verify that all covers are back on the motors and zone control panels and that all tools are removed.

Copyright Goodheart-Willcox Co., Inc. 2017

Chapter Review

Summary

- In basic terms, a thermostat is a sensing device that reacts to temperature change. To the average person, a thermostat is the controller used to start, stop, or modulate the operation of a heating and cooling system.
- Common temperature-sensing devices used in thermostats include thermistors and bimetal coils. A temperature-sensing device is used with a switching device, such as a reed switch, contacts and magnets, or a mercury switch.
- Modern thermostats have numerous features and options, including various power sources, different temperature-sensing and switching devices, display options, service reminders, programming options, and Internet/mobile device communication capabilities.
- To prevent indoor temperature from moving too far from set point, thermostats use anticipators. A heat anticipator is a resistance heating coil that produces just enough heat to cycle off heat production so that air temperature does not overshoot set point beyond acceptable temperature swing. A cooling anticipator is a resistance heating coil that produces just enough heat to cycle on cooling mode before air temperature rises to cut-in set point.
- A multistage thermostat can control the heating or cooling capacity of a system. These thermostats often have extra wiring terminals for heat stage (W1, W2, etc.) and cooling stage (Y1, Y2, etc.) operation.
- Line-voltage thermostats operate on line voltage: 120 Vac or 240 Vac. These thermostats can control high current loads, such as electric heating elements.
- Low-voltage thermostats operate on 24 Vac from a step-down transformer.
- Millivolt thermostats operate on mere millivolts supplied by a thermocouple or thermopile.
- When installing a thermostat, follow the manufacturer's wiring diagrams. Set subbase DIP switches according to the type of system that the thermostat will control. Test wiring for proper connections and operation before programming the thermostat.
- Free cooling is the use of an air-side economizer. The economizer operates when outdoor air temperature (and sometimes humidity) is low. Duct dampers are adjusted so that the indoor blower draws in outdoor air for cooling.
- Wireless thermostats allow an HVAC system to be controlled from anywhere. These systems still require one or more temperature sensors.
- When troubleshooting an HVAC system, begin at the thermostat and determine whether the problem is in the wiring, in the furnace or air handler, or in the thermostat.
- When troubleshooting a line-voltage thermostat, be mindful of electrical dangers and set a multimeter to read appropriate voltage levels.
- Zoned systems are designed to heat or cool different areas of a building to different comfort, humidity, and ventilation standards. Forced-air zoning operates using ductwork, dampers, sensors, and related controls. Often, a barometric damper controls a bypass duct to handle some of the airflow when one or more zones are not calling for conditioning. Forced-air zoned systems may use a master-slave thermostat arrangement or a zone control panel communicating with different room thermostats.
- A freezestat is a thermostat that opens when evaporator temperature drops to around 33°F. This protects that evaporator from freezing over.
- When troubleshooting forced-air zoned systems, observe system operation to determine what is not happening and then determine why it is not happening. View the system as a whole. Work from big to small, beginning with overall airflow and working down to individual zone dampers.

Review Questions

Answer the following questions using the information in this chapter.

1. A sensing device that reacts to temperature change is a _____.
   A. humidistat
   B. pressurestat
   C. sensostat
   D. thermostat

Copyright Goodheart-Willcox Co., Inc. 2017

2. A common temperature-sensing component that reacts to temperature change by changing shape to actuate a reed switch or mercury switch is a _____.
   A. bimetal strip
   B. diaphragm
   C. thermistor
   D. thermocouple
3. To reduce or eliminate electrical arcing in an electrical control, use _____.
   A. a long bimetal strip coiled tightly
   B. magnets to pull in electrical contacts
   C. a mercury switch
   D. Any of the above.
4. What is the condition called in which the residual heat blown through the ductwork raises the temperature of the conditioned space above the thermostat set point after a heating thermostat has shut off a furnace?
   A. Heat wave.
   B. System lag.
   C. System overshoot.
   D. Temperature swing.
5. The total difference of the high and low temperature in a room, including values below the cut-in temperature and above the cut-off temperature, is called _____.
   A. contact point bounce
   B. system lag
   C. system overshoot
   D. temperature swing
6. A condition in which a furnace turns on but the temperature of a room drops too low before the heating effect is felt is called _____.
   A. chill wave
   B. system lag
   C. system overshoot
   D. temperature droop
7. The devices used by mechanical heating thermostats to turn on early enough to prevent temperature from dropping below its cut-in set point are called _____.
   A. cooling anticipators
   B. heat anticipators
   C. temperature limit switches
   D. zone controls
8. The devices used by mechanical cooling thermostats to turn off early enough to prevent system overshoot or temperatures below the thermostat set point are called _____.
   A. cooling anticipators
   B. heat anticipators
   C. temperature limit switches
   D. zone controls
9. A combination thermostat is used to control a(n) _____.
   A. combination lock
   B. cooling contactor only
   C. heating and cooling system
   D. indoor blower's operation only
10. A gas furnace with a multistage thermostat uses _____ to control its heat capacity.
    A. a cooling anticipator
    B. multiple sets of electric resistance heating coils
    C. a reed switch
    D. a two-stage or modulating gas valve
11. Line-voltage thermostats typically operate at _____.
    A. 30 mVdc to 50 mVdc
    B. 1 Vdc to 5 Vdc
    C. 24 Vac to 30 Vac
    D. 120 Vac to 240 Vac
12. Low-voltage thermostats typically operate at _____.
    A. 30 mVdc to 50 mVdc
    B. 1 Vdc to 5 Vdc
    C. 24 Vac to 30 Vac
    D. 120 Vac to 240 Vac
13. Low-voltage thermostats often use _____ to switch and control high current, line-voltage devices, such as fans and compressors.
    A. expansion valves
    B. relays
    C. solenoids
    D. verbal commands
14. The temperature-sensing component that reacts to temperature change by changing its electrical resistance is a _____.
    A. bimetal strip
    B. diaphragm
    C. thermistor
    D. thermocouple

Copyright Goodheart-Willcox Co., Inc. 2017

15. To calculate the amperage load that a low-voltage thermostat's step-down transformer can handle, perform the following calculation: _____.
    A. volt-amperes ÷ resistance
    B. volt-amperes ÷ volts (primary side)
    C. volt-amperes ÷ volts (secondary side)
    D. volt-amperes ÷ watts
16. A millivolt thermostat generates its own electric current from heat applied to its _____.
    A. bimetal coil
    B. Bourdon tube
    C. thermistor
    D. thermocouple
17. Millivolt thermostats can be used to control _____ systems.
    A. central air conditioning
    B. centrifugal chiller
    C. heat pump
    D. standing-pilot light heating
18. Being able to adjust conditioned space temperature remotely using a tablet PC, smartphone, or laptop is specifically an advantage of a _____ thermostat.
    A. multistage
    B. millivolt
    C. power-stealing
    D. wireless
19. Tapping into a fan, cooling, or heating terminal and drawing a small milliamp current to recharge its internal battery is a feature of a _____ thermostat.
    A. multistage
    B. millivolt
    C. power-stealing
    D. wireless
20. A programmable thermostat uses a(n) _____ that functions as a clock and controls indoor climate for different blocks of time.
    A. anticipator
    B. mercury switch
    C. microprocessor
    D. reed switch
21. The thermostat wiring designation for cooling mode is _____.
    A. C
    B. R
    C. W
    D. Y
22. The thermostat wiring designation for power from the step-down transformer is _____.
    A. C
    B. R
    C. W
    D. Y
23. The thermostat wiring designation for heating is _____.
    A. C
    B. R
    C. W
    D. Y
24. The thermostat wiring designation for the fan relay is _____.
    A. Aux/E
    B. C
    C. G
    D. O/B
25. The thermostat wiring designation for energizing a heat pump's reversing valve is _____.
    A. Aux/E
    B. C
    C. G
    D. O/B
26. When installing a thermostat's subbase, some system settings may need to be managed using _____ switches.
    A. bellows
    B. diaphragm
    C. DIP
    D. reed
27. When outdoor air is low in temperature and humidity, a forced-air system can provide free cooling by using the following components, *except* _____.
    A. a barometric damper for exhaust air
    B. duct dampers
    C. the compressor
    D. the indoor blower
28. A good location where a thermostat should be installed is _____.
    A. behind a door or in a tight corner
    B. in direct sunlight
    C. on an inner wall
    D. on an uninsulated outer wall

Copyright Goodheart-Willcox Co., Inc. 2017

29. When taking measurements on an energized circuit for low-voltage thermostat diagnostics, set a multimeter to the _____ setting.
    A. Hz
    B. Vac
    C. Vdc
    D. Ω

30. When taking measurements on an energized circuit for low-voltage thermostat diagnostics, a 0 V reading indicates a(n) _____.
    A. closed switch
    C. good relay coil
    B. open switch
    D. All of the above.

31. In a forced-air system, zone controls prominently use _____ to regulate the temperatures of the different zones.
    A. duct dampers
    B. exhaust venting
    C. steam traps
    D. water solenoid valves

32. In a forced-air zoned system, what device operates to regulate airflow and compensate for when one of several zone dampers closes?
    A. Bypass damper.
    B. Economizer damper.
    C. Exhaust air damper.
    D. Fresh air inlet damper.

33. When pressure from airflow is reduced, most barometric dampers close due to _____.
    A. adjustable weights
    B. power-close motor
    C. shaded-pole motor
    D. spring tension

34. In a forced-air zoned system, a _____ opens when temperature right above the evaporator coil drops to around 33°F.
    A. condensate drain
    B. freezestat
    C. refrigerant relief valve
    D. zone damper

35. After speaking with the customer, begin a service call for troubleshooting a forced-air zoned system by _____.
    A. checking overall airflow in the different zones
    B. dismantling each zone damper, looking for mechanical problems
    C. replacing the zone control panel
    D. taking electrical measurements on each room thermostat

- 37.5.5 Air Leakage
- 37.5.6 Ducts, Appliances, and Miscellaneous Loads
- 37.5.7 Total Load

37.6 Software and Apps for Load Calculations

Learning Objectives

Information in this chapter will enable you to:

- Understand the principles of heat loss and heat gain.
- Compare the sources of heat loads for heating and heat loads for cooling.
- Explain the relationship between a material's K-value, C-value, U-value, and R-value and the rate at which heat is transferred through the material.
- Summarize the use of indoor and outdoor design temperatures in calculating heat loads.
- Understand the relationship between surface area and heat transfer rate.
- Compare the techniques for finding a building component's heat transfer rate using the component's C-values, K-values, U-value, and R-values.
- Explain how heat load calculations differ depending on whether the building is built on a basement, a slab, or a crawl space.
- Understand infiltration and exfiltration and explain their effects on heat load.
- Summarize the effect of sunlight on cooling loads and methods of reducing sun loads.
- Understand heat lag and its effect on heat loads.
- Identify miscellaneous smaller heat loads within a building that affect the calculation of total heating or cooling loads.
- Use a worksheet or computer program to properly calculate total heating and cooling loads for a building.

Review of Key Concepts

Reviewing these concepts from earlier chapters will help you understand new concepts presented in this chapter:

- Heat can be transferred through radiation, conduction, convection, or a combination of any of these three methods. Heat always flows from a warmer substance to a cooler substance. (Chapter 4)
- Latent heat is heat absorbed or released as a substance changes physical state (solid, liquid, gas). Latent heat has no effect on the temperature of a substance. Sensible heat is the heat energy absorbed or released to change the temperature of a substance. (Chapter 4)
- The amount of heat energy required to raise the temperature of one pound of a substance by 1° Fahrenheit or one kilogram of a substance by 1 Kelvin is the substance's specific heat capacity. (Chapter 4)
- Air temperature can be expressed as a dry-bulb temperature or a wet-bulb temperature. A dry-bulb temperature is a measurement of the air's temperature without adjusting for the effect of humidity. Wet-bulb temperature is a measurement of the air's temperature that is adjusted for the effect of the air's humidity on evaporative cooling. (Chapter 27)
- Indoor air conditions can be affected by sun loads, heat sinks, and heat and humidity migration. (Chapter 27)

Introduction

Heating and cooling systems must be properly sized for the size and environmental conditions of the space being conditioned. The heating system should be capable of keeping the occupied space warm even on the coldest winter days for the given location. In much of the United States, typical heating systems are called upon to maintain a 70°F (21°C) inside temperature while outside temperatures fall below 0°F (–18°C) with strong winds. Air conditioning systems must be sized to provide adequate cooling capacity for the warmest days in the summer.

As new buildings are constructed and existing buildings are renovated, architects and builders strive to incorporate sustainable design. ***Sustainable design*** is the use of materials and processes that lower energy costs, reduce operating and maintenance costs, increase productivity, and decrease the amount of pollution that is generated.

All of a building's heating and cooling loads must be accurately accounted for in order to determine the specific needs for HVAC equipment. The calculation of the heating and cooling loads should be the first step in an energy audit of a building, which includes identifying sources of heat leakage and recommendations for improvement.

Thinking Green

Green Building Construction

Guidelines for green building construction and equipment can be obtained from numerous sources: National Home Builders (NAHB); US Green Building Council's Leadership in Energy Environmental Design (LEED) committee; and ASHRAE's *GreenGuide*.

37.1 Heat Transfer

Heat always flows from hot to cold. This transfer of heat results in *heat loss* in the warmer object or space and *heat gain* in the cooler object or space. The transfer of heat continues until the two temperatures are equalized.

In the context of HVAC, ***heat loss*** is transfer of heat from inside to outside by means of conduction, convection, and radiation through all surfaces of a house. In the winter, a conditioned space must be heated with enough heat energy (Btu) to compensate for the heat loss to the cold outside air. For heating purposes, it is desirable to reduce heat loss.

On the other hand, during the summer, enough heat must be removed from the conditioned space to cool it as heat enters from the warm outside air. In the context of HVAC, ***heat gain*** is the increase of heat within a given space as a result of direct heating by solar radiation and of heat radiated by other sources, such as lights, equipment, or people. In summer conditions, it is desirable to minimize heat gain. In the winter, it is necessary to reduce the transfer of heat from inside the conditioned space to the outdoors. In the summer, it is necessary to prevent heat transfer from the outdoors into the conditioned space.

The amount of heat transfer from a building is determined by the building's design, construction materials, and location. Buildings should be designed to reduce heat transfer. This is referred to as making the building envelope tight. However, studies have shown that making a building too tight may result in insufficient air changes within the building. In turn, this can lead to sick building syndrome. To prevent insufficient air changes in a building with a tight envelope, it is important to bring in some fresh outside air and to maintain continuous air changes within a building. This is possible through mechanical ventilation, such as fresh outside air inlets into the supply plenum or the use of HRVs/ERVs.

37.2 Heat Loads

The ***heat load*** is the amount of heat that must be added or removed from a space in order to maintain the desired temperature in that space. For the purpose of sizing an HVAC system, the maximum heat load is determined for a period of one hour. Charts (found in numerous manuals) are used to make the computation. Heat load calculation manuals are available through various sources. The Air Conditioning Contractors of America (ACCA) publish *Manual J—Residential Load Calculation*. They also publish *Manual N—Commercial Load Calculation*.

Code Alert

Calculating Heating and Cooling Loads

The method used to calculate heating and cooling loads is typically identified in local building codes. For low-rise residential buildings, the load calculation method is typically based on ACCA *Manual J—Residential Load Calculation*. For commercial buildings, the method is typically based on ANSI/ASHRAE/ACCA Standard 183.

There are several major heat loads:

- Heat that is transmitted through walls, ceilings, and floors (conduction).
- Heat added to or removed from the air to control humidity.
- Heat added or removed by the air entering the building due to infiltration or brought in for ventilation.
- Heat produced by the sun that enters the building directly through the windows or by heating the surfaces it strikes.
- Heat from powered devices such as light fixtures, electric motors, electric or gas stoves, etc. People, too, release a considerable amount of heat.

In all cases, the heat load can be described as either sensible heat load (temperature change) or latent heat load (moisture evaporating or condensing).

37.2.1 Heat Loads for Heating

During the heating season, all heat lost from a building must be replaced in order to maintain the desired temperature within the building. The heat loads for heating include the means by which a significant amount of heat will be lost from a building, **Figure 37-1**.

The major sources of heat loss appear in the following list:

- Heat lost by conduction through walls, windows, ceilings, and floors.
- Heat lost due to warm air leaking out of the building (exfiltration) and cool air leaking into the building (infiltration) as a result of inadequate sealing.
- Heat lost due to combustion air from furnaces or fireplaces leaving the flue.

Normally, all other heat losses are ignored when calculating heat loads. They are too small to have a significant effect on the size of heating system required to meet the heating demands.

Figure 37-1. Heating loads. Large heat losses occur during heating season due to cold air entering into building and warm air exiting out. 1—Heat loss through walls, doors, and windows. 2—Heat loss through slab, basement, or crawl space. 3—Heat loss through ceiling. 4—Cold air infiltration.

37.2.2 Heat Loads for Cooling

The first step in selecting the proper size for a cooling system is to determine the heat load of the space that is to be cooled. The heat load is the sum of all of the heat added to a space. A large number of factors can affect the heat load of a space, including the size, design, and construction of the space; types of equipment operating in the space, and the way the space is used.

This heat must be removed to keep the temperature and relative humidity in the space at the values desired. There are numerous sources of heat gain in warm weather. Heat gain in warm weather is often the result of heat conduction. This takes place through the walls, ceilings, floors, windows, and doors of the enclosure. Other common sources of heat gain include hot air leaking into the building (infiltration), hot air brought in for ventilation, sun load, heat from appliances and lights, and heat from occupants and any warm objects brought into the space. See **Figure 37-2**.

37.3 Calculating Heat Leakage

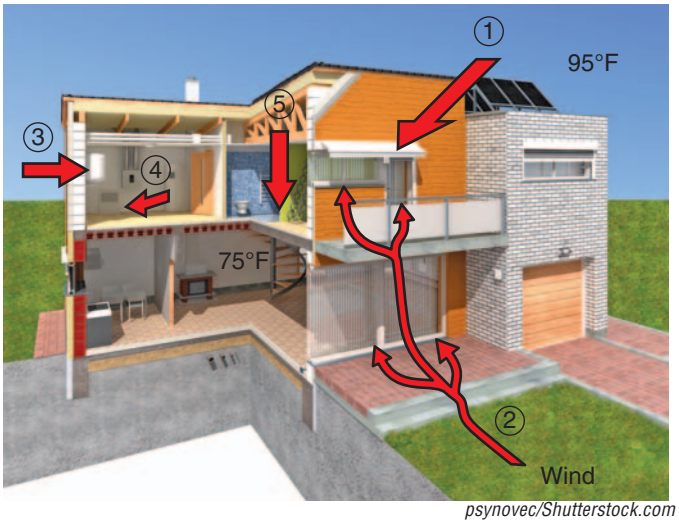
Heat leakage is the heat that is conducted through the walls, ceilings, and floors when there is a temperature difference between spaces. When the temperature outside a conditioned space is warmer than the temperature inside the space, heat leakage results in heat gain. When the temperature outside a conditioned space is lower than the temperature inside the space, heat leakage results in heat loss.

To calculate the total heat leakage for a space, a technician must first determine the types of materials through which heat is leaking. Keep in mind that many building components, such as walls, windows, and doors, are constructed from several different materials. In some cases, these composite components are treated as a single entity. In other cases, the type and thickness of each material in the component are considered separately.

The second step in calculating how much heat is leaking is to determine the rate at which heat transfers through the various materials. These values have been determined by building material manufacturers under laboratory conditions and are expressed as C-values, K-values, U-values, or R-values. These values can be looked up in charts and will be discussed in greater detail in the sections that follow. The formulas used to calculate heat leakage vary slightly depending on which of these values is used for the calculation.

After determining the types of materials through which heat is leaking and the rate at which heat is transferred through those materials, the third step is to determine the surface area of each type of material. The greater the surface area, the more heat will leak through the material over a given period of time.

The fourth step is to determine the temperature difference between the inside surface of the material and the outside surface. The rate that heat is



psynovec/Shutterstock.com

Figure 37-2. Cooling loads. 1—Sun load. 2—Infiltration. 3—Heat gain through walls, doors, and windows. 4—Heat gain from appliances and occupants. 5—Heat gain through ceilings.

Copyright Goodheart-Willcox Co., Inc. 2017

transferred through a material is directly proportional to the temperature difference between the two sides of the material.

With the preliminary data collected, the total amount of heat that leaks through the material in a one hour period can be calculated. The formula used to calculate heat leakage varies slightly, depending on whether the materials' C-values, K-values, U-values, or R-values are used in the calculation. However, all of the formulas for calculating heat leakage require that the technician know the types (and in some cases, the thicknesses) of materials through which heat is leaking, the surface areas of those materials, and the temperature difference from one side of the material to the other.

37.3.1 Thermal Conductivity (K-Value) and Thermal Conductance (C-Value)

A material's ***thermal conductivity***, or ***K-value***, is a measure of the amount of heat that will pass through one square foot of the material one inch thick, in one hour, when there is a 1°F temperature difference between the two sides of the material. The units used with K-values are Btu·in/hr·ft²·°F. Materials with high K-values transfer heat at a greater rate than those with low K-values.

A K-value is typically used to describe the thermal conductivity of a homogenous material, like insulation, drywall, wood, or glass. When calculating the heat transfer through a composite building component, like a framed wall or a foam-cored door, the K-values for the individual materials in the component are divided by the thickness of their respective materials. This calculation yields the thermal conductance (C-value) of individual materials.

$$C_1 = \frac{K_1}{X_1}$$

$$C_2 = \frac{K_2}{X_2}$$

$$C_3 = \frac{K_3}{X_3}$$

K = thermal conductivity of the material
X = thickness of the material in inches

A material's ***thermal conductance***, or ***C-value***, is a measure of the amount of heat that will pass through one square foot of the component in one hour when there is a temperature difference of 1°F between one side of the component and the other. Notice that the thermal conductance is not based on a 1" thickness, but describes the thermal properties of the material based on its measured thickness. In most cases, a material's C-value can be looked up on a chart. In some cases, the technician may need to calculate the material's C-value based on the K-value and the thickness of the material.

37.3.2 Thermal Resistance (R-Value)

The ***thermal resistance***, also known as the ***R-value***, of a material or building component is a measure of its resistance to heat transfer. The R-value of a homogenous material is the reciprocal of the material's K-value multiplied by the thickness of the material. A *reciprocal* of a number is one divided by that number.

Formula for calculating thermal resistance (R-value) using a K-value:

$$R = \frac{1}{K} \times X$$

This equation can also be simplified into the following:

$$R = \frac{X}{K}$$

K = thermal conductivity of the material
X = thickness of the material

A material's thermal resistance can also be described as the reciprocal of the material's C-value.

Formula for calculating thermal resistance (R-value) using a C-value:

$$R = \frac{1}{C}$$

C = thermal conductance of the material

Building materials have been tested to determine the rate at which they will transfer heat. Those values are recorded in numerous charts, which can be referenced when performing load calculations. These charts usually list the thermal resistance of materials and common building components. Occasionally, a technician will need to calculate the resistance of a composite building component (like a wall made from various materials) manually.

To manually calculate the thermal resistance of a composite building component, begin by finding the thermal resistance of the individual materials in the component. Next, the thermal resistances of the individual materials are added together to find the total thermal resistance of the component.

Formula for calculating thermal resistance of a composite building component:

$$R_T = R_1 + R_2 + R_3 \ldots$$

The higher a material or component's R-value, the slower the rate at which heat will transfer through that

Copyright Goodheart-Willcox Co., Inc. 2017

material or component. For example, **Figure 37-3** shows how adding insulation (which has a high R-value) to a wall slows down the rate of heat transfer through the wall. As a result, less heat conducts through the wall over a given period of time.

With rising fuel and energy costs and a growing focus on conservation, energy management has become a greater concern in recent years. Therefore, it is recommended that all homes and apartments have adequate thermal insulation. The purpose of thermal insulation is to slow down the transfer of heat through a wall, floor, or ceiling. The effectiveness of the insulation is directly related to its R-value. A higher R-value indicates greater effectiveness in insulating.

Many different types of insulation are used in modern construction. From an HVAC technician's perspective, the composition of the insulation is less important than its overall effectiveness, or R-value. Most insulation is made of fiberglass, but different types can be used. The type of insulation installed will depend on the type of area to be insulated, the degree of thermal resistance (R-value) required, and the space available for the insulation. Different types of insulation require different thicknesses to achieve the same level of effectiveness.

The recommended R-values for common insulation applications are shown in **Figure 37-4**. Notice that the insulation's U-value, which will be explained in the following section, is inversely proportional to the insulation's R-value. This means that a low U-value corresponds to a high R-value, and vice versa.

Recommended Thermal Insulation Values

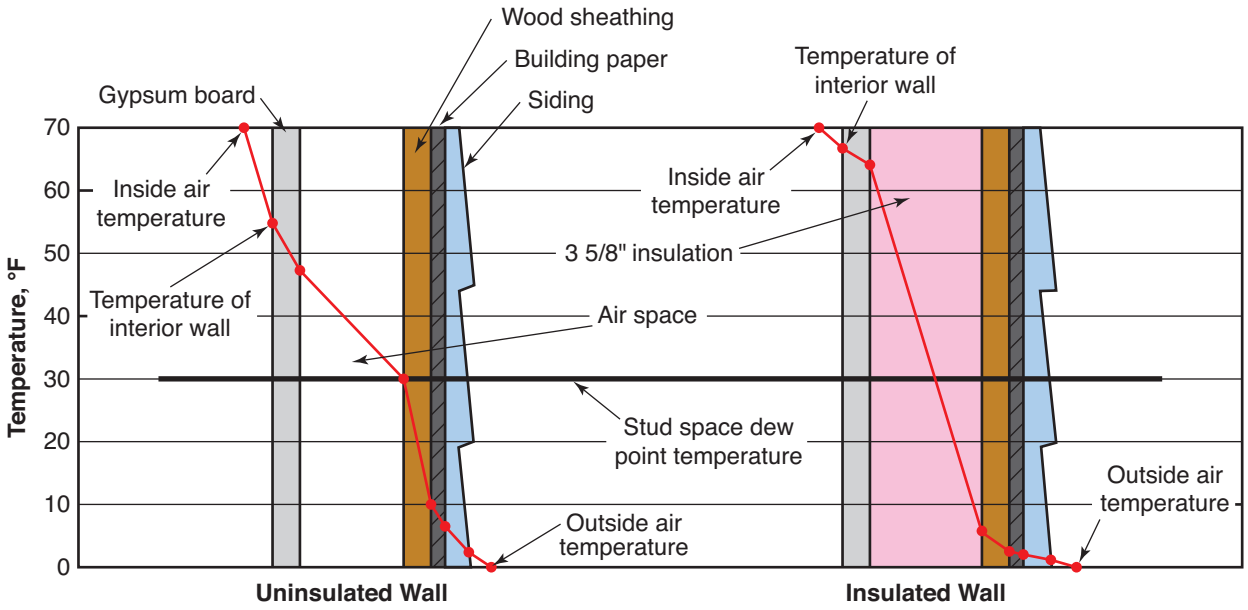
Areas to be insulated	Recommended values	
	U-value	R-value
Ceiling with unheated space above	.08	12
Exterior wall	.07	14
Wall with unheated space on one side	.10	10
Floor over unheated space	.07	14

Goodheart-Willcox Publisher

Figure 37-4. Some recommended thermal insulation values for homes and apartments.

37.3.3 Thermal Transmittance (U-Value)

The ***thermal transmittance***, or ***U-value***, of a building component is very similar to the component's thermal conductance, or C-value, but it includes an adjustment for boundary air films. A boundary air film is a thin layer of air that is molecularly attracted to a surface. Because of this attraction, the boundary air film is not replaced as frequently as the surrounding air.



Goodheart-Willcox Publisher

Figure 37-3. This drawing compares the temperature change through an uninsulated wall and an insulated wall. Because heat transfers through the uninsulated wall quicker, the temperature of the interior wall surface drops as low as 55°F (13°C). The insulated wall maintains a temperature of 67°F (19°C) at the interior wall surface.

10

Copyright Goodheart-Willcox Co., Inc. 2017

Every surface of a building has one of these thin layers of air clinging to it. Because these air films have a slightly different temperature than the surrounding air, they add a little extra insulation between the building component and the surrounding environment. See **Figure 37-5**.

The U-value of a material or component is the reciprocal of the total thermal resistance of the structure and the boundary air films associated with it. To find the U-value, add together the thermal resistances of the materials in the structure and the thermal resistances of the air films on the inside and outside surfaces. The reciprocal of this sum is the U-value for the structure.

Formula for calculating U-value:

$$U = \frac{1}{(R_{of} + R_1 + R_2 + R_3 + R_{if})}$$

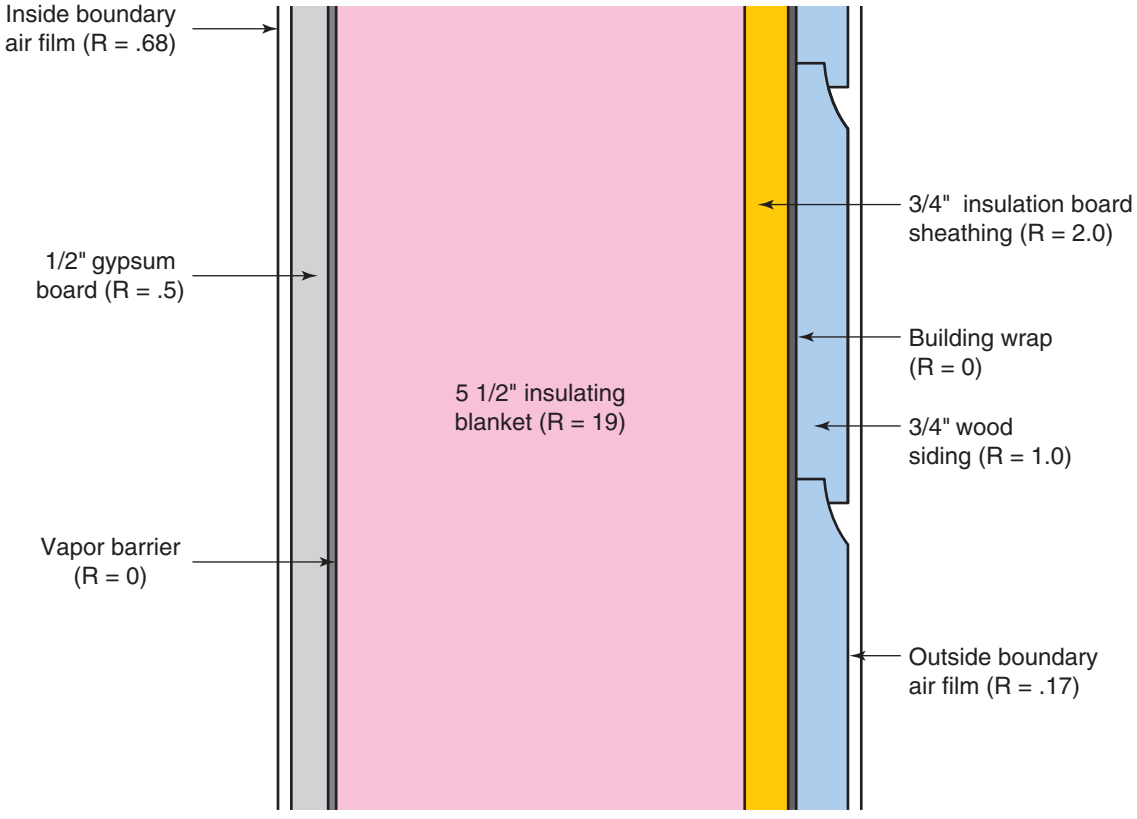
R_{of} = thermal resistance of the outside air film

R_1 through R_3 = thermal resistances of the building components

R_{if} = thermal resistance of the inside air film

Like C-values, U-values are expressed in units of Btu/ft^2·°F·hr. However, unlike C-values or K-values, which are measured in a laboratory with perfectly still air, U-values assume a 15 mph wind on the outside surface and a 15 fps (1/6 mph) draft on the inside surface of the building component. Since the air in the real world is very rarely perfectly still, U-values are generally slightly more accurate than K-values or C-values.

The U-value for most types of construction can be obtained from reference books published by the American Society of Heating, Refrigerating and Air-Conditioning Engineers (ASHRAE). **Figure 37-6** is a condensed table that includes some of the more common constructions. Note that this table lists both the component's U-value and R-value.



$$\text{U-value} = \frac{1}{.68 + .5 + 0 + 19 + 2 + 0 + 1 + .17}$$

$$= \frac{1}{23.35}$$

$$= .043$$

Figure 37-6. Continued.

37.3.4 Design Temperatures

C-values, K-values, and U-values represent heat leakage rates based on a 1°F temperature difference between the inside and outside surfaces of a material or building component. In other words, these values are only accurate when the outside air is exactly 1°F warmer or cooler than the inside air. In order to find the heat leakage rate when the temperature difference is not 1°F, the value must be multiplied by the actual temperature difference.

When heat leakage is being calculated as a step in determining heat loads for sizing a heating or cooling system, the temperature differences used must accurately represent the most extreme conditions under which the system will be expected to perform.

Code Alert

Climate Zones and Design Temperatures

Local building codes typically specify a climate zone and design temperatures to use for calculating heating and cooling loads and other system design considerations. Always use the design temperatures and climate zones specified by the local building code.

Design Temperatures for Calculating Heating Loads

The design temperatures used to calculate heat loss are often referred to as *winter* design temperatures. The ***indoor design temperature (IDT)*** is the ideal indoor temperature, which the heating or cooling system works to maintain. The indoor design temperature is generally set to 70°F (21°C) or 72°F (22°C). The ***outdoor design temperature (ODT)*** represents extremely cold conditions for the geographical

Copyright Goodheart-Willcox Co., Inc. 2017

region where the heating system is installed. For actual values for outdoor design temperatures, the technician must contact the local weather bureau or the local chapter of the American Society of Heating, Refrigerating, and Air-Conditioning Engineers (ASHRAE).

The outdoor design temperature is never as low as the lowest temperature recorded for the area. This is because such extreme low temperatures are usually of short duration. Residual heat in the building usually enables the furnace to cope with the extreme low temperatures for a short period of time. Instead, the outdoor design temperature represents the lowest temperature that is expected to persist for an extended period of time.

ASHRAE lists outdoor design temperatures (ODT) by latitude and elevation. In addition, the ODT temperatures are adjusted periodically to account for gradual changes in climate and long-term weather patterns. When working with design temperatures, be sure to use values that are correct for the location and are up-to-date. These are available from the local ASHRAE chapter.

ASHRAE charts give three different values for each locality. The 99.6% temperature is used for residences and small, poorly insulated office buildings. The outdoor air in the geographical region covered by the chart only falls below this temperature 0.4% of the time. In a typical year, the air temperature will only drop below this level for a total of 35 hours.

The next lowest temperature listed in the charts is the 99% temperature. This temperature is used for well-constructed and well-insulated buildings having a standard number of windows. The outdoor air in the region covered by the chart will fall below this temperature only 1% of the time. In a typical year, the temperature will drop to this level for a total of only 88 hours.

A 97.5% value, also given for each locality, means that the outside temperature is above the value listed 97.5% of the time. In a typical year, the temperature will only spend a total of 219 hours below this level. The 97.5% temperatures are used in load calculations for large buildings with considerable thermal capacity and small total window area.

For example, at one point in time, technicians in the Detroit area used –10°F (–23°C) as the outdoor design temperatures for all buildings. Now, it is recommended that 0°F (–18°C) (99.6% factor) be used for small, uninsulated buildings. For well-constructed, insulated buildings with a standard window area, 4°F (–16°C) (99% factor) is used. For large buildings with a standard number of windows, 8°F (–13°C) (97.5% factor) is used.

If the indoor design temperature is 72°F (22°C), an outdoor design temperature of 0°F (–18°C) results in a 72°F (22°C) temperature difference (TD). The 99% outdoor design temperature of 4°F (–16°C) results in a 68°F (38°C) temperature difference. The 97.5% outdoor design temperature of 8°F (–13°C) results in a 64°F (35°C) temperature difference.

Since the temperature differences are used to calculate the required system size, using the 97.5% outdoor design calculation rather than the 99% outdoor design temperature will result in an 11% decrease in the recommended size of the system. Reducing the size of the system will reduce the initial cost of the system as well as operational costs. As long as the building has a large thermal capacity and a small total window area, the smaller system will still heat the building adequately.

Be careful to use the proper outdoor design temperature (99.6%, 99%, or 97.5%) for the type of building in which the system will be installed. If the proper design temperature is in doubt, always choose the outdoor design temperatures (ODT) on the low side. Heating plants that are overworked (undersized) can cause excessive stack and chimney temperatures and may cause fires. Oversized units will be less efficient and waste energy.

In many buildings, certain areas such as closets, hallways, and attics are unheated. These spaces receive their heat from heat leakage through partitions, ceilings, and floors. These unheated areas are assumed to be halfway between the indoor design temperature and the outdoor design temperature.

Design Temperatures for Calculating Cooling Loads

The design temperatures used to calculate cooling loads are often referred to as *summertime* design temperatures. When calculating heat gain for the purpose of sizing a cooling system, technicians typically use 75°F (24°C) at 50% relative humidity (rh) for the indoor design temperature. The outdoor design temperatures are looked up on a chart and selected according to geographic region. Typically, multiple temperatures are given in the chart, including a design dry-bulb temperature and either design humidity information or a design wet-bulb temperature. The design dry-bulb temperature is used for calculating the temperature difference, and the design humidity information is used to calculate the latent cooling load.

37.3.5 Heat Transfer Multipliers (HTMs)

Depending on which worksheets or software a technician uses to calculate a building's heat loss or

Copyright Goodheart-Willcox Co., Inc. 2017

heat gain, the technician may be required to enter a heat transfer multiplier for a building component. The term ***heat transfer multiplier (HTM)*** refers to a building component's U-value multiplied by a temperature difference. For ***heat loss HTMs***, that temperature difference is simply the indoor design temperature minus the outdoor design temperature. For ***heat gain HTMs***, the temperature difference is calculated the same way, but then adjusted for factors such as sun exposure and heat storage. Heat gain HTMs are generally looked up on a chart rather than calculated by the technician.

37.3.6 Heat Leakage Surface Areas

Regardless of how heat losses and heat gains are being calculated, the technician must know the area of all surfaces through which heat is leaking. These must be entered into the computer program, spreadsheet, or worksheet being used to calculate the heat losses or gains.

Calculating Rectangular Areas

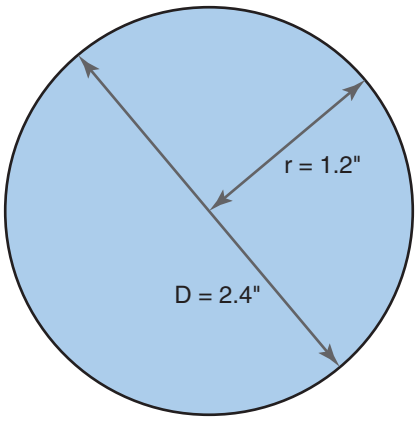
Area is a measurement of two-dimensional space. The area of a rectangular surface is found by multiplying the surface's length by its width.

Formula for calculating the area of a rectangle:

Area of a rectangle = Length × Width

Calculating Areas for Non-Rectangular Shapes

Some special formulas must be used when finding the area of certain objects. For example, the area of a circle is found by using the formula $A = \pi r^2$. The symbol, π, is always 3.1416. The letter *r* represents the radius of a circle, which is one-half of the circle's diameter. The area of a circle is shown in **Figure 37-7**.



Goodheart-Willcox Publisher

Figure 37-7. The area of a circle is calculated using the formula: Area = πr^2. Diameter (D) is the width of the circle at its widest point, and the radius is 1/2 of that value.

Formula for calculating the area of a circle:

Area = πr^2

US Customary Units for Area

The US Customary units used to measure area are square inches (in^2), square feet (ft^2), and square yards (yd^2). The following are the conversion factors for converting from one US Customary unit to another:

144 in^2 = 1 square foot

9 ft^2 = 1 square yard (yd^2)

The relationship between these units is shown in **Figure 37-8**.

SI Units for Area

The SI system uses units of square centimeter (cm^2), square decimeter (dm^2), and square meter (m^2) to measure area. The relationship between these units is shown in **Figure 37-9**.

Occasionally it is necessary to convert from SI units to US Customary units. The following are conversion factors that are used:

1 square centimeter (cm^2) = 0.155 in^2

1 square decimeter (dm^2) = 15.5 in^2

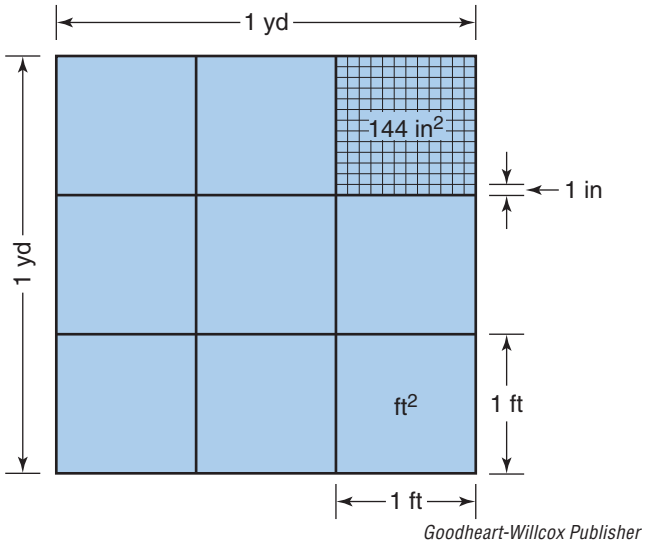
1 square meter (m^2) = 1550 in^2 = 10.76 ft^2

Walls

The area and U-value of the building's walls, as well as the temperature difference from one side of the wall to the other, are required in order to calculate the amount of heat that leaks through the walls.

Formula for calculating heat leakage through walls:

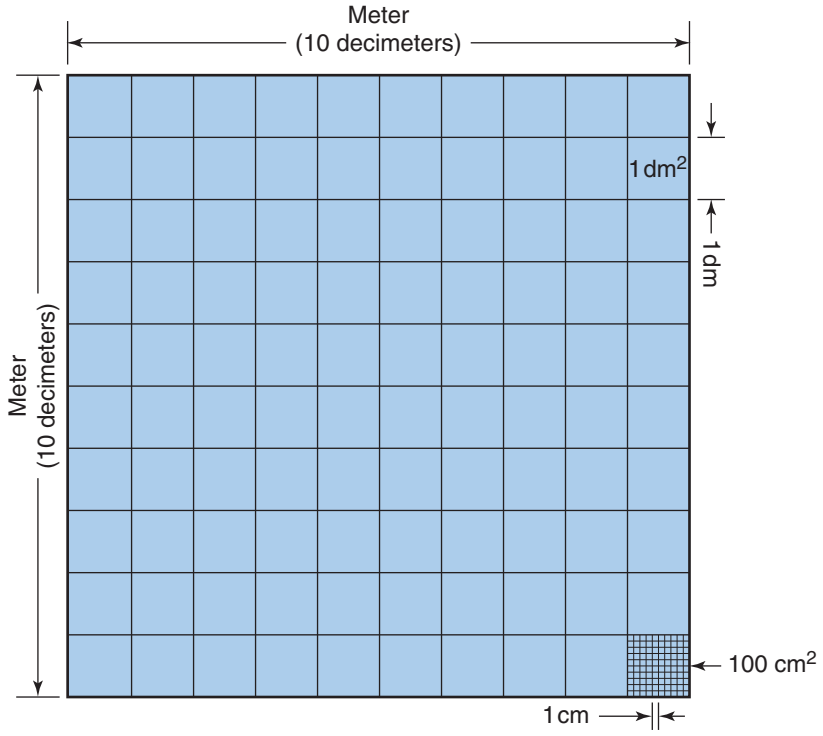
Wall heat leakage = U-value × wall area × temperature difference



Goodheart-Willcox Publisher

Figure 37-8. This illustration shows that 12 linear inches equal 1 linear foot, and 144 square inches (144 in^2) equal 1 square foot (1 ft^2). Note that 3 linear feet equal 1 linear yard, and 9 square feet (9 ft^2) equal 1 square yard (1 yd^2).

Copyright Goodheart-Willcox Co., Inc. 2017



Goodheart-Willcox Publisher

Figure 37-9. This illustration shows that 10 linear centimeters equal 1 linear decimeter, and 100 square centimeters (100 cm^2) equal 1 square decimeter (1 dm^2). Therefore, 10 linear decimeters equal 1 linear meter, and 100 square decimeters (100 dm^2) equal 1 square meter (1 m^2).

To calculate the surface area of a building's external walls, the exterior dimensions of the building should be used. These dimensions result in slightly higher heat leakage loads than if the inside dimensions are used. In other words, heat losses and gains based on outside dimensions are more conservative than heat losses and gains based on interior dimensions would be.

For calculating the areas of the walls, begin by measuring the perimeter of the house. This can be accomplished by measuring the lengths of all of the exterior walls and adding them together. The perimeter of the house is then multiplied by the interior ceiling height to determine the total surface area of the building's exterior walls.

Formula for calculating total wall area:

Total wall area = perimeter × ceiling height

Example:

The house shown in **Figure 37-10** has exterior dimensions of 24′ × 32′. It has an 8′ ceiling. The total exterior surface area of the house is calculated as follows:

$$\begin{aligned}\text{Perimeter} &= L + W + L + W \\ &= 32' + 24' + 32' + 24' \\ &= 112'\end{aligned}$$

$$\begin{aligned}\text{Total wall area} &= 112' \times 8' \\ &= 896\ ft^2\end{aligned}$$

Next, the window and door areas must be subtracted from the total wall area. The result is the practical surface area of the building's exterior walls. This value is often referred to as the net wall area.

10

Pro Tip

Vaulted Ceilings

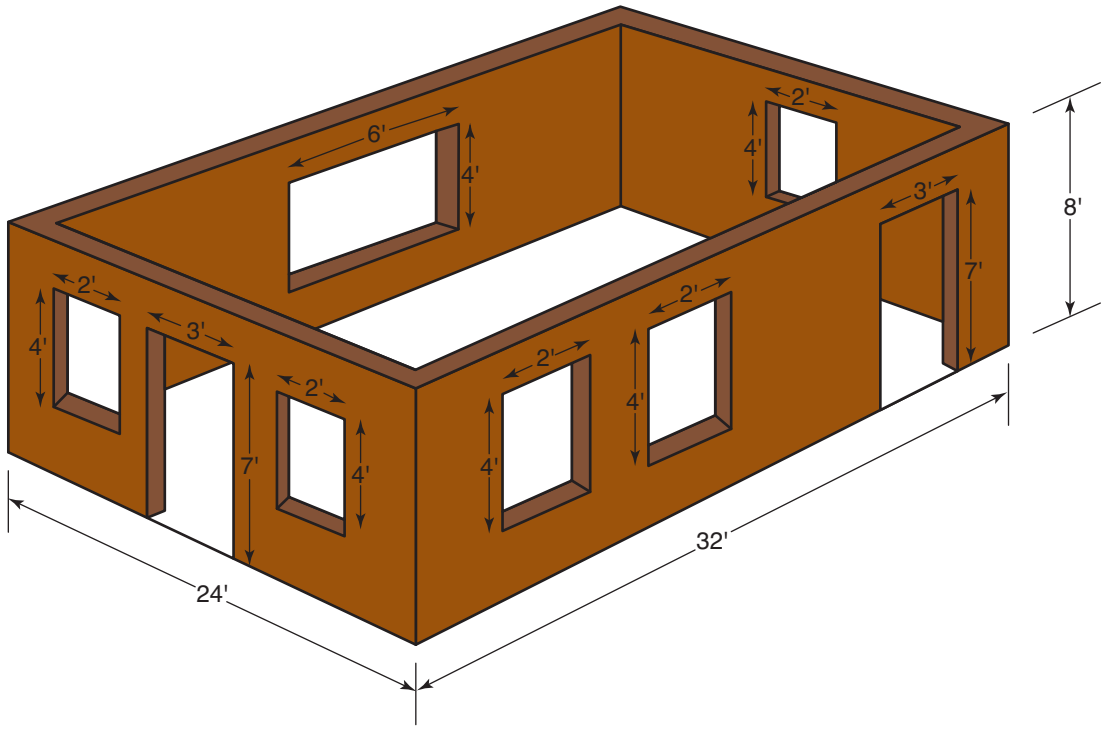
If a home has vaulted ceilings, any area calculations of the exterior walls must include the total area exposed to outdoor conditions. In other words, the triangular area at the top of the walls must be added to the rectangular area of the lower portion of the wall.

Windows

To calculate the area of a window, measure the width and height of the window, as shown in **Figure 37-11**. Then, simply multiply the width by the height.

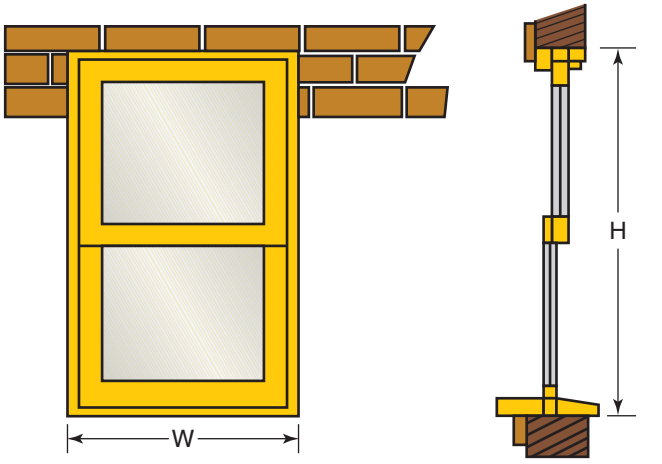
Window construction varies considerably. Windows are commonly available as single-pane, double-pane using a storm window, or permanent double-pane. Energy-efficient windows may even have three permanent layers of glass. The permanent window (single-, double-, or triple-pane) is called the primary window.

Copyright Goodheart-Willcox Co., Inc. 2017



Goodheart-Willcox Publisher

Figure 37-10. Drawing of a one-story home showing wall, window, and door areas. The building is 32′ (9.8 m) long by 24′ (7.3 m) wide. The room height is 8′ (2.44 m). Five windows are 4′ (1.22 m) high by 2′ (0.61 m) wide. The two doors are each 7′ (2.13 m) high by 3′ (0.914 m) wide. The large window in the back of the house is 4′ (1.22 m) high by 6′ (1.83 m) wide.



Goodheart-Willcox Publisher

Figure 37-11. A typical double-hung window. The window's width is measured from the outside edge of one side of the frame to the outside edge of the other side of the frame. The height of the window is measured from the top of the frame to the bottom of the windowsill.

An additional framed pane of glass may be attached to the outside of the window to provide additional insulation. This is called a storm window or storm sash.

The most energy-efficient type of window construction is the permanent double-pane or triple-pane. Two or three panes of glass with sealed air spaces between panes provide excellent insulation. These air spaces are dehydrated, evacuated, and then filled with nitrogen, argon, krypton, or some other dry gas to prevent sweating (condensation), **Figure 37-12**.

Windows are installed in a variety of ways. Some possibilities include:

- Fixed (picture windows).
- Single- or double-hung (where either one or both sashes move up and down).
- Sliding horizontal or casement (hinged on one side and open out with a crank mechanism).

The frame around windows may be made of wood or metal. Vinyl-clad aluminum frames are used to minimize frosting, as they add an additional layer of sealing. The R- and U-values of window pane assemblies are shown in **Figure 37-13**.

Doors

Doors are constructed in a variety of designs. They may be made of solid wood or of wood veneers over foam cores. Many energy efficient doors are constructed of a metal shell filled with insulation. Some doors have windows as part of their design. Large sliding glass doors are often called patio doors. They are responsible for as much as 20% of solar heating and

Andersen Corp.

Figure 37-13. The thermal resistance (R) and heat transfer coefficient (U) of various windowpane assemblies are specified.

heat leakage in some homes. The area used to calculate heat leakage for a door is the height of the door opening times the width of the door opening.

Calculating Net Wall Area

To compute the wall heat leakage area, add the area of the doors in the outside walls to the area of the windows. Then, subtract this amount from the total wall area.

Formula for calculating net wall area:

Net wall area = total wall area – combined area of windows and doors

Example:

Back in **Figure 37-10**, there are five windows measuring 2′ × 4′, two doors measuring 3′ × 7′, and one window measuring 6′ × 4′.

Area of windows = [(2′ × 4′) × 5] + (6′ × 4′)
= 64 ft²

Area of doors = (3′ × 7′) × 2
= 21 ft² × 2
= 42 ft²

Combined area of windows and doors = 106 ft²

The total wall area of the building shown in **Figure 37-10** is 896 ft². The net wall area is calculated by subtracting the door and window areas from the total wall area:

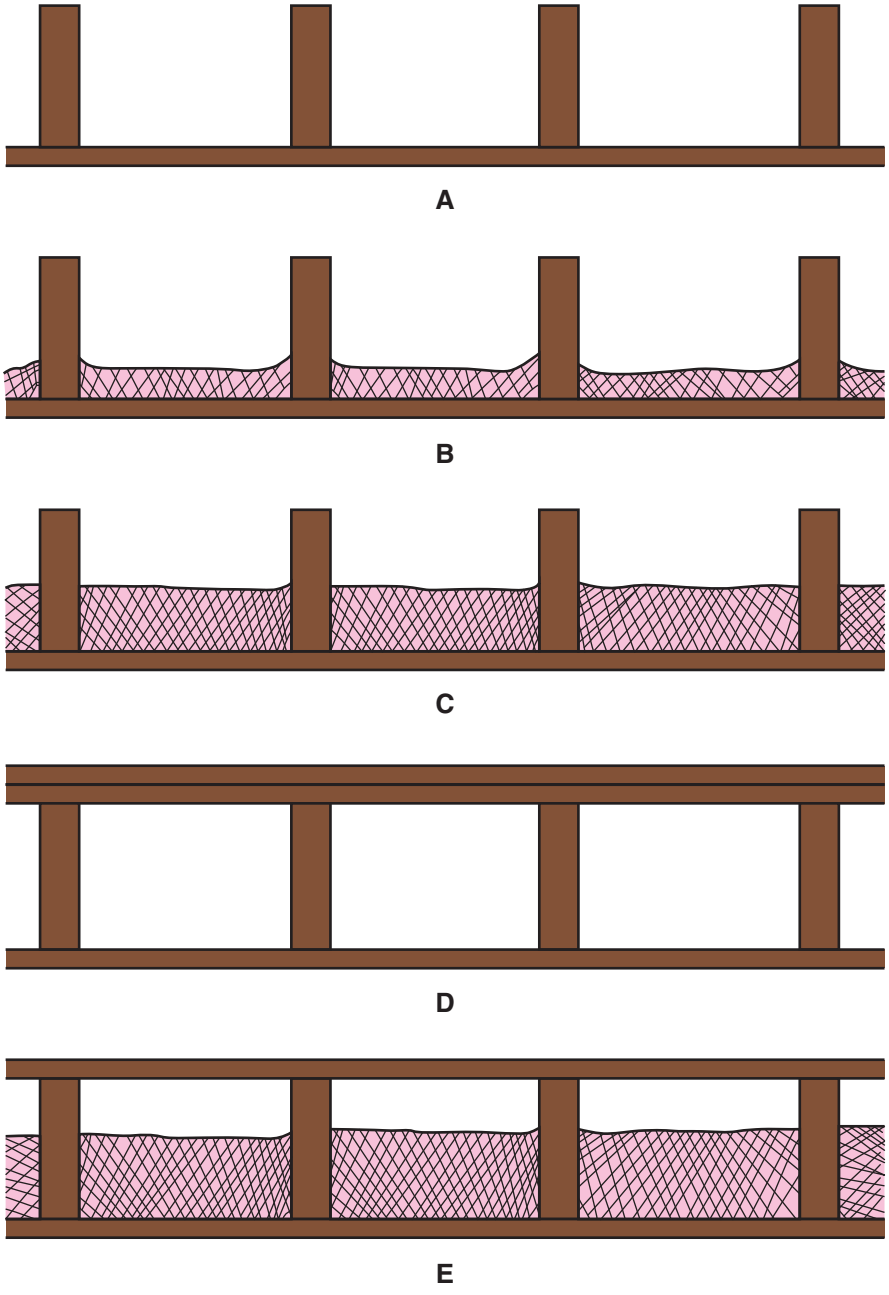
Net wall area = total wall area – combined area of windows and doors
= 896 ft² – 106 ft² = 790 ft²

The area of each window and door, as well as the net wall area, will be used later to find the building heat load.

Ceilings

Ceilings generally are made by fastening drywall to the ceiling joists. **Figure 37-14** shows several typical ceiling constructions. Heat leakage will be considerable if the joists do not have a floor over them. It will

Copyright Goodheart-Willcox Co., Inc. 2017



Goodheart-Willcox Publisher

Figure 37-14. Ceiling construction. A—No floor or insulation. B—No floor, 2″ insulation. C—No floor, 4″ insulation. D—Double floor, no insulation. E—Floor, 6″ insulation.

also be considerable if there is no insulation between the joists. See **Figure 37-6** for U-values for ceilings.

Formula for calculating area of ceiling:

Ceiling area = width of ceiling × length of ceiling

Example:

Using the sample house in **Figure 37-10**, the ceiling area is calculated as follows:

Ceiling area = 24′ × 32′ = 768 ft^2

Pro Tip

Ceilings

Most homes have an 8′ (2.4 m) ceiling height. A low ceiling helps to keep warm air closer to the occupied space, where it helps to keep conditions comfortable. However, some homes have 9′ (2.7 m) or 10′ (3.0 m) first floor ceilings. ACCA's Manual J lists different values for different types and heights of ceilings.

Copyright Goodheart-Willcox Co., Inc. 2017

37.3.7 Heat Transfer Rate

The ***heat transfer rate*** is the amount of heat conducted through a structure for a given unit of time. It is usually represented by the letter Q and expressed in Btu/hr. The heat transfer rate can be calculated using the U-values or the R-values of the building components.

Using U-Values to Calculate Heat Transfer Rate

If the U-values of a component, the surface area of the component, and the temperature difference between the inside surface and outside surface of the component are known, the amount of heat transferred through the component over a given period can be calculated using the following formula:

Formula for calculating heat transfer rate using U-values:

$$Q = (U \times \text{area}) \times (T_o - T_i)$$

Q = heat transfer rate in Btu/hr
U = U-value of component
T_o = outside temperature in °F
T_i = inside temperature in °F

Example:

A structure has 790 ft² of wall surface. The temperature difference is 70°F. The wall is brick veneer with no insulation. It has a U-value of 0.25.

Solution:

This U-value means that 0.25 Btu will transfer through each square foot of wall for each one degree Fahrenheit temperature difference in one hour.

$$Q = (0.25 \text{ Btu/ft}^2\cdot\text{°F}\cdot\text{hr} \times 790 \text{ ft}^2) \times (70\text{°F} - 0\text{°F})$$
$$= 197.5 \text{ Btu/°F}\cdot\text{hr} \times 70\text{°F}$$
$$= 13{,}825 \text{ Btu/hr}$$

Using R-Values to Calculate Heat Transfer Rate

In some cases, the construction of a wall may be unusual or customized, and a U-value for the complete component may not be available in reference charts. In these cases, it is possible to use the R-values or C-values of the building materials to calculate a U-value for the component. Then, the U-value can be used to find the heat transfer rate.

For a composite wall, the individual R-values for a composite wall can be totaled. The U-value will equal the reciprocal of the sum of the materials' resistances.

$$R_{\text{Total}} = R_1 + R_2 + R_3 + R_4 + R_5$$
$$U = \frac{1}{R_{\text{Total}}}$$

The R-values can be looked up in a table like the one shown in **Figure 37-15**.

Example:

For example, the R-values for the materials in a typical brick veneer wall are as follows:

Building Material	R-value
Outside air film	0.17
Face brick veneer (3″ thick)	0.39
Wood siding and building paper	0.86
Air space	0.97
3/8″ gypsum wallboard	0.32
Inside air film	0.68
Total R =	3.39

Once the thermal resistances of the individual materials are totaled, the reciprocal of the total yields the U-value for the wall:

$$U = \frac{1}{R_{\text{Total}}}$$
$$= \frac{1}{3.39}$$
$$= 0.295 \text{ Btu/ft}^2\cdot\text{°F}\cdot\text{hr}$$

Then, the U-value can be used to calculate the heat transfer rate for the wall:

$$Q = (U \times \text{Area}) \times (T_o - T_i)$$

If the surface area of the wall is 790 ft² and the temperature difference is 70°F, as in previous examples, the heat transfer rate would be calculated as follows:

$$Q = (0.295 \text{ Btu/ft}^2\cdot\text{°F}\cdot\text{hr} \times 790 \text{ ft}^2) \times 70\text{°F}$$
$$= 233.05 \text{ Btu/°F}\cdot\text{hr} \times 70\text{°F}$$
$$= 16{,}313 \text{ Btu/hr}$$

R-Values of Building Materials

Construction	(R) Resistance Value
Surface (still air)	0.68
Air space	0.97
Gypsum wallboard 3/8″	0.32
Outside surface (15 mph wind)	0.17
Face brick	0.39
Concrete block 4″	1.11
Urethane insulation	9.1
Siding (wood) 1/2″ × 8″	0.85
Building paper	0.06
Wood sheathing	0.98
Wood floor 1″	0.98
Linoleum or tile	0.05
Asphalt shingles or plywood	0.95

Figure 37-15. This table lists typical thermal resistance (R) values for various parts of a building.

Copyright Goodheart-Willcox Co., Inc. 2017

Using C-Values or K-Values to Calculate Heat Transfer Rate

In some cases, the R-values for some, or all, of the materials that compose the wall (or other building components) may not be listed on available charts. If a material's C-value or K-value is known, it can be used to determine the R-value. If the K-value is known, the R-value equals the reciprocal of the K-value multiplied by the thickness of the material:

$$R = \left(\frac{1}{K}\right) \times \text{thickness}$$

If a material's C-value is known, the R-value for the material is simply the reciprocal of the C-value:

$$R = \frac{1}{C}$$

For a composite wall (a typical building), the total R-value equals the sum of the individual reciprocals of the C-values of the materials used to construct the wall and the boundary air films:

$$R_{\text{Total}} = \frac{1}{C_1} + \frac{1}{C_2} + \frac{1}{C_3} + \frac{1}{C_4} + \frac{1}{C_5} + \frac{1}{C_6} \ldots$$

Example:

Going back to the composite wall that was described earlier, imagine that you are given the following values for the materials that make up the wall:

Building Material	Values
Outside air film	$R_1 = 0.17$ (found on chart)
Face brick veneer (3" thick)	$C_2 = 2.56$ (provided by manufacturer)
Wood siding and building paper	$R_3 = 0.86$ (found on chart)
Air space	$R_4 = 0.97$ (found on chart)
3/8" gypsum wallboard	$C_5 = 3.125$ (provided by manufacturer)
Inside air film	$R_6 = 0.68$ (found on chart)

The first step in calculating the heat transfer rate is to convert the different types of values into R-values and add them together:

$$\begin{aligned} R_{\text{Total}} &= R_1 + \left(\frac{1}{C_2}\right) + R_3 + R_4 + \left(\frac{1}{C_5}\right) + R_6 \\ &= 0.17 + \left(\frac{1}{2.56}\right) + 0.86 + 0.97 + \left(\frac{1}{3.125}\right) + 0.68 \\ &= 0.17 + 0.39 + 0.86 + 0.97 + 0.32 + 0.68 = 3.39 \end{aligned}$$

The next step is to find the U-value for the complete wall. The wall's U-value is simply the reciprocal of the combined R-values for the wall:

$$U = \frac{1}{R_{\text{Total}}}$$

$$= \frac{1}{3.39}$$

$$= 0.295 \text{ Btu/hr·ft}^{2}\text{·°F}$$

The final step in calculating heat transfer rate through the wall is to multiple the wall's U-value times the surface area of the wall and the temperature difference from one side of the wall to the other. For the purpose of this demonstration, we will use the familiar surface area of 790 ft² and temperature difference of 70°F:

$$\begin{aligned} Q &= (U \times \text{area}) \times (T_o - T_i) \\ &= (0.295 \text{ Btu/hr·ft}^{2}\text{·°F} \times 790 \text{ ft}^2) \times 70°\text{F} \\ &= (233.05 \text{ Btu/hr·°F}) \times 70°\text{F} \\ &= 16{,}313.5 \text{ Btu/hr} \end{aligned}$$

As you can see, the heat transfer rate that is calculated using the mix of R-values, a C-value, and a K-value is identical to the heat transfer rate calculated using just R-values. As long as you are aware of the relationships between these values, you can easily convert one type of a value to another type as needed.

37.3.8 Unit Conversions

To this point, all of the calculations in the chapter have been based on US Customary units. Specifically, thermal characteristics have been described using units of Btus, hours, feet, and degrees Fahrenheit. Watts are another type of US Customary (and SI) unit that are commonly used to measure and describe thermal characteristics. **Figure 37-16** shows typical heat leakage listed in watts per square foot (W/ft²), rather than the more familiar Btu/hr·ft² unit. To obtain the watt load per degree Fahrenheit, divide the "35" column by 35. To convert watts to Btu/hr, multiply watts by 3.414368.

Technicians should be aware that they may also encounter SI units from time to time, possibly in reference to the thermal characteristics of building materials or the airflow output of blowers. Technicians must be able to convert units as needed. A comparison of US Customary and SI values follows:

Characteristic being measured	Units	
	US Customary	SI
Specific heat at constant pressure	Btu/lb·°F	kj/kg·K
Heat conductance (C- and U-values)	Btu/hr·ft²·°F	W/m²·K
Heat conductivity (K-values)	Btu·in/hr·ft²·°F	W/m·K
Heat transfer rate	Btu/hr, watts (W)	J/sec, kcal/hr, watts (W)
Thermal resistance (R-value)	hr·ft²·°F/Btu	m²·K/W
Velocity	ft/min	m/s

Figure 37-16. Continued.

Heat leakage is calculated the same way whether SI or US Customary units are used in the calculations. Joules/second, kilocalories/hour, and watts are all common SI units used to express heat transfer. These values are used with square meter or square centimeter units of area in order to express heat transfer rates per unit of area. The watt unit is the most popular SI unit used to express heat transfer rates. The watt unit is included in both the US Customary and SI measuring systems. It can be easily applied to heating and cooling unit capacities.

To convert heat conductance values from US Customary to SI units, multiply the value given in Btu/hr·ft²·°F by 5.674 to obtain an equivalent value in units of W/m²·K. To change SI units to US Customary units, multiply the value given in W/m²·K units by 0.1762 to obtain an equivalent value in Btu/hr·ft²·°F units.

37.4 Other Factors Affecting Heat Loads

In addition to the heat transferred through the walls, doors, and windows of a building, there are other factors that can affect a building's heating and cooling loads. The following sections explain other factors that must be considered when calculating heating or cooling loads.

37.4.1 Basement Heat Loss

Heat losses or gains for basements vary widely. **Figure 37-17** shows the construction of a basement built five feet into the ground. The deeper the basement, the less the heat loss. It is usually assumed that a basement is at 60°F (16°C). Leakage through the basement floor is usually not calculated. It is assumed that the basement is not a conditioned space. The heat leakage to the outside walls is minimal.

However, if the basement is to be used as a living space, the overall area should be considered in sizing the heat load. The heat leakage load is calculated through the first floor of the above-ground structure (the basement ceiling). For basement living spaces, heat loss is calculated by using the appropriate U-value for the concrete floors and walls (this is usually around 0.10). The ground temperature is found from the local weather bureau and is often known as ground water temperatures. The total basement heat loss is the concrete and insulation U-values times the temperature difference between the basement and the ground times the area of basement floor and walls.

Basement walls are often tarred on the exterior and a layer of plastic sheeting is then applied to seal the walls from the soil. The plastic sheeting is known as a vapor barrier. Refer to the American Society of Heating, Refrigerating and Air-Conditioning Engineers' recommendations for

Figure 37-17. The temperature conditions and construction of a building with a basement. The depth of the frost line will vary depending on the local climate.

additional data. The addition of vapor barrier provides a waterproof seal between the soil and the basement walls. It has negligible effect on the heat load but helps to seal the wall from moisture.

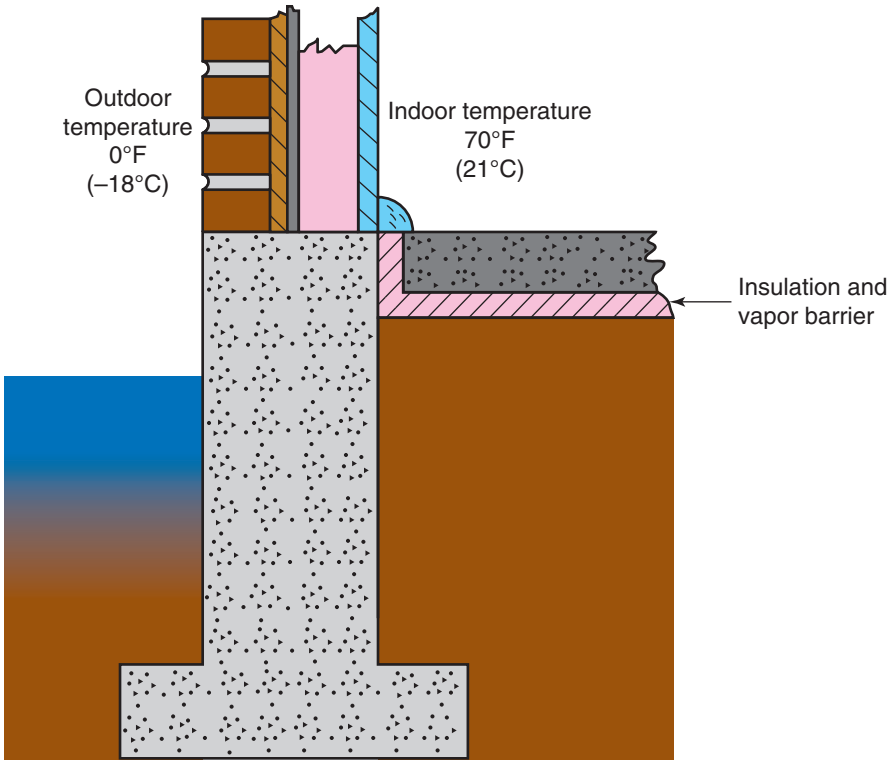
37.4.2 Slab-on-Grade Heat Loss

Buildings built on a concrete slab have different heat losses than those built with a basement. See **Figure 37-18**. Ice and frost may form around the outside of a slab building. Ice and frost formation at the base of the walls can act as a heat sink, which can speed up heat loss through the walls.

One method for minimizing frost and ice buildup is to install a rigid slab of urethane insulation parallel to the foundation walls. The insulation provides an extra thermal barrier, which helps the walls retain heat. This trapped heat prevents ice and frost from forming. The urethane slab should be at least 2″ thick and installed 2′ to 4′ in the ground. **Figure 37-19** shows a typical installation.

For a building on a slab, heat loss above ground is calculated as previously described. Heat losses due specifically to the slab construction are usually calculated as follows:

1. The perimeter of the building is determined.
2. The total length of the perimeter is multiplied by 18 Btu/hr for each foot of length (for an outdoor design temperature of 0°F [–18°C]).



Goodheart-Willcox Publisher

Figure 37-19. A method is shown for preventing ice and frost from forming around perimeter of building built on slab. Rigid urethane insulation is installed as close to building as possible.

3. The heat losses due to slab construction are then added to the above ground heat losses.

37.4.3 Crawl Space Heat Loss

Another popular type of foundation leaves just enough space between the floor and the ground to allow access. This is referred to as a ***crawl space***. The earth floor of a crawl space should have a vapor barrier on it. This could be plastic sheeting, roofing paper, or other materials that prevent moisture from passing through. In addition, the floor can be insulated from underneath to provide maximum thermal protection. A crawl space must have sufficient venting to minimize moisture problems in the summer. The venting also minimizes the amount of cold air entering in the winter. Vents with dampers are installed to serve this dual purpose. The heat loss through a floor above a crawl space is calculated the same as that of an exterior wall, as the floor is exposed to outside air.

37.4.4 Infiltration and Exfiltration

Buildings are not airtight, and air will leak through openings if there is any difference between inside and outside air pressure. If the air pressure inside the building is lower than the air pressure outside the building, air will leak in, which is known as air *infiltration*. If the air pressure inside the building is greater than the air pressure outside the building, the air will leak out, which is known as air *exfiltration*. The air pressure difference is usually caused by wind. Parts of the building that the wind presses against are those through which air enters. The remaining areas are those through which the air escapes, **Figure 37-20**.

During the heating season, any cold air that enters a building must be heated. Air that leaks out represents lost heat. During the cooling season, warm air that enters a building must be cooled. Cooled air that leaks out is a heat gain (some cooling effect is lost). If the building can be sealed, infiltration and exfiltration can be minimized. However, care must be taken to provide enough fresh air for proper ventilation and operation of fuel-burning appliances (such as gas- or oil-fired furnaces, stovetops, water heaters, etc.).

One method for reducing infiltration and exfiltration is to wrap the entire structure in a thin protective sheet. This eliminates the normal gaps between building materials that occur during construction. **Figure 37-21** shows a typical building wrap product.

Figure 37-21. Building wrap can be used to reduce infiltration and exfiltration. The thin material is wrapped around exterior walls prior to applying the final siding of the building.

Pro Tip

Preventing Infiltration with Positive Pressure

One way to prevent unwanted infiltration is to maintain a positive air pressure within the building. The pressurized air will escape through cracks and openings in the building. With this practice, a special fresh air intake is needed. Incoming air can be conditioned before it is admitted to the building's conditioned space.

Infiltration calculations can be based on the total volume of the building, or they can be based on the length and size of all the cracks in the building. **Figure 37-22** provides rough estimates for the number of air changes in a space based on the percentage of wall area exposed to the outside environment. An exposed wall is any wall with an outside surface that serves as the building's exterior. The percentage of exposed wall in the room can be calculated by measuring the length of each wall in the room. The combined length of all of the exposed walls is then divided by the combined lengths of all of the walls in the room, both interior walls and exposed walls.

Caution

Air Change Tables

The table in **Figure 37-22** is for rough estimates only. ACCA Manual J has tables with greater detail, including different entries for different size spaces. The tables in Manual J also list different values for calculating heating and cooling loads, based on the seasonal changes in average wind strength. All final load calculations should be performed in accordance with local codes.

To find the volume of air replaced in an hour, multiply the number of air changes by the volume of the room. For example, a room with a volume of 1920 ft^3, will typically have at least 1920 ft^3 of fresh air infiltration per hour if one quarter of the room's wall area is exposed to the outside environment. If half of the wall area is exposed to the outside environment, the rate of air exchange increases to 2880 ft^3/hr. If three quarters or more of the wall area is exposed, the air exchange rate increases to 3840 ft^3/hr.

Estimated Air Changes—Loose Construction

Types of Space (Percentage of Wall Area Exposed to Outdoor Conditions)	Air Changes/Hr
25% of wall area exposed	1
50% of wall area exposed	1 1/2
75% of wall area exposed	2
>75% of wall area exposed	2
Entrances	2–3

Copyright Goodheart-Willcox Co., Inc. 2017

Once the volume of air infiltration is known, the actual heat loss or gain can be calculated. The amount of heat lost or gained is dependent on the temperature and humidity of the infiltrating air and the indoor design conditions. The temperature difference results in a loss or gain of sensible heat, and the difference in humidity results in loss or gain in latent heat. For heating load calculations, only the sensible heat loss is considered.

Formula for sensible heat loss or gain due to infiltration:

$$Q_s = 0.018 \times CFH \times TD$$

where

Q_s = sensible heat gain in Btu/hr
CFH = air exchange rate in ft³/hr
TD = difference between outdoor and indoor design temperatures in °F

Example:

A room with a 150 ft² floor plan and 8′ ceiling has a volume of 1200 ft³. Two sides are exposed, resulting in an estimated 1.5 air changes per hour. The indoor design temperature is 70°F (21°C) and the outdoor design temperature is 0°F (–18°C). The sensible heat loss due to infiltration is calculated as follows:

$$Q_s = 0.018 \times 1800 \text{ ft}^3/\text{hr} \times 70°\text{F}$$
$$= 2268 \text{ Btu/hr}$$

When cooling loads are calculated, both the latent and sensible heat gains due to infiltration must be considered.

Formula for latent heat gain due to infiltration:

$$Q_l = 0.01133 \times CFH \times \Delta W$$

where

Q_l = sensible heat gain in Btu/hr
CFH = air exchange rate in ft³/hr
ΔW = difference in humidity of outdoor and indoor air in grains/lb

Example:

A room with a 150 ft² floor plan and 8′ ceiling has a volume of 1200 ft³. Two sides are exposed, resulting in an estimated 1.5 air changes per hour. The design difference in grains of water to maintain 50% relative humidity is 49 grains/lb. The latent heat gain due to infiltration is calculated as follows:

$$Q_l = 0.01133 \times 1800 \text{ ft}_3/\text{hr} \times 49 \text{ grains/lb}$$
$$= 999.3 \text{ Btu/hr}$$

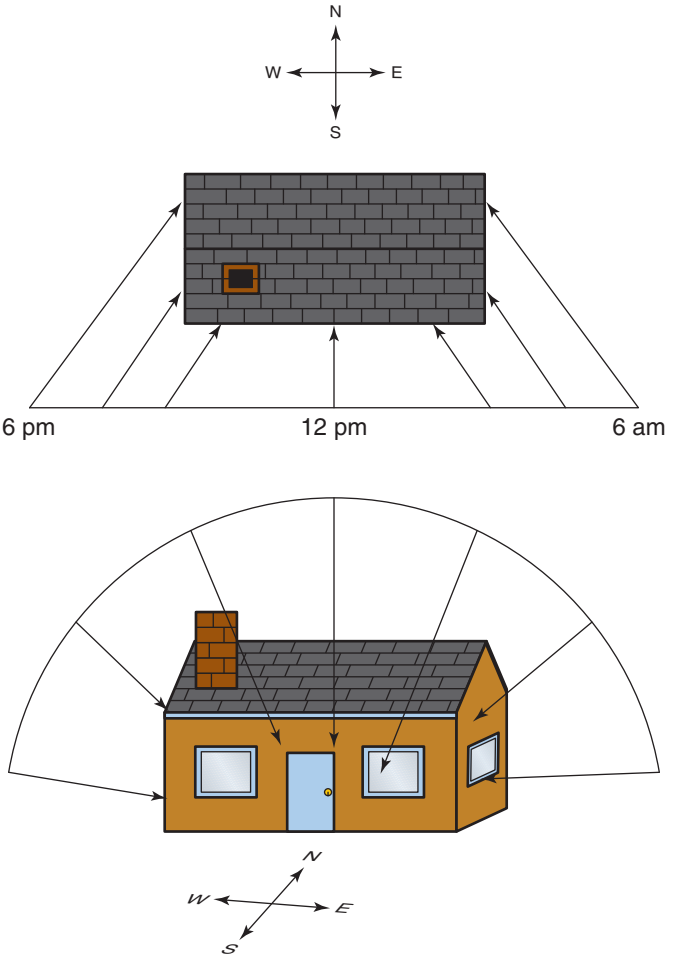
Thinking Green

Reducing Infiltration

The air change rate is reduced considerably if the building is constructed with vapor barriers. Fitting all doors and windows with weather-stripping will also reduce the air change rate. Thermal (infrared) scans of a building's exterior will show areas of heat leakage. Infiltration can be reduced by improving the insulation or weather stripping in these areas.

37.4.5 Sun Loads

Heat energy from the sun adds considerable heat load during the summer. In the northern hemisphere, the sun's rays shine on the east, south, and west walls. They also shine on those roof sections that are exposed to the sun. This is shown in **Figure 37-23**.



Goodheart-Willcox Publisher

Figure 37-23. The direction of the sun's rays and their impact on the walls of a building changes during each day. The sun's position over a 12-hour period is shown here.

Copyright Goodheart-Willcox Co., Inc. 2017

When computing total heat load, heat from the sun must be considered based on the following conditions:

- On the east wall in the morning.
- On the south wall all day long.
- On the west wall in the afternoon.

In the northern hemisphere, a building's south wall receives sunlight the entire day. The east and west walls receive sunlight for a smaller period of time. However, during the periods of direct exposure, the east and west walls receive more sunlight than the south wall. In the morning, when the sun is in the east, a maximum amount of sunlight strikes the east wall. As the sun goes down, a maximum amount of sunlight strikes the west wall. As the sun rises in the east, passes overhead, and sets in the west, a relatively small amount of direct sunlight strikes the south wall at a highly acute angle.

From the middle of winter to the middle of summer, the sun's path gradually shifts to the north, and the days get longer. From the middle part of summer to the middle part of winter, the sun's path gradually shifts to the south and the days get shorter.

The sun releases different amounts of heat to surfaces, depending on the geographical region where the building is located. The approximate maximum heat gain from the sun is 330 Btu per hr per ft^2 (97 watts/ft^2 [1040 W/m^2]). This is for a black surface at right angles to the sun's rays, near the equator (tropic). Any other color surface at an angle to the sun's rays will receive less heat. At the 42nd parallel (a line going through New York City, Cleveland, and Salt Lake City), the maximum heat from the sun's rays is about 315 Btu per hr per ft^2 (92 watts/ft^2 [993 W/m^2]).

Much of the heat from the sun is reflected back into the atmosphere. **Figure 37-24** indicates the window heat gain for windows facing different directions. This is heat passing through the window *in addition to* the heat leakage through the window due to the temperature difference between the indoor and outdoor temperatures. In the summertime, this heat gain must be removed with air conditioning.

Unless windows are protected with awnings, use a temperature of 15°F (8°C) higher than outside ambient temperature when calculating the cooling load on a wall or window that faces south. The south facing windows and walls receive more direct sunlight during the day than the other three walls.

Approximate values obtained by using the 15°F (8°C) temperature correction generally are usable. However, there are many special cases that require careful study, such as buildings with a significant amount of windows and walls facing south in southern latitudes where the solar load may be extreme. Consider the changing position of the sun relative to the surfaces of the building when determining solar loads. Also consider the time lag required for this heat to reach the building's interior.

Effect of Sun on Windows

Exposure	Heat Absorption Btu/hr·ft
Southwest	110
West	100
South	75
East	55
Single skylights	110
Double skylights	60
North	1
Northeast	2
Northwest	3

Goodheart-Willcox Publisher

Figure 37-24. Chart showing the heat absorbed during sunny conditions by windows that face different directions.

Reducing Window Heat Load for Cooling

There is considerable heat flow through ordinary window glass. It is approximately three times as great as flow through ordinary residential roofs and ceilings. Therefore, air conditioning areas containing a large amount of ordinary glass can become a problem. To reduce the heat conductivity through glass, a storm sash is used. To reduce the solar heat through glass, special types of glass with high heat-reflecting qualities can be used.

Special heat-absorbing glass can reduce the solar heat load by as much as 30%. A bluish gray tint can also reduce the amount of light passing through the glass, thereby reducing the cooling load. The ability for light rays to pass through is known as ***emissivity***. Windows with special coatings on the glass reduce the amount of solar radiation that passes through the window. Energy efficient, low-emissivity (low e) windows block much of the infrared and near-infrared light striking the glass, but allow visible light to pass. Since infrared and near-infrared light is deflected off the glass, it does not heat the interior of the building. Energy Star rated windows also may use double-pane and triple-pane glass with an inert gas such as argon between the layers of glass. One popular type of energy efficient windows is the triple-pane argon gas filled window. The gas between the panes creates a thermal barrier that reduces heat transfer through the window.

Copyright Goodheart-Willcox Co., Inc. 2017

Safety Note

Low-Emissivity Windows

Since a low-emissivity window reflects infrared radiation, it can redirect radiant heat onto nearby objects. Care must be taken to ensure that low-emissivity windows do not inadvertently focus heat on neighboring structures that could be damaged or negatively affected.

Double-glazed windows reduce solar heat absorption by 15%. Roof extensions over a window will reduce the area exposed to the sun. Roof extensions or awnings that shade windows from direct exposure to the sun can reduce the heat load by 55%.

Thinking Green

Leadership in Energy and Environmental Design (LEED)

The US Green Building Council developed the *Leadership in Energy and Environmental Design* rating system to evaluate the environmental sustainability of buildings. The USGBC also certifies building trades workers based on their knowledge of the LEED rating criteria.

Heat Lag

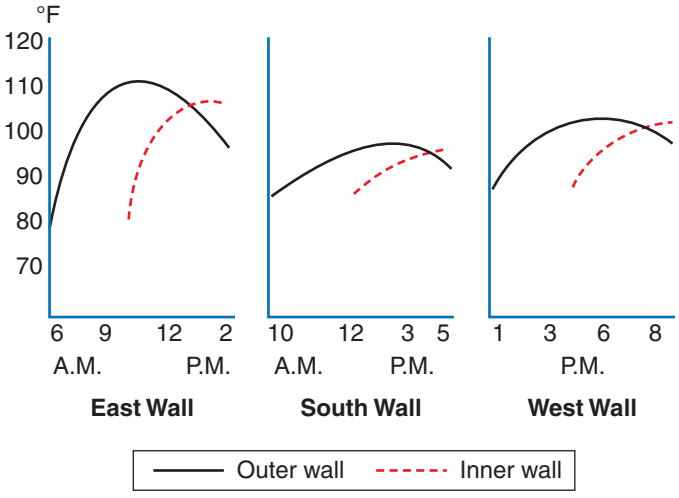
Heat lag refers to the time it takes for heat to travel through a substance heated on one side. When the sun heats the outside wall of a building, several hours pass before the heat reaches the inner wall. In normal buildings, this time varies between three and four hours. With well-insulated or thick walls, the sun may have already set by the time the heat "soaks" through.

In the southwest, adobe walls are made quite thick. The heat from sunlight passes into the wall as the sun shines. However, the wall is thick enough to prevent the heat from reaching the interior during the daylight hours. During the night, when outdoor temperatures fall below those inside, some of the heat flow reverses itself and travels outward through the wall. If the room is cooler than the wall, heat from the wall is also transferred into the room. This heat lag helps keep the rooms warm even after the sun goes below the horizon and the outdoor temperature drops. See **Figure 37-25**.

Thinking Green

Heat Lag

Because of the effect of heat lag, it is more efficient to keep a building cool all day and run the air conditioning in the morning than to wait until midafternoon, when the thermal mass of the building has heated up. For split systems with an outdoor condensing unit, this also takes advantage of cooler outdoor temperatures that allow more heat to be rejected more easily than in the hotter midday and afternoon temperatures.



Goodheart-Willcox Publisher

Figure 37-25. These temperature/time graphs show the heat lag in various wall temperatures following exposure to the sun.

37.4.6 Heat Sources in Buildings

Heat sources may or may not be a benefit, depending on whether it is summer or winter. There are several sources of heat besides infiltration and sun load. All sources must be considered when figuring the comfort cooling load.

During the heating season, the heating system is aided by these other sources. Much of the energy expended in a building becomes heat. Yet, these sources are usually ignored when figuring heating loads of small buildings. These are small amounts compared to the total heat load in temperate zones.

However, when figuring cooling loads, all heat energy sources must be considered. This includes heat released by people, stoves, lights, and electric motors. **Figure 37-26** lists some of these heat sources. Notice that the two types of heat gain (sensible heat and latent heat) are itemized. Latent heat raises the relative humidity, while sensible heat raises temperature.

During the cooling season, the heat released by people must be taken into account. The sensible heat released by one person weighing about 150 lb (68 kg) is roughly 110 W (370 Btu/hr) when that person is at rest. It is about 440 W (1,500 Btu/hr) when that same person is working. An additional 40 W (140 Btu/hr) of latent heat is released from a person due to moisture evaporation from their respiratory system and skin. The total heat load of a person is a combination of the sensible heat and latent heat. For a person at rest, the total heat load is approximately 150 W (510 Btu/hr). For a person at work, the total heat load is approximately 480 W (1,640 Btu/hr).

Figure 37-26. Technicians use charts similar to this one to look up the heat released by various energy sources within a building.

37.5 Heating and Cooling Load—Manual J Method

Total heat load calculations are usually set up in table form. **Figure 37-27** shows an example of calculating heat loss due to thermal conduction for a 30′ × 60′, 1,800 ft² (9.14 m × 18.28 m, 167 m²) house. The individual heat loads are calculated and then added together to determine the total heat load.

Pro Tip

ACCA Manual J and N

Most national and local building codes require the use of the ACCA Manual J (residential) or Manual N (commercial) procedure for calculating building loads. This provides a common process so that heating and cooling loads are comparable from one building to another, **Figure 37-28**.

The Air Conditioning Contractors of America (ACCA) publishes standardized forms and software for calculating heating and cooling loads of buildings. The two basic ACCA workbooks for calculating heat loads are Manual J (residential) and Manual N (commercial buildings). ***Manual J*** includes reference tables with U-values and R-values for various building materials and construction methods. The building load may be calculated by hand on a paper spreadsheet, entered into an electronic spreadsheet, or input into a smartphone app. ACCA offers detailed training and certification in use of Manual J and Manual N procedures.

Manual J software requires looking up data in reference tables and inputting the specific building information into tabs in the spreadsheet for glass, doors, walls, ceilings, and floors. U-value is a measure of the amount of heat that will transfer through a specific material per degree of temperature difference. The heat transfer multiplier (HTM) is used to calculate heat transfer across a specific temperature difference:

$$U = \text{Btu/hr/°F}$$
$$HTM = U \times \Delta \text{ (temperature difference)}$$
$$HTM = \text{Btu/hr}$$

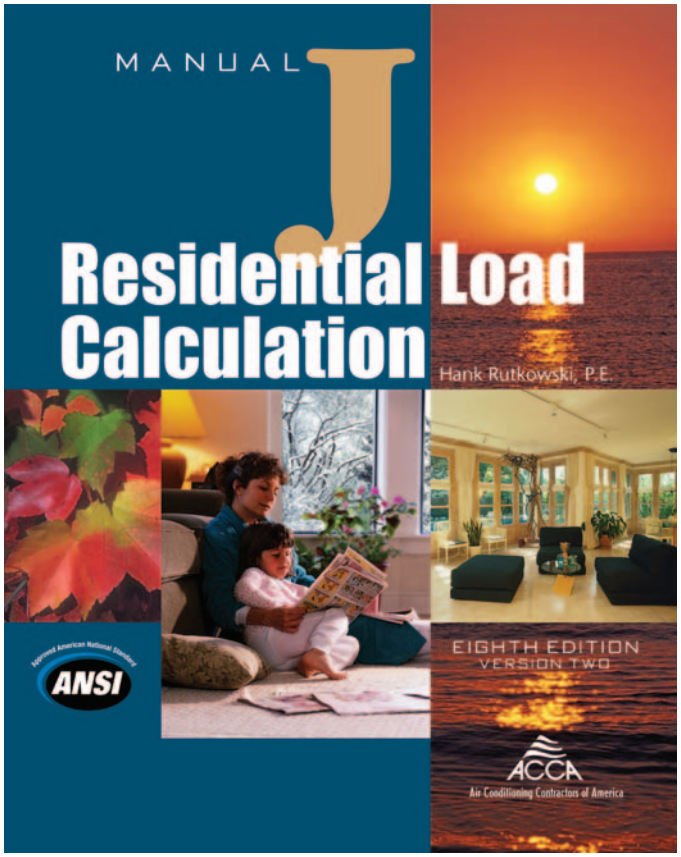
Figure 37-27. Typical heat load calculation for 30′ × 60′ home having an 8′ ceiling height.



ACCA – The Indoor Environment & Energy Efficiency Association

Figure 37-28. ACCA Manual J contains procedures for determining HVAC equipment sizing loads for single-family detached homes, small multiunit structures, condominiums, town houses, and manufactured homes.

The U and HTM values for building materials are found in tables and appendices in the Manual J. Manual J includes the following tables:

- Tables 1A and 1B—outdoor design conditions for the United States and Canada.
- Table 2A—U-values for glass, windows, and skylights.
- Table 2B—U-values for energy efficient windows, doors, and skylights.
- Tables 3A through 3I—U-values for glass.
- Tables 4A through 4C—F-values for walls, doors, floors, and ceilings.
- Tables 5A through 5E—infiltration (air leakage).

The data input into each tab automatically calculates an HTM, which is shown on the summary sheet. The total load is added from each worksheet to provide the overall heat load for the building. **Figure 37-29** shows the ACCA Manual J summary sheet. These spreadsheets can serve as a template for the HVACR technician during the gathering of information required to make an accurate heating and cooling load estimate of a building.

37.5.1 Local Conditions

Manual J has many base assumptions such as type of building and climate. The first step in using Manual J is to populate the J1 spreadsheet to adjust to local conditions, such as location humidity, altitude, and climate. This information is looked up in Table 1A and 1B and input into Manual J Form J1. The outdoor conditions are input at the top of the spreadsheet for both heating and cooling seasons. These numbers generate an HTD (heating temperature difference) and a CTD (cooling temperature difference), **Figure 37-30**.

37.5.2 Glass Loads

Windows, skylights, and doors are a significant source of heat loss and heat gain. Construction of each window, number of panes, type of glazing, and frame construction all contribute to the heat loss and heat gain of a door or window. Any opening in a building is known as fenestration. Manual J refers to windows as such. Windows and doors are rated by the National Fenestration Rating Council (NFRC) as to their ability to allow light transfer.

Table 2A is used to gather U-value heat loss for windows, skylights, and glass door walls. The type of window (fixed or sliding sash, single or double pane, bay or garden, low-e) is used to find the U-value specific for each window or glass door. The U-values from Tables 2A and 2B are then multiplied by the temperature difference to calculate the HTM for each piece of glass, **Figure 37-31**.

Table 2A/3A -- Construction Numbers 1 through 7 & 10 -- Vertical Glass Heat Loss	Heating	Cooling HTM

Population Instructions for Windows, Glass Doors and Skylights

1) Input values are entered in the white cells (as requested by column headings; notes provide additional guidance).
2) Input values for windows and glass doors are extracted from Table 2A and Table 3A in the printed MJ8ae book; Table 3C applies to skylights.
3) Begin with Table 2A (the construction number applies to heating and cooling, the U-value applies to heating).
   * Construction attributes are extracted from plans or by site inspection.
   * The construction number and U-value are extracted from Table 2A.
   * Input values from Table 2A or Appendix 10 of the unabridged version of ***Manual J*** are valid entries.
   * You can enter up to 8 different vertical glass types for heat loss
   * For example

Construction Number; Glass Type; Number of Panes; Type of Sash; Type of Frame	U-Value
1C-cm, Clear, Single Pane / Storm, Operable, Metal no Break	0.870

   * You can enter up to 5 different skylight types for heat loss
   * For example

Construction Number; Glass Type; Number of Panes; Type of Sash	U-Value
8Bc-4, Flat Clear, Double Pane, Wood	0.940

4) Refer to Table 3A for cooling HTM values for windows and glass doors.

ACCA – The Indoor Environment & Energy Efficiency Association

Figure 37-31. Manual J Table 2A provides U-values for glass.

Copyright Goodheart-Willcox Co., Inc. 2017

Tables 3A through 3I include HTM values for windows, skylights, and glass door walls and take into consideration the amount of shading that the glass receives. Table 3A assumes no shade on the window. See **Figure 37-32**. Table 3B assumes that there is some type of overhang or awning that shelters the window from direct sunlight.

37.5.3 Wall, Floor, Door, and Ceiling Loads

Walls, doors, floors and ceilings are all non-fenestration parts of a building. Sunlight does not pass through them. **Figure 37-33** shows Table 4A, which has U-values for various types of doors and walls.

Table 3A
Default Cooling HTM for Generic Windows and Glass Doors
No External Sun Screen, Clear Glass

Cooling Load (Btuh) = HTM × Reference Area
Bay Window HTM = 1.15 × Table HTM
Garden Window HTM = 2.00 × Table HTM
French Door HTM = 0.70 × Table HTM
Use Single Pane, Clear Glass for Jalousie Window

Default indoor design temperature = 75°F.
Outdoor design temperature provided by Table 1.
Load area appears above HTM values.
Table note 2 (after Table 3E-5) specifies the order of application of the HTM adjustment procedures.

Recommended Adjustments

1) Full outdoor insect screen = 0.80 × Table HTM
Half outdoor insect screen = 0.90 × Table HTM
Full indoor insect screen = 0.90 × Table HTM
Half indoor insect screen = 0.95 × Table HTM
2) Shade by external overhang (See Table 3E-1)

Optional Adjustments

1) See Table 3E-3 for foreground reflectance adjustment.
2) 40° North latitude, see Table 3E-2 for latitude adjustment.
3) Medium color blind, drape or roller shade. See Table 3E-4 for light or dark color adjustment.

ACCA – The Indoor Environment & Energy Efficiency Association

Figure 37-33. Manual J Table 4A provides U-values for doors and walls.

Doors are categorized by type of outside construction (metal or wood) and their type of core (such as fiberglass, solid, hollow, or paper). The U-values for each door, wall, ceiling, and floor are input into Manual J1 and the HTM is calculated as shown in **Figure 37-34**.

37.5.4 Field Measurements

The next step is to review the blueprints of the residence (if available) or to field measure each room of the house, noting the location of each door, window, and type of construction. Each room is given a name, such as living room or dining room. The area of doors, windows, walls, and ceilings are input into the J1 spreadsheet. See **Figure 37-35**.

37.5.5 Air Leakage

Air leakage through a building causes the volume of air within a house to change over time. Unintentional air leakage is known as infiltration. One air change occurs when the entire volume of air contained within a residence is replaced by fresh outside air. Infiltration is measured in air changes per hour (ACH). Air changes assume that wind blowing by the building and leaks in the construction of the house allow the air inside the house to escape to the outdoors. It is usually higher in the winter as there is a greater temperature difference between the inside and outside of the house and higher winds in the winter. Tables 5A through 5E contain estimated air changes per hour for typical types of construction.

Tables 5A and 5B are the simplest form for basic designs and are suitable for most residential load calculations. **Figure 37-36** shows Table 5A, which rates buildings as tight, semi-tight, average, semi-loose, or loose. Most quality constructed buildings can be rated as average. If the house was built with building wrap and good caulking around all openings, it could be rated as tight. A leaky house would be an older construction where minimal effort had been made to seal the residence to outside air. The infiltration loss is then multiplied by total building area and temperature difference to yield an infiltration load in Btu/hr.

37.5.6 Ducts, Appliances, and Miscellaneous Loads

In addition to heat losses due to fenestration and infiltration, there are significant sources of heat gain and loss inside a building. If a supply duct is located in an unconditioned space, such as many attics, it will gain heat during the summer and lose heat during the winter. If return ducts are located on an outside wall, it will increase the heat load for the HVAC system.

For residential heat load calculations, the basic items mentioned above are usually sufficient to calculate the heating and cooling loads for an average house. However, appliances, occupants, and lighting all contribute to the total heating and cooling loads. There are a number of additional tables and spreadsheets used to account for these loads. For example, if a residence has more than two people living in each room, these people should be accounted for. If the home has a significant amount of lights or heavy use of appliances, it may require further study.

37.5.7 Total Load

The Manual J summary sheet as shown in **Figure 37-37** includes several totals:

- Total heat loss.
- Sensible heat gain.
- Latent heat gain.
- Total cooling load.

The ***total heat loss*** is the amount of heat required to be added to the building in Btu/hr for cold weather heating. The ***total cooling load*** is a combination of sensible and latent heat gain required to be removed from a building for hot weather cooling. These numbers are used to size the equipment to be installed or retrofit into an existing house.

Thinking Green

Efficient Sizing of Equipment

The past practice of "ballpark" sizing of HVACR equipment is inaccurate and inefficient. When selecting new or replacement equipment, elect to use a two-stage furnace, variable-speed compressor, and an air handler with a blower that uses an ECM. These newer technologies provide energy efficiencies over older equipment that was traditionally oversized. The accurate assessment of heating and cooling loads allow the HVACR technician to select equipment that meets the duty cycle of a residence for maximum comfort.

37.6 Software and Apps for Load Calculations

As stated earlier, many municipal codes require the use of an ACCA Manual J method of calculating heating and cooling loads. This means that the Manual J methodology should be followed. However, the HVACR technician is not required to use the specific ACCA programs.

ACCA has a list of approved software companies that utilize the Manual J method. There are companies that provide load calculation services. The HVACR contractor provides the detailed building information to the company. The company generates a report that includes duct sizing, layout, and equipment selection.

Many HVACR technicians seldom do in-depth load calculations. This is usually performed by a technician or contractor who performs this service full time. However, the use of ACCA programs and mobile device apps has made performing load calculations much easier. Some apps require minimal input from the user to produce a load calculation report.

Chapter Review

Summary

- In summer, heat from outdoors enters a building. This is referred to as heat gain. In the winter, heat from indoors transfers to outdoors. This is referred to as heat loss.
- A building's heat loads include heat transferred through walls, ceilings, floors, and windows; latent heat in water vapor; heat gains and losses due to infiltration and ventilation; heat from sunshine; and heat from appliances and occupants.
- Heat loads considered for calculating heating loads include heat lost through conduction through walls, ceilings, and floors; heat lost due to exfiltration and infiltration; and heat lost due to combustion air being drawn from the conditioned space.
- Cooling loads include all of the heat loads used to calculate heating loads, plus additional miscellaneous heat loads. These miscellaneous heat loads include heat from the sun, heat from appliances and lights, and heat from the building's occupants.
- Heat leakage refers to heat conducted through walls, ceilings, and floors due to a temperature difference between indoor and outdoor air.
- A material's K-value is a measure of its thermal conductivity. It indicates how much heat will transfer through one square foot of the material one inch thick in one hour when there is a 1°F temperature difference between the two sides of the material. A material's thermal conductance, or C-value, is similar to its K-value, but is not dependent on the thickness of the material.
- A material's R-value is a measure of its thermal resistance. It is the reciprocal of the material's K-value. The higher the material's R-value, the slower heat will transfer through the material.
- The U-value of a building component is a measure of its thermal transmittance. It is similar to a component's C-value, but it takes into account the insulating effect of boundary air films.
- The temperature difference between indoor design temperature and outdoor design temperature is used to calculate the rate of heat transfer by conduction through walls, ceilings, and floors. The greater the difference, the higher the rate of heat transfer.
- Heat loss through basement walls is only considered if the basement is used as living space. Heat loss through a slab on grade is determined based on the perimeter of the slab. Heat loss and gain through a floor above a crawl space is calculated the same way as heat loss through a wall.
- Infiltration refers to outdoor air entering a building through gaps in the construction. Exfiltration refers to air leaving a building through gaps in the construction. The amount of heat lost or gained due to infiltration and exfiltration is dependent on the tightness of the building's construction, the amount of exposure to outdoor conditions, and the temperature and moisture content of the indoor and outdoor air.
- Regarding heat loss due to infiltration, only sensible heat loss (not latent heat loss) is considered for calculating heating loads. For calculating cooling loads, both sensible and latent heat gains due to infiltration are included.
- As the sun moves across the sky, it shines on different areas of a building at different angles, heating them up. The areas affected by the sun load vary with the season and time of day. The heat added by the sun load must be included in cooling load calculations, but is not included in heating load calculations.
- Heat lag refers to the time it takes for heat to be conducted through a substance. Because of heat lag, a wall that is heated by the sun can continue to release heat into the conditioned space after the sun has gone down. With no sun and lower temperature outdoors than indoors, heat transfer can reverse direction.
- People, lights, and appliances all release heat into a conditioned space. In the case of people and animals, both sensible and latent heat are released. These miscellaneous heat loads must be included in cooling load calculations.
- Many local authorities and building codes require the use of the Manual J method to calculate a residential building's heating and cooling loads. For commercial buildings, Manual N is used. These manuals take into account local weather conditions, building materials, building layout, and numerous aspects of construction. Numerous tables and values are compiled to calculate a building's heating and cooling needs.

Copyright Goodheart-Willcox Co., Inc. 2017

- Total heat loads are the sum of the individual heat loads. Heating and cooling load software is available for personal computers, tablets, and smartphones. Use of this software greatly speeds up the process of determining the heating and cooling loads and properly sizing the equipment.

Review Questions

Answer the following questions using the information in this chapter.

1. The term "heat loss" refers to _____.
   A. a reduction in the heating capacity of the furnace
   B. a reduction in the rate at which heat is transferred through a material
   C. a transfer of heat from inside a building to outside a building
   D. a transfer of heat from outside a building to the inside of a building
2. Most local building codes require that heat loads for residential buildings be performed in compliance with the ACCA _____ specification.
   A. Manual D
   B. Manual J
   C. Manual N
   D. Manual R
3. Most local building codes require that heat loads for commercial buildings be performed in compliance with the ACCA _____ specification.
   A. Manual D
   B. Manual J
   C. Manual N
   D. Manual R
4. Which of the following heat loads is *not* considered when calculating heating loads for a building?
   A. Heat from appliances and occupants.
   B. Heat transferred by exfiltration and infiltration.
   C. Heat transferred through ceilings.
   D. Heat transferred through floors.
5. Which of the following heat loads would be considered *only* when cooling loads are being calculated?
   A. Heat transferred by conduction through walls, doors, and windows.
   B. Heat transferred due to infiltration and exfiltration.
   C. Sun load.
   D. None of the above.
6. A material's _____ indicates how much heat will transfer through one square foot of the material one inch thick in one hour when there is a 1°F temperature difference between the two sides of the material.
   A. C-value
   B. K-value
   C. R-value
   D. U-value
7. Which of the following accounts for the insulating effect of boundary air films?
   A. C-value
   B. K-value
   C. U-value
   D. All of the above.
8. The rate at which heat is transferred through a wall by conduction is dependent on the materials the wall is made of, the area of the wall, and _____.
   A. the pressure on each side of the wall
   B. the temperature difference between sides of the wall
   C. the volume of space enclosed by the wall
   D. All of the above.
9. For a heating load calculation, heat transfer through basement walls is *only* considered if the basement _____.
   A. is more than 6′ deep
   B. is used as a living space
   C. walls are less than 12″ thick
   D. walls are uninsulated
10. Heat loss due to construction of a concrete slab on grade is calculated based on _____.
    A. the area of the slab
    B. the perimeter of the slab
    C. the volume of the slab
    D. None of the above.

Copyright Goodheart-Willcox Co., Inc. 2017

11. Because a vented crawl space is exposed to outdoor air, heat loss through a floor over a crawl space is calculated the same as that of a(n) _____.
    A. basement
    B. exterior wall
    C. insulated ceiling
    D. unvented attic

12. Adding weather-stripping to all doors and windows, using building wrap and plenty of insulation during construction, and using a fresh air intake for positive pressure in a building are effective methods of reducing _____.
    A. design temperatures
    B. exfiltration
    C. infiltration
    D. sun load

13. Heat loss or gain due to infiltration and exfiltration is dependent on _____.
    A. the tightness of a building's construction
    B. the amount of wall area exposed to outdoor conditions
    C. the temperature difference between the indoor and outdoor air
    D. All of the above.

14. The relative ability of a surface to allow light rays to pass through describes _____.
    A. emissivity
    B. heat leakage
    C. heat loss
    D. luminescent transmittance

15. Total heat load is calculated by _____.
    A. adding together the individual heat loads
    B. dividing the individual heat loads by the area to which they apply
    C. multiplying the individual heat loads by the volume of the space to which they apply
    D. rough estimate

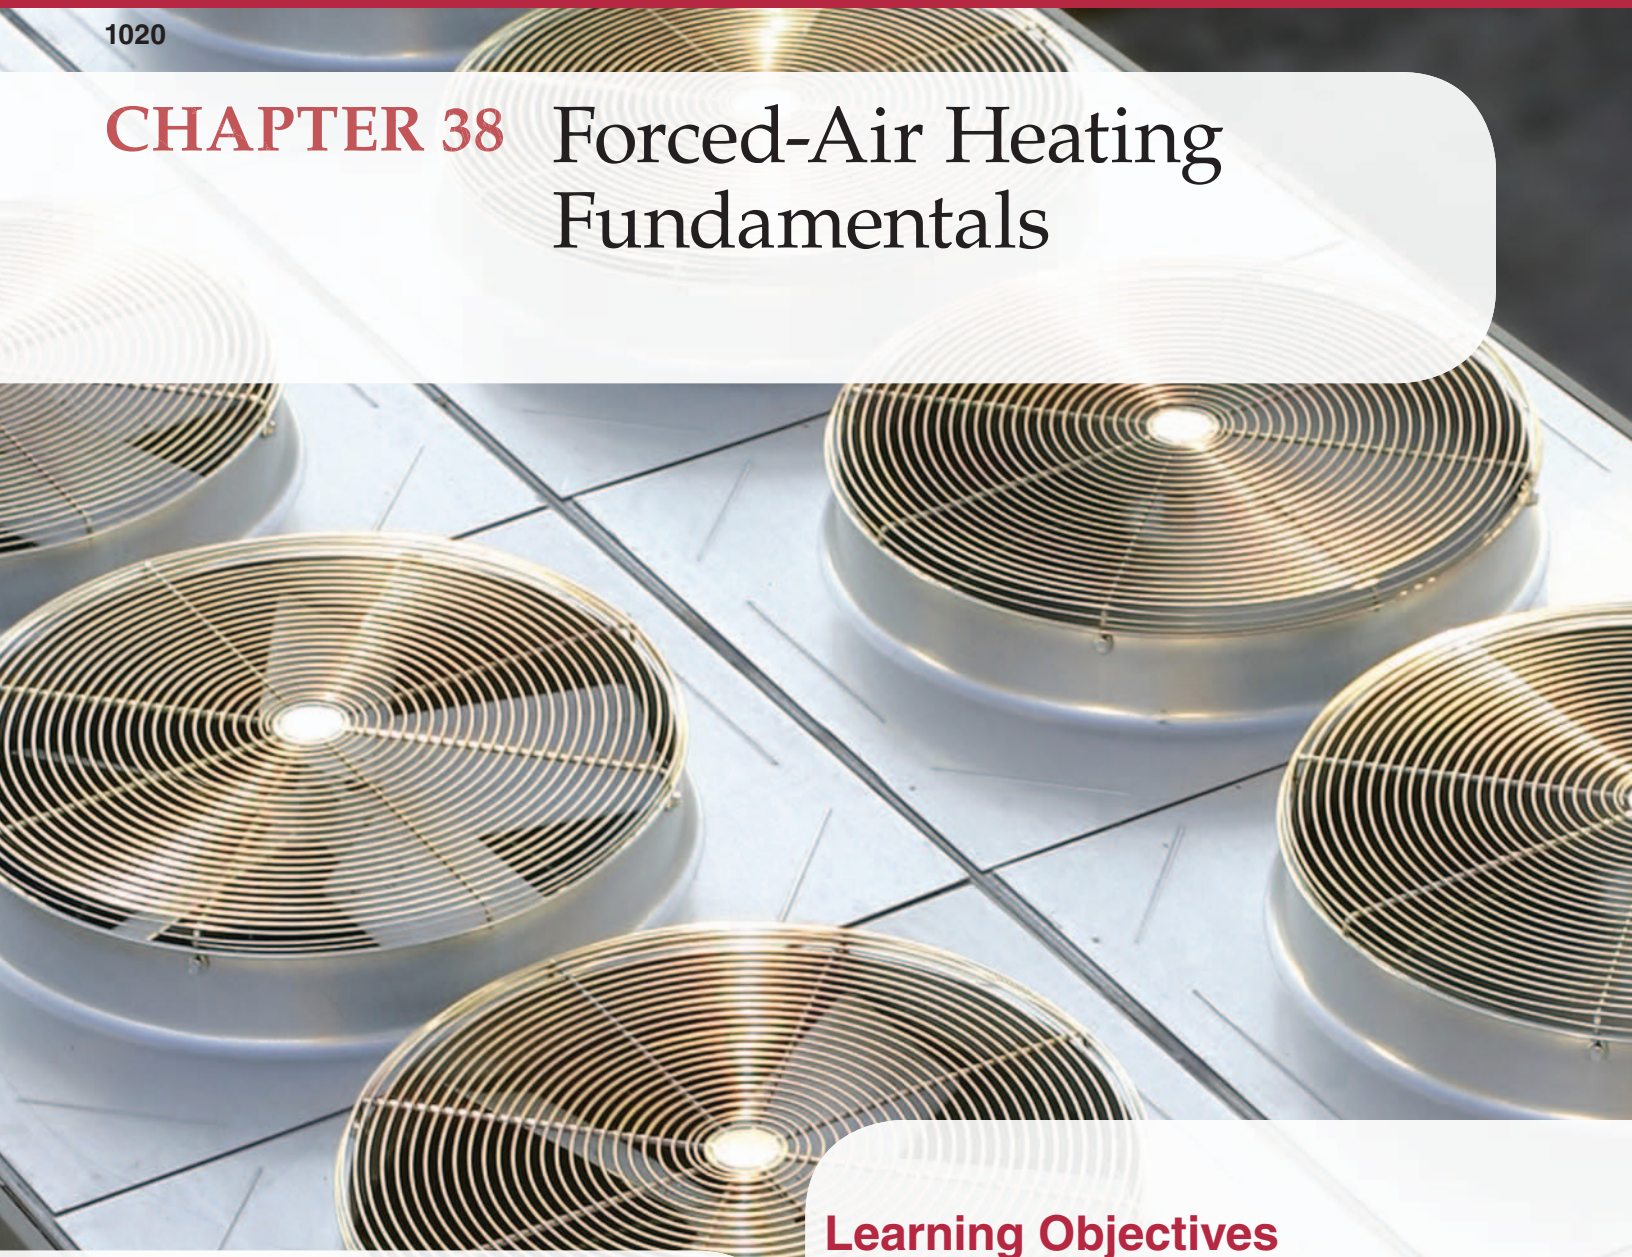
CHAPTER 38 Forced-Air Heating Fundamentals



Chapter Outline

38.1 Basic Components
- 38.1.1 Heat Sources
- 38.1.2 Heat Exchangers
- 38.1.3 Indoor Blowers
- 38.1.4 Combustion Blowers

38.2 Furnace Types and Construction
- 38.2.1 Upflow Furnace
- 38.2.2 Downflow Furnace
- 38.2.3 Horizontal Furnace
- 38.2.4 Two-Stage Furnace
- 38.2.5 Modulating Furnace

38.3 Forced-Air Duct Arrangements
38.4 Makeup Air Units
38.5 Blower Controls
38.6 Unit Heaters

Learning Objectives

Information in this chapter will enable you to:

- Identify the basic components of a forced-air heating system and explain their functions.
- Understand the difference between a condensing and a noncondensing furnace.
- Describe the different types of indoor blower and combustion blower arrangements.
- Compare and contrast upflow, downflow, and horizontal furnaces.
- Summarize the operation of two-stage furnaces and modulating furnaces.
- Explain how makeup air units improve system efficiency and prevent negative pressure from developing in a house.
- Understand how blower function can be controlled using time-delay controls and thermostatic controls.
- Summarize the design and purpose of unit heaters.

Review of Key Concepts

Reviewing these concepts from earlier chapters will help you understand new concepts presented in this chapter:

- Heated air moves from a furnace to the rooms of a house through convection, which is the movement of heat from one place to another by way of a liquid or gas. (Chapter 4)
- Heated or cooled air from an air handler is forced by a blower into conditioned space through a network of fixed ducts. (Chapter 32)
- Fuel-burning furnaces need air for proper and complete combustion. If the combustion air is drawn from inside the house, the combustion exhaust leaving through the flue or vent creates a slightly negative pressure inside the house. (Chapter 29)
- Many HVAC systems provide continual replacement of air by slowly bringing in fresh air from outside to be heated or cooled. This fresh air is called makeup air. (Chapter 27)
- Sensing bulbs and bimetal devices are two common types of temperature sensors used as thermostatic controls. (Chapter 16)

Introduction

Heating systems can be classified in a number of ways. Two common ways of classifying heating systems are by heat source and by heat distribution method. Common heat sources include oil, gas, electricity, geothermal energy, and air. Methods of heat distribution include forced-air, hydronic, and radiant distribution. Forced air and hydronic are the types of heating systems most commonly used in homes and offices. Radiant heating systems are often used in large, open commercial environments, such as warehouses and workshops.

A complete heating system combines one or more heat sources with one or more methods of heat distribution. Gas, oil, and electric heating systems can all transfer heat through forced-air, hydronic, or radiant distribution. This chapter provides an overview of heating systems that distribute heat using the forced-air method. Later chapters in this section will address hydronic and radiant distribution and provide more detailed information about the various methods of generating heat.

Copyright Goodheart-Willcox Co., Inc. 2017

38.1 Basic Components

The majority of heat pumps and heating systems that use gas, oil, or electricity to produce heat use forced air to distribute that heat. In a ***forced-air heating system***, a motor-driven fan, called a ***blower***, circulates air. By circulating heated air through ducts to conditioned space and drawing cool air from those conditioned spaces, forced-air heating systems produce an evenly conditioned space.

Before forced-air heating systems were developed, heating systems relied on natural convection to distribute heated air. These are called ***gravity heating systems***. Since heated air is lighter than cool air, gravity heating systems function on the principle that hot air rises and cool air drops. With the furnace or heat source in the lower part of a building, the heated air in a gravity heating system naturally rises into the rest of the building, and the cool air drops back to the furnace, where it is reheated. This method of heat distribution is inefficient and has largely been replaced by forced-air heating systems.

Oil and gas furnaces contain the following basic components:

- Combustion chamber.
- Fuel delivery method and burning device (burner).
- Flue or outlet.
- Heat exchanger.

The combustion chamber must be leakproof and provide efficient heat transfer. The basic components of a gas-fired or oil-fired, forced-air furnace are the same whether the furnace is a high-efficiency model or a lower-efficiency model, with the exception that an extra heat exchanger is added to high-efficiency models. Typical forced-air furnaces are equipped with a burner, a combustion blower to move combustion gases, one or more heat exchangers, and an indoor blower to circulate air through the ductwork. Electric heating systems consist of one or more electric resistance heating elements with a fan and duct system circulating air across them.

38.1.1 Heat Sources

Every forced-air heating system requires a heat source. The heat source may consist of a gas flame, an oil flame, the indoor coil of a heat pump, or an electric resistance heating element. The circulating air in the forced-air system is warmed by the heat source and then circulated to the spaces where heat is needed.

38.1.2 Heat Exchangers

A furnace's ***heat exchanger*** is a chamber where the heat of combustion is transferred to the surrounding air. A heat exchanger is sealed to prevent the combustion gases from mixing with the air that will be circulated through the conditioned space. In addition to providing heat to the circulating air, a heat exchanger carries combustion (flue) gases to the exhaust flue or vent where they are released outdoors. Heat exchangers are also used in hydronic heating systems to transfer the heat from combustion gases to water in a boiler. Hydronic systems are covered in Chapter 39, *Hydronic Heating Fundamentals*.

Heat exchangers are categorized as either primary or secondary. A ***primary heat exchanger*** is connected directly to the combustion chamber and transfers sensible heat from its surface to the air circulated through the conditioned space. The combustion chamber is often indistinguishable from the heat exchanger and is just the first part of the heat exchanger itself. Primary heat exchangers can be constructed from a variety of materials to provide different rates of heat transfer.

High-efficiency furnaces are also equipped with a secondary heat exchanger. A ***secondary heat exchanger*** is attached at the outlet of the primary heat exchanger and transfers both sensible and latent heat from the combustion gases to the circulating air, **Figure 38-1**.

Traditional furnaces quickly exhaust combustion gases, losing some of the heat potential from the fuel combustion process. ***Condensing furnaces*** are high-efficiency furnaces with annual fuel utilization efficiency (AFUE) ratings above 90%. Condensing furnaces differ from traditional furnaces in that they use both primary and secondary heat exchangers to extract additional heat from the combustion process. In a condensing furnace, heat is extracted for a longer period until the combustion gases give up enough heat to condense, hence the name condensing furnaces.

Combustion gases pass through the primary heat exchanger and then into the secondary heat exchanger. In a condensing furnace's heat exchanger, the air circulated from conditioned space travels in the opposite direction as the combustion gases. Circulating air traveling through a furnace passes the secondary heat exchanger and then passes the primary heat exchanger. Since the circulating air passes over the secondary heat exchanger first, it is able to absorb the maximum amount of heat possible, including the latent heat released by the combustion gases as they condense. The prewarmed circulating air then passes over the primary heat exchanger where it absorbs additional heat. See **Figure 38-2**.

Heat is removed from the combustion gases in the secondary heat exchanger until condensate (condensed gas) drips out. Because condensing furnaces have lower temperature exhaust fumes, the combustion gases can be routed through a PVC or CPVC pipe instead of a chimney or metal flue.

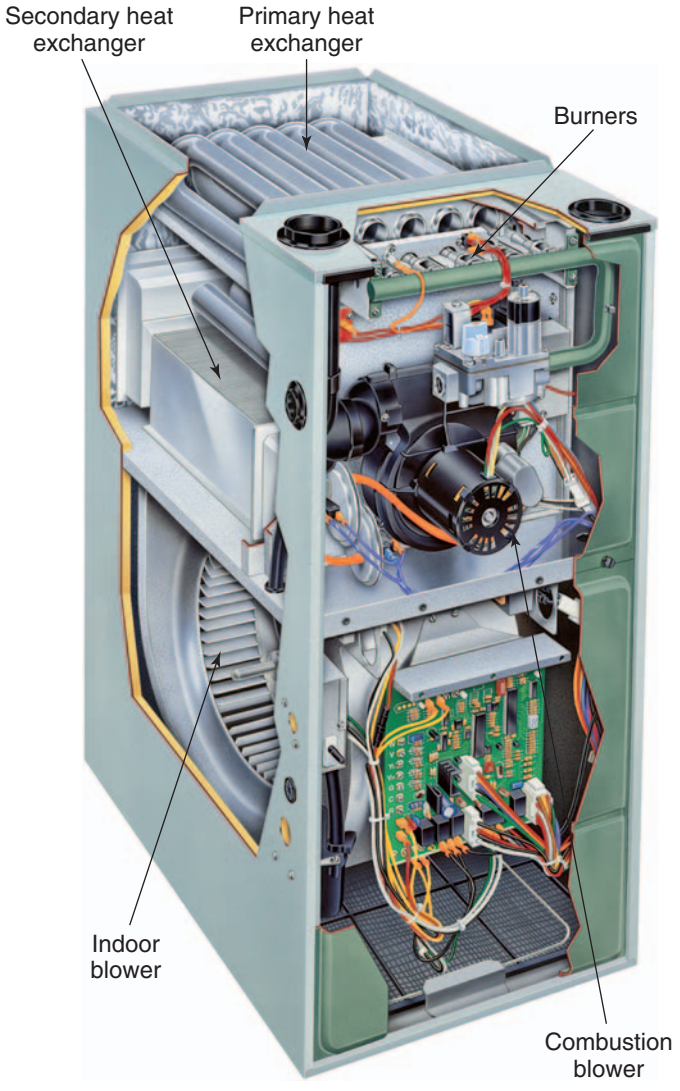
Copyright Goodheart-Willcox Co., Inc. 2017

Code Alert

Chimneys and Vents

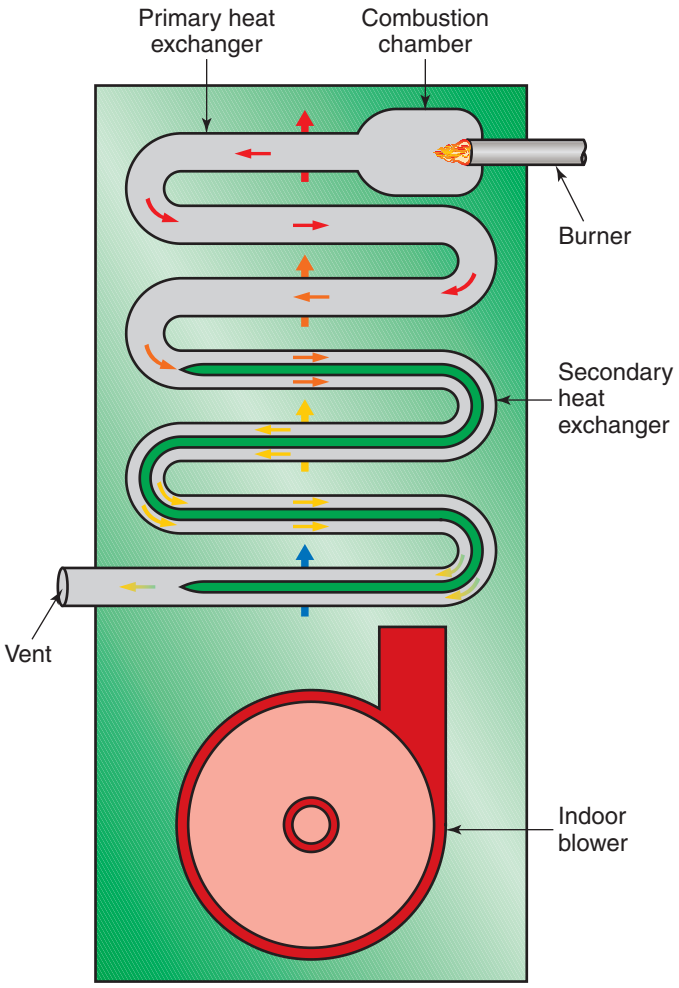
Proper combustion venting is absolutely critical for equipment efficiency and for the health and safety of building occupants. Local building codes specify acceptable designs, approved materials, and any special considerations for the venting of combustion gases.

Most condensing furnaces are gas-fired furnaces. However, some oil-fired condensing furnaces are available. Because the condensate generated in a secondary heat exchanger can be somewhat corrosive, secondary heat exchangers are typically made of stainless steel and include a drain to remove accumulated condensate. If an acceptable drain is not readily available, a condensate pump may be used to redirect the condensate.



Rheem Manufacturing Company

Figure 38-1. Cutaway of a high-efficiency gas furnace showing the primary and secondary heat exchangers.



Goodheart-Willcox Publisher

Figure 38-2. In a condensing furnace, circulating air passes over the secondary heat exchanger before it passes over the primary heat exchanger. This counterflow of combustion gas to circulating air allows for the maximum exchange of heat.

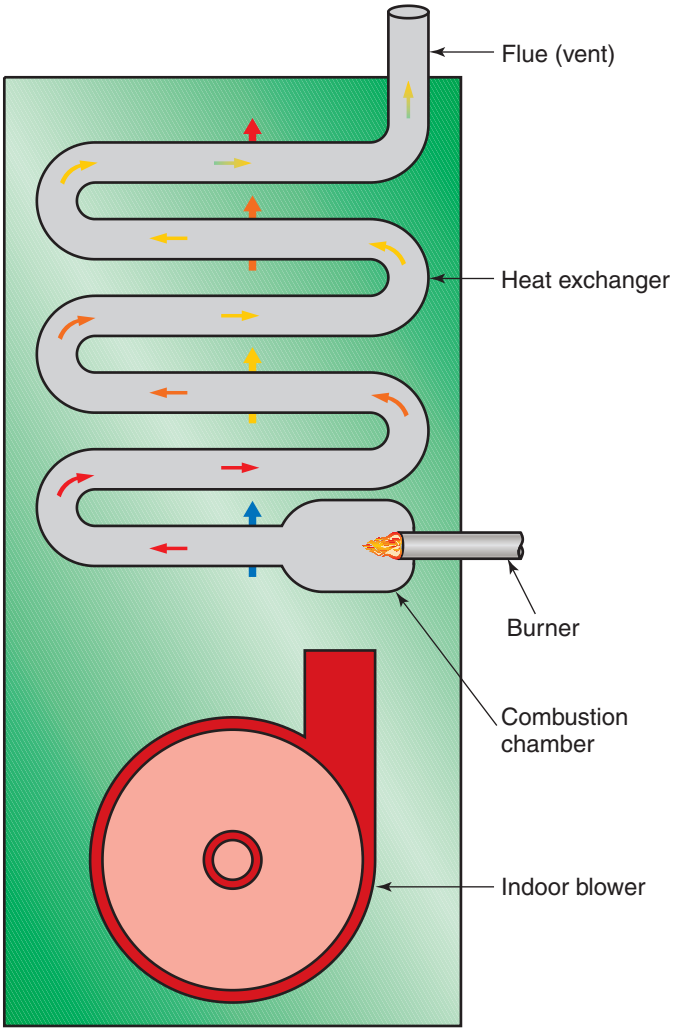
Noncondensing furnaces have lower-efficiency with an AFUE rating between 80% and 90%. In these furnaces, a single heat exchanger transfers heat from the combustion gases to air circulated to the conditioned space. The combustion gases are vented to a flue or chimney with a flue liner. Since up to 20% of the heat produced goes up the chimney, the combustion gas flows outside without condensing. See **Figure 38-3**.

Safety Note

Heat Exchanger Cracks

Before each cold season begins, heat exchangers should be checked for cracks. Deadly gas (such as carbon monoxide, CO) can seep through cracks and into conditioned spaces. This can result in illness and even death.

Copyright Goodheart-Willcox Co., Inc. 2017



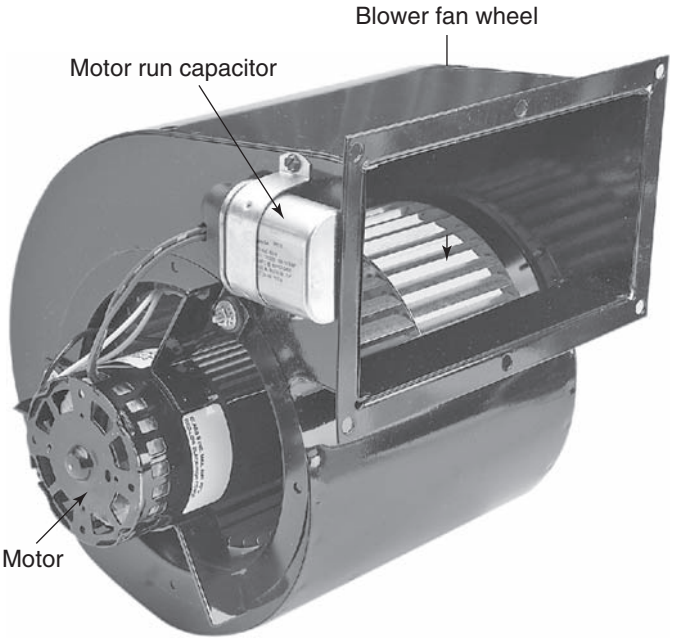
Goodheart-Willcox Publisher

Figure 38-3. In a noncondensing furnace, circulating air passes over a single heat exchanger.

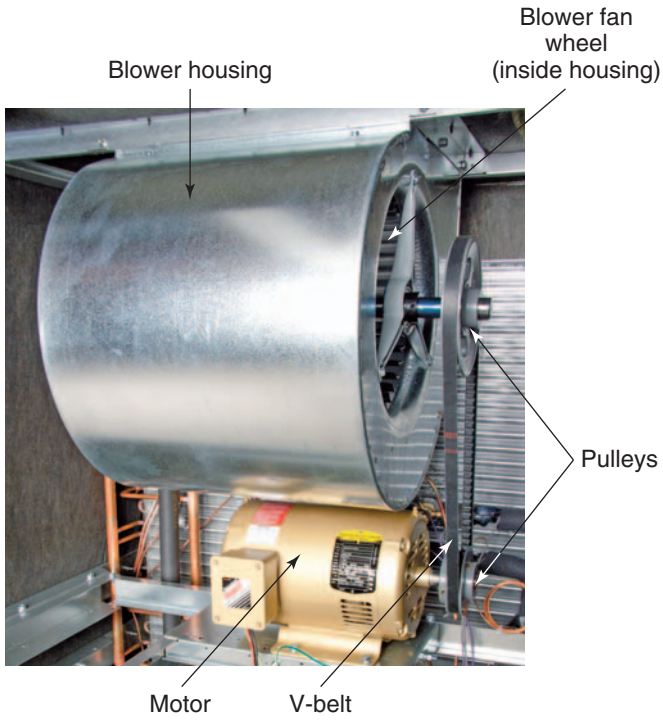
38.1.3 Indoor Blowers

A furnace's ***indoor blower*** creates airflow through the heat exchanger and ductwork to deliver warm air to the conditioned space and draw cool air into the furnace to be heated. These blowers are typically equipped with electric motors with up to 3/4 hp. Two basic types of blower setups are commonly used in residential systems: belt-driven blowers and direct-drive blowers, **Figure 38-4**.

Belt-driven blowers are mostly found on older oil-fired furnaces and large commercial units. On a belt-driven blower, the blower motor is separate from the blower fan. A standard V-belt connects a pulley on the motor to a pulley on the blower fan. The pulleys can be different sizes. The larger the pulley on the motor, the faster the blower fan turns. The larger the pulley on the fan, the slower it turns. A variable-pitch pulley is



Direct-Drive Blower



Belt-Driven Blower

Figure 38-4. A direct-drive blower's fan is attached directly to the motor shaft, while a belt-driven blower's fan is connected to a motor using a pulley and belt arrangement.

Copyright Goodheart-Willcox Co., Inc. 2017

available that can open and close to differing diameters. By varying the diameters of the motor pulley and fan pulley, a technician can make the blower fan turn faster or slower. However, belt-driven blowers are less efficient than direct-drive blowers due to belt and bearing energy losses.

Pro Tip

Belt Width

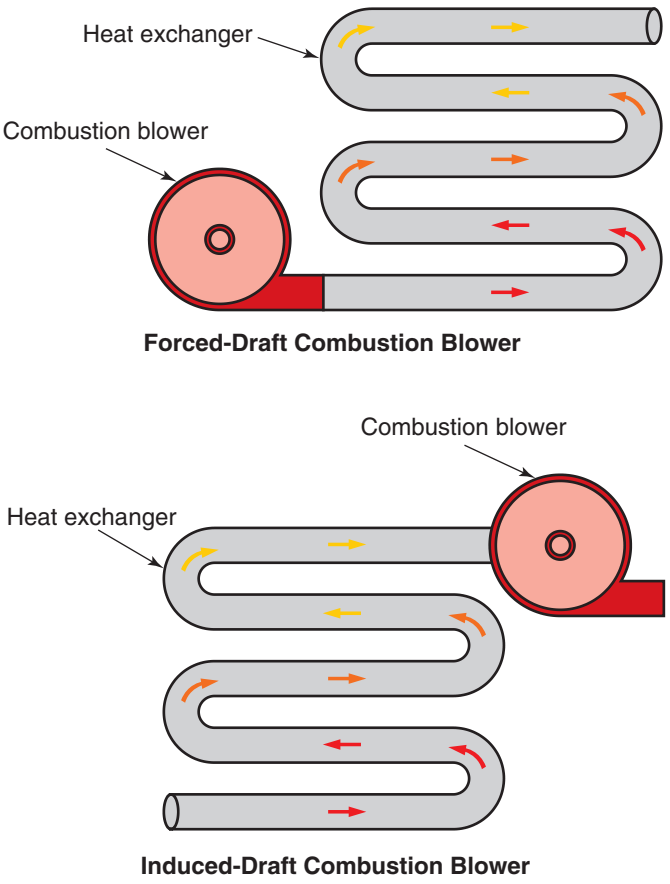
A V-belt must have the same width as the grooves in the motor and fan pulleys in which it rides. Inspect this on service calls when applicable.

In direct-drive blowers, the shaft of the blower motor is connected directly to the blower fan. Since they are directly connected, the blower and motor turn at the same speed (RPM). Blower motors with variable frequency drives can vary their speed as needed to meet the conditioned area's heating requirements. Solid-state controls can be used to constantly monitor a furnace's heat output, firing rate, and blower speed.

Belt-driven blowers and large, heavy direct-drive blowers demand the high starting torque of a split-phase, capacitor-start, or three-phase motor. In both direct-drive and belt-driven blower arrangements, the blower fan must be clean, and the blades should not be bent or broken. Bent or broken blades will place the fan off balance and result in vibration, which will shorten the life of the motor.

38.1.4 Combustion Blowers

A ***combustion blower*** is a motor-driven fan that brings fresh air into the combustion chamber and expels combustion gases out through the heat exchanger and flue. There are two types of combustion blowers: induced-draft blowers and forced-draft blowers. Induced-draft blowers are located downstream from the heat exchanger and pull combustion gases through the heat exchanger. Forced-draft blowers are located upstream from the heat exchanger and push combustion gases through the heat exchanger. See **Figure 38-5**.



Goodheart-Willcox Publisher

Figure 38-5. A combustion blower is categorized as a forced-draft or an induced-draft blower depending on its position relative to the heat exchanger.

38.2 Furnace Types and Construction

Furnace design is based on several factors. These include the fuel used, the space available, and the heat-transfer medium. Common heat-transfer mediums include air, water, and steam.

Most furnaces are made of steel. Blower compartments are lined with insulation to reduce heat loss. The insulation also serves as a noise barrier. Furnaces also require return air ductwork. This ductwork supplies the furnace with air to be reheated (or recooled by a central air-conditioning evaporator during the cooling season). There are three common furnace designs: upflow, downflow, and horizontal. A fourth type of furnace, called a ***multipoise furnace***, can be configured as an upflow, downflow, or horizontal furnace.

In addition to the classifications based on airflow, furnaces can also be categorized by the shape of their cabinets. A ***highboy furnace*** is typically taller than it is wide or long. These types of furnaces are installed in basements or in utility rooms where vertical space is not an issue. The internal components of a ***lowboy furnace*** are arranged in a way that minimizes the height of the cabinet. A lowboy furnace is much shorter than a highboy furnace of comparable capacity. However, the lowboy furnace may be longer or wider. Lowboy furnaces are installed in spaces where there is limited vertical clearance.

Copyright Goodheart-Willcox Co., Inc. 2017

Code Alert

Forced-Air Furnaces

Local building codes specify the types of furnaces that can be installed, restrictions on the placement of furnaces, and minimum duct requirements. Codes also address special considerations and restrictions associated with the installation of a furnace. Codes may even regulate the installation of burners to convert furnaces from fuel oil to gas.

38.2.1 Upflow Furnace

An ***upflow furnace*** takes in return air from the bottom and forces it upward around the heat exchanger and into the supply plenum. Upflow furnaces are the most common type of furnace installed in basements and utility rooms, where the ductwork runs above the level of the furnace. In upflow systems, the supply (warm) air is delivered upward, from the top of the furnace into an overhead duct system, **Figure 38-6**.

38.2.2 Downflow Furnace

A ***downflow furnace*** takes in return air from the top and forces it downward around the heat exchanger. Downflow furnaces are also referred to as *counterflow furnaces*. These types of furnaces are commonly used if the ductwork runs below the level of the furnace. For example, if a house is built on a crawlspace and the ductwork is located under the floor, a downflow furnace is used. Supply air is delivered from the bottom of the furnace to the duct system below it, **Figure 38-7**.

38.2.3 Horizontal Furnace

Horizontal furnaces are placed on their side. In a ***horizontal furnace***, return air flows in a horizontal path through one end of the furnace, across the heat exchanger, and out through the opposite end of the furnace. Horizontal furnaces are typically installed in tight spaces, such as in attics or in crawlspaces, **Figure 38-8**.

Figure 38-8. Return air enters a horizontal furnace from one side and exits through the other side after flowing past the heat exchanger.

Safety Note

Interlocks and Access Panels

A safety interlock switch is often provided inside a furnace's blower access door (panel). When the door or panel is opened or removed, this switch turns off electrical power to all components and eliminates the possibility of personal injury due to moving parts.

38.2.4 Two-Stage Furnace

A standard furnace has only one heat level—high. It waits until the temperature in the conditioned space drops, then it starts up and runs at one constant output when it receives a call for heat. A ***two-stage furnace*** can produce two different levels of heat, allowing it to adjust heat output to meet demand. The flame can be on high, low, or off. When less heat is required, a two-stage furnace operates on the first stage, which uses a lower percentage of its capacity to produce sufficient heat. This stage consumes less energy, thereby increasing efficiency and cost-effectiveness. In addition, two-stage furnaces are much quieter than single-stage furnaces.

On colder days, the furnace functions on the second stage to provide high heat. This allows the unit to meet the demands for more extreme temperatures. The blower motor speed increases when the furnace switches to the second stage. By producing more or less heat for a given amount of time, a two-stage furnace adjusts to changing heat loads. This adaptability helps to maintain a consistent temperature in the conditioned area by reducing the temperature fluctuation caused by excessive heat being distributed too quickly. In addition, the blower fan slowly increases or decreases speed during start-up and shutdown, eliminating the sound of rushing air as it enters or exits ducts.

Thinking Green

Variable Speed Blower Motors

Variable speed blower motors adjust speed automatically to meet the temperature requirements set on the thermostat, creating a more comfortable environment and increasing efficiency. They also keep air circulating at a low speed between cycles, thereby limiting energy waste significantly. The consistent airflow also allows the air filter to trap more pollutants, providing better indoor air quality.

38.2.5 Modulating Furnace

A ***modulating furnace*** is a furnace that can vary its heat output. In some models, heat output can be controlled from 40% to 100% of their total capacity. Solid-state integrated controls act as the "brain" of the furnace. After receiving a call for heat from the thermostat, the controls initiate and manage a sequence of events directing the furnace so that it supplies heat to the building efficiently. Some furnaces can automatically choose the most efficient indoor blower speed when continuous air circulation is desired. An induced-draft combustion blower quietly provides air for combustion and vents the products of combustion from the heat exchanger to the outdoors.

38.3 Forced-Air Duct Arrangements

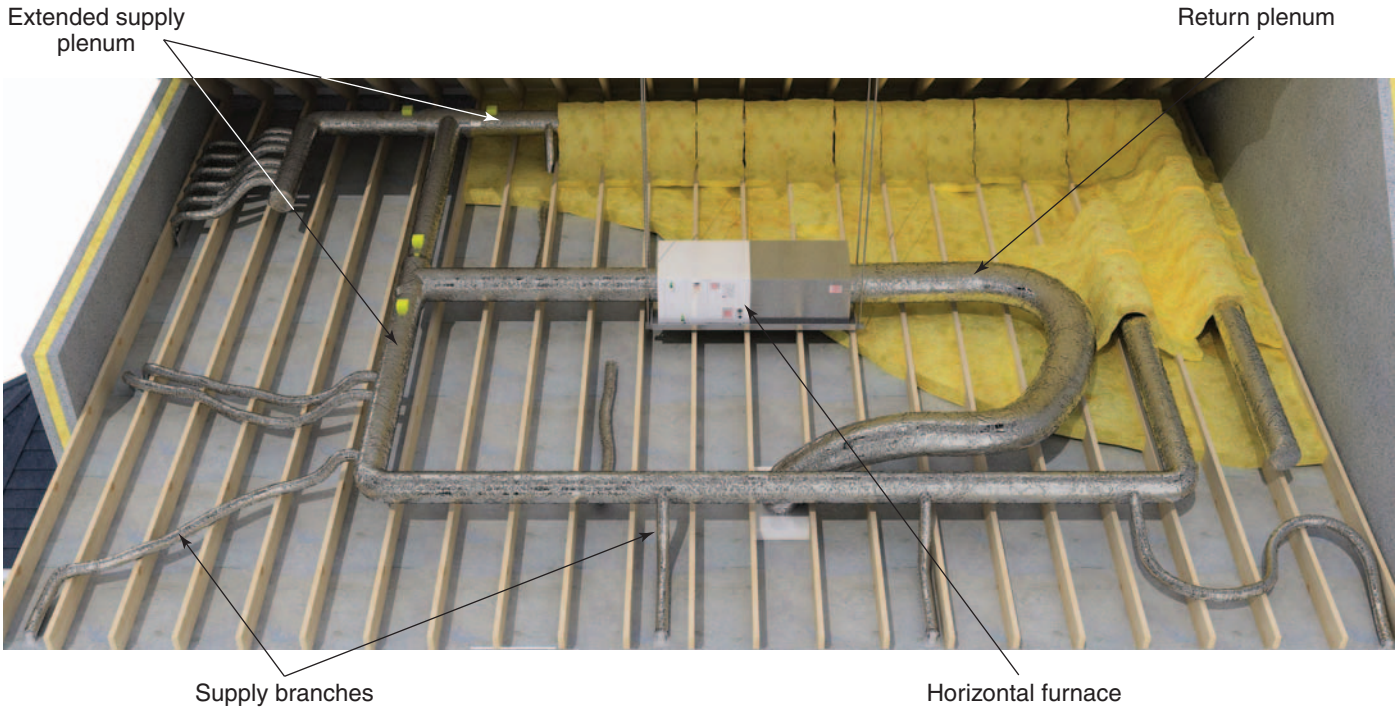
A forced-air heating system uses a motor-driven fan called an indoor blower to circulate heated air. With this heating arrangement, a system of ducts, referred to as supply air ducts, delivers warm air to the conditioned spaces. Another system of ducts, referred to as return air ducts, brings air back to the furnace for reheating. Both supply and return air ducts should be carefully sized to provide the correct amount of airflow to each room, **Figure 38-9**.

Forced-air duct systems usually include an air filter in the return air duct to the furnace. A humidifier is often installed in the supply airflow to provide the desired relative humidity conditions. Duct systems often include numerous dampers, grilles, diffusers, and registers to manage airflow. To review these components or for information about duct sizing, see Chapter 29, *Air Distribution*.

38.4 Makeup Air Units

Negative pressure problems are often caused by forced-air heating systems, which require oxygen and fresh air if they use combustion in the furnace (gas-fired

Copyright Goodheart-Willcox Co., Inc. 2017



Hi-Velocity Systems

Figure 38-9. This SDHV (small duct, high-velocity) system uses a horizontal furnace installed in an attic.

or oil-fired). If a dedicated fresh air supply is not available for the furnace, a home that is sealed and insulated well can result in negative pressure developing due to the furnace's need for fresh air. Rather than allowing this negative pressure to cause infiltration around doors, windows, or wherever an unintended opening might be, a technician can install a makeup air unit.

A ***makeup air unit*** is a device that controls and regulates the necessary intake of fresh air into a building. Current codes and regulations in many states require the use of makeup air units to prevent negative pressure from developing in a house. In a single-family residence, a makeup air unit is usually an automatic, passive device with few controls. Makeup air units for larger installations and commercial applications are often automatic, active devices with more controls.

Although variety exists in manufacturing, there are two common places where makeup air is deposited in a building: directly into the return air duct or into the furnace room. **Figure 38-10A** shows a makeup air unit that deposits makeup air into the return air duct. One part is installed along an exterior wall, where outside fresh air can enter it, and the other part is installed on the return air duct. A run of duct connects the two parts. The part connected to the return air duct has a weighted arm attached to a damper. When the indoor blower runs, it creates a low pressure in the return air duct. This allows the outside air, which has a higher pressure, to push open the damper. Outside air flows into the return air duct as long as the blower remains on. Outside air regulated by this type of makeup air unit is immediately filtered and conditioned as it flows from outside into the air handler.

Figure 38-10B shows a makeup air unit that delivers makeup air into a building's furnace room or mechanical room. This makeup air unit is installed on or very near the air handler. Outside air flows in through a screened opening installed on the outside of the building and through ductwork that connects to the makeup air unit. The unit operates based on positive and negative pressure. When the indoor air pressure is reduced, outside air flows through the makeup air unit and into the furnace or mechanical room to equalize indoor and outdoor air pressures. Outside air may also flow in to provide oxygen for combustion in a furnace that draws its combustion air from within the building.

Thinking Green

Makeup Air Units and Combustion

In addition to causing unwanted air infiltration, another side effect of negative pressure is that a gas-fired or oil-fired furnace can become starved for air. A lack of air negatively affects combustion, reducing a system's efficiency. Since makeup air units bring in a supply of fresh air from the outside, ample air is available for combustion, maintaining high furnace efficiency.

Figure 38-10. Two types of makeup air units. A—The screened opening installed on the outside of the building allows fresh air to pass inside. Ductwork connects each part. The part attached to the return air duct uses a weighted arm on a damper to control airflow. B—Outside air flows through a screened opening, a length of duct, and the makeup air unit into a building's mechanical room to equalize inside and outside air pressure.

Pro Tip

Makeup Air Unit Location

Refer to manufacturer instructions for makeup air unit installation details. Outside air inlets typically must be installed a certain distance away from appliance exhaust outlets. Also, some makeup air units must be installed within a certain distance of the furnace.

38.5 Blower Controls

There are several different devices that engage or disengage a forced-air heating system's blower fan. These overlapping controls are used for normal operation and for preventing personal harm and property damage in case of malfunction. Normally, a forced-air heating system turns on the blower fan automatically. This is initiated when the thermostat calls for heat. When and how the blower turns on varies for gas, oil, and electric heating systems.

Blower controls generally use measurements of time or temperature to regulate when to turn on or turn off a blower fan. When a furnace responds to a thermostat's call for heat, the blower turns on in response to a time-delay control or thermostatic control. For gas and oil systems, the time delay allows air in the plenum to warm up before circulating, which prevents or minimizes an initial blast of cold air from the supply registers.

A time-delay control may come in a variety of forms. Time-delay controls may be simple electromechanical devices with a switch that changes after a set amount of time. In other cases, time-delay control may be built into a circuit board or other electronic control unit. These electronic controls can often be adjusted by toggling dual in-line package (DIP) switches or by changing jumper terminals mounted directly on the circuit board. See **Figure 38-11**.

A thermostatic blower control turns on the blower after the plenum has reached a specific temperature, typically around 140°F (60°C). Once the thermostat has ended its call for heat, the burner shuts down, but the blower continues to operate. As the blower continues to circulate air, the temperature in the plenum gradually drops. When the temperature has dropped enough, usually around 90°F (32°C), the thermostatic control opens its contact points to stop blower operation. Thermostatic blower controls are often adjustable. These devices vary in form but generally consist of an electric switch operated by a bimetal disc, a bimetal helix, or a fluid-filled sensing bulb, **Figure 38-12**.

Pro Tip

The Term "Thermostat"

Specific industries, such as HVACR, develop their own jargon. As a result, when an industry person and a non-industry person use the word *thermostat*, each person may not mean the same thing. To most non-HVACR people, the thermostat is the device they operate to change the temperature in their building. To HVACR people, a thermostat may be any kind of switch that automatically responds to a change in temperature, such as a bimetal disc. Many HVACR parts manufacturers list bimetal switches as thermostats. Be mindful of the word *thermostat* and what that term may mean to the person using it.

In some cases, a blower control is in the same casing as a limit control. In a heating system, a limit control is a temperature-sensing switch that remains closed as long as the plenum temperature remains below its set point. If the temperature in the plenum reaches the limit control's set point, the control opens its switch to shut down the burner or heating elements. This action stops heat production in the furnace. The limit control's high set point temperature indicates a system malfunction, such as the blower fan no longer operating or a lack of airflow, both of which allow excessive heat to build up in the furnace. To avoid furnace damage from overheating, the limit control switches off the system to stop the production of heat.

Pro Tip

Fan Switch or Limit Switch

Many fan switches are designed by manufacturers to have adjustable controls and a broad range of operation. When a device has an adjustable set point, it can be set to function as either a fan switch or a limit switch.

38.6 Unit Heaters

A ***unit heater*** is a ductless, forced-air heating unit that is designed to heat a large, open area or to be used in a specific heating application. These units may be gas-fired, oil-fired, or electric. In a unit heater, an electric blower moves air across the heating element and into the space to be heated. See **Figure 38-13**.

Many stores, commercial buildings, and factories use unit heaters to heat rooms or spaces that cannot be effectively or efficiently heated using a centralized forced-air system. For instance, unit heaters may be installed above doorways to direct a high-velocity flow (about 2500 fpm) of warm air over large door openings, such as shipping and receiving doors to businesses and warehouses. This helps to warm any cold air that enters from the outside. Unit heaters are mounted about 3′ above and 4′ away from the opening. Operation is controlled by a door switch and a thermostat connected in parallel. Doors less than 8′ high and 10′ wide are typically not protected by unit heaters. With a unit heater's heating element switched off, the fan may be turned on in summer to help keep out dust and insects. In this way, a unit heater can operate as an air curtain.

Chapter Review

Summary

- In a forced-air HVAC system, a motor-driven fan, called a blower, circulates air. Before the development of forced-air heating systems, heated air was distributed by natural convection and cool air was returned to the furnace by gravity.
- Oil-fired and gas-fired forced-air furnaces consist of a combustion chamber, a fuel delivery method and burning device (burner), a flue or exhaust outlet, one or two heat exchangers, an indoor blower, and often a combustion blower.
- Condensing furnaces have a primary heat exchanger that transfers sensible heat from the combustion gases to the circulating air or water (in a hydronic system). A secondary heat exchanger transfers additional sensible heat and latent heat to the circulating air or water, causing the combustion gases to condense.
- Noncondensing furnaces have a single heat exchanger that transfers heat from the combustion gases to the circulating fluid. Since noncondensing furnaces are less efficient than condensing furnaces, the combustion gases do not lose enough heat to condense before reaching the outside.
- Indoor blowers create airflow through the heat exchanger and ductwork by drawing cool air into the furnace from the return air ducts and pushing heated air into conditioned space through the supply air ducts. Combustion blowers bring fresh air into a furnace's combustion chamber and expel combustion gases out through the flue.
- In an upflow furnace, return air is drawn in through the bottom of the furnace and heated supply air is discharged from the top of the furnace. In a downflow furnace, return air is taken in through the top of the furnace, and the heated supply air exits through the bottom of the furnace. A horizontal furnace is a furnace placed on its side, so the return air flows in a horizontal path from one end of the furnace to the other.
- A two-stage furnace is capable of running at a high output during periods of high heat demand and at a lower heat output during periods of low heat demand. Modulating furnaces can vary their heat output over a wide range to meet changing demands for heat.
- Makeup air units deliver fresh air to the furnace or building when needed. This additional air from the outside prevents a negative pressure from developing in the building.
- Forced-air heating systems typically have a time-delay control or thermostatic control that turns on the indoor blower a short time after the furnace turns on. A time-delay control allows air in the plenum to warm up before turning on the blower to circulate the air. A thermostatic control monitors the temperature in the plenum and turns the blower on and off at specific plenum temperatures.
- Unit heaters are ductless, forced-air heating units. They can be gas-fired, oil-fired, or electric. Unit heaters are commonly installed in large open areas or above large doorways, such as those in loading docks, to offset heat lost through the open doorway.

Review Questions

Answer the following questions using the information in this chapter.

1. Which of the following heat distribution methods relies on only natural convection to distribute heated air?
   A. Forced air.
   B. Gravity.
   C. Hydronic.
   D. All of the above.
2. Which of the following is *not* a basic component of a gas-fired furnace?
   A. Blower motor.
   B. Electric resistance heating element.
   C. Flue.
   D. Heat exchanger.
3. In a condensing furnace, circulating air passes over the _____ before passing over the primary heat exchanger.
   A. burner
   B. combustion blower
   C. flue
   D. secondary heat exchanger

Copyright Goodheart-Willcox Co., Inc. 2017

4. Secondary heat exchangers are frequently made of stainless steel because they _____ other metals.
   A. are exposed to temperatures that would melt most
   B. are less likely to warp than heat exchangers made from
   C. can transfer heat much more rapidly than heat exchangers made from
   D. can withstand corrosive condensate much better than heat exchangers made from

5. Unlike a noncondensing furnace, a condensing furnace can use _____ for its exhaust flue.
   A. a chimney
   B. galvanized steel
   C. PVC or CPVC
   D. stainless steel

6. Noncondensing furnaces typically have an AFUE rating between _____.
   A. 10% and 25%
   B. 40% and 60%
   C. 80% and 90%
   D. 90% and 100%

7. Which of the following statements regarding direct-drive blowers is true?
   A. The blower fan spins at the same speed as the blower motor.
   B. The blower fan spins faster if it is equipped with a larger pulley.
   C. The blower fan spins faster if it is equipped with a smaller pulley.
   D. The blower fan speed is adjusted by varying pressure on the fan clutch.

8. Which of the following best describes the function of a combustion blower?
   A. It atomizes the fuel as it enters the combustion chamber.
   B. It brings fresh air into the combustion chamber and expels combustion gases.
   C. It compresses the fuel mixture as it enters the combustion chamber.
   D. It reduces draft in the flue.

9. The two types of combustion blowers are _____ blowers.
   A. primary and auxiliary
   B. downdraft and updraft
   C. forced-draft and induced-draft
   D. pre-combustion and post-combustion

10. If a house is built with the furnace in the basement and the ductwork running above the furnace, a(n) _____ furnace would most likely be installed.
    A. upflow
    B. downflow
    C. horizontal
    D. sideflow

11. Which of the following statements regarding two-stage furnaces is *not* true?
    A. Blower speed increases when the furnace switches to the second stage to provide high heat.
    B. Two-stage furnaces are much quieter than single-stage furnaces.
    C. Two-stage furnaces are more efficient than single-stage furnaces.
    D. Two-stage furnaces produce less consistent room temperatures than single-stage furnaces.

12. The purpose of a(n) _____ is to control and regulate the necessary intake of fresh air into a building.
    A. diffuser
    B. forced-draft blower
    C. induced-draft blower
    D. makeup air unit

13. A _____ furnace can control its heat output from 40% to 100% of their total capacity.
    A. high-boy
    B. modulating
    C. multipoise
    D. thermovariable

14. When a furnace responds to a call for heat, there is usually a brief delay before the blower activates that _____.
    A. may be based on either elapsed time or a temperature set point
    B. minimizes the blast of cold air leaving the ducts when the blower turns on
    C. provides time for the plenum to heat up
    D. All of the above.

15. Which of the following statements about unit heaters is *not* true?
    A. Unit heaters are ductless.
    B. Unit heaters are primarily used in residences.
    C. Unit heaters can be gas-fired, oil-fired, or electric.
    D. Unit heaters may be mounted above warehouse receiving door openings.

- 39.5.5 Expansion Tank Problems
- 39.5.6 Other Hydronic System Problems
- 39.5.7 Servicing a Steam Heating System

39.6 Preparing a Boiler for the Heating Season

Learning Objectives

Information in this chapter will enable you to:

- List the basic components of a hydronic system and explain their functions.
- Explain the purpose of hydronic system water treatment.
- Describe the different types of hydronic system designs.
- Summarize the different methods for installing radiant heating systems.
- Identify various controls used in hydronic systems and explain their functions.
- Explain how to balance a hydronic system and prepare it for initial start-up.
- Troubleshoot boiler and water circulation problems in a hydronic system.
- List the steps required to purge series loop systems, one-pipe systems, and zoned systems.
- Perform regular maintenance and service on a steam heating system.
- Inspect a boiler and prepare it for the heating season.

Review of Key Concepts

Reviewing these concepts from earlier chapters will help you understand new concepts presented in this chapter:

- Boilers use heat exchangers to transfer heat from combustion gases to water in hydronic systems. (Chapter 38)
- Adding heat causes most substances to expand, and removing heat causes them to contract. (Chapter 4)
- Gas-fired and oil-fired heating systems can transfer heat through forced-air, hydronic, or radiant distribution. (Chapter 38)
- Thermostats are wall-mounted devices that use contact points or a circuit to control the operation of heating units. (Chapter 36)

Introduction

Hydronic systems distribute conditioned water or steam to occupied spaces in order to heat or cool those spaces. Since this section of the textbook deals with heating, this chapter focuses on hydronic heating systems rather than hydronic cooling systems, which utilize chillers. Compared to forced-air heating systems, hydronic heating systems offer the following benefits:

- More consistent temperature levels. Even when a hydronic system's pump is not circulating water, the piping still contains heated water that continues to radiate heat. For this reason, temperatures remain steady for longer periods of time in hydronic systems than in forced-air systems.
- Increased heat transfer efficiency.
- Hydronic tubing requires less room than standard air ducts in forced-air systems.
- Less moisture removed from indoor air than in forced-air systems.
- Do not introduce any dust, allergens, or mold into the conditioned space.

Hydronic systems are used in some single-family homes and apartment buildings. The boilers that are used to heat water for hydronic systems may also be used for domestic water heating. Although hydronic systems can be designed to distribute either water or steam, water is now more commonly used than steam. This choice allows the system to be more easily modified to provide comfort cooling with chilled water. Using hot water instead of steam also allows the user to adjust the temperature of the circulating water based on heating demand, which is not possible with steam. The ability to reduce the circulating water's temperature during periods of low demand makes hot-water hydronic systems more efficient than their steam counterparts.

Copyright Goodheart-Willcox Co., Inc. 2017

In some older hydronic systems, steam circulates upward through the system piping by thermal convection and returns to the boiler through the same piping due to gravity. These older systems typically use radiators. Because these systems are unable to control the flow of steam or deliver high rates of heat, they are no longer used. Systems are now designed for individual zone controls. Radiators for single rooms or zones connect to a main pipe supplied by the boiler. These individual zones each have a control valve that allows the temperature of one zone to be adjusted independent of another zone.

39.1 Hydronic System Components

Although a wide variety of hydronic system designs are in use, the same basic components are used in all designs. These basic components include a boiler, piping, and terminal units (heat emitters). The boiler heats the water or steam, the piping carries the hot water or steam to the area in need of heating, and the terminal units release the heat into the conditioned space.

In addition to these essential components, hydronic systems require other components in order to function properly. These additional components include a pump to circulate the water through the boiler, piping, and terminal units. A variety of valves are used to control the flow of water or steam through various parts of the system. An expansion tank provides extra room for water as it is heated and expands. The expansion tank also helps maintain a consistent pressure in the system as the water expands and contracts. Finally, special components may be installed in the system to eliminate excessive amounts of air in the circulating water.

39.1.1 Boilers

A ***boiler*** is a closed vessel that heats water for circulation through a hydronic system. Hydronic boilers often burn fuel to heat or boil water. Some boilers use electric heating elements to boil the water. Boilers can operate with water temperatures ranging from 90°F to 200°F (32°C to 93°C). Boilers can be classified in several ways. One way of classifying boilers is based on operational water temperatures. This method has two classes of boilers: conventional and condensing.

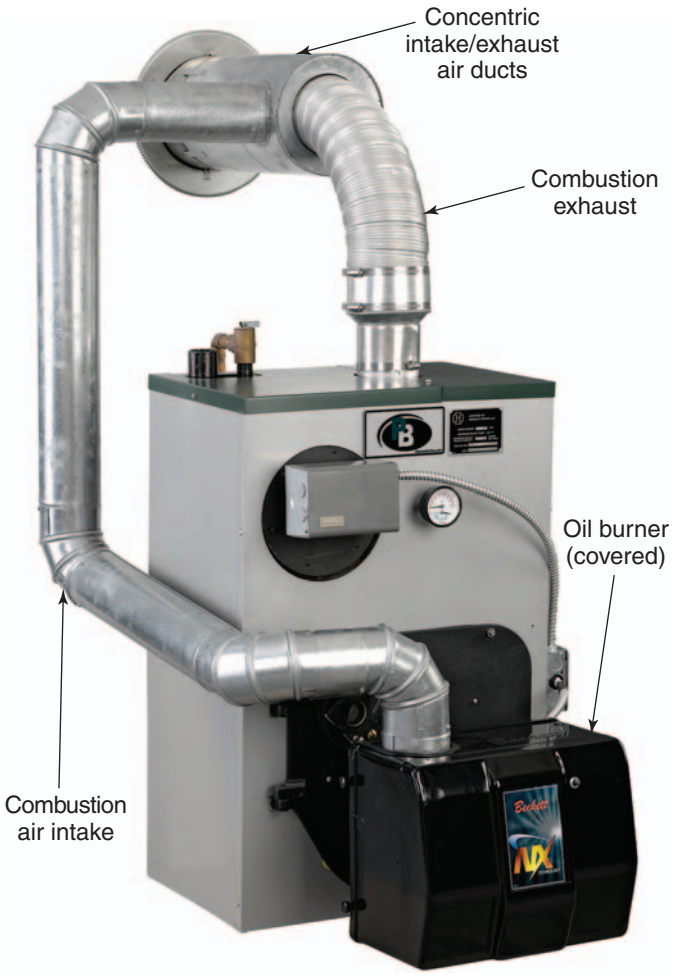
Conventional Boilers

Conventional boilers operate at water temperatures above 140°F (60°C). This high operating temperature prevents combustion gases from condensing. If the water in the boiler drops below 140°F (60°C), it absorbs so much heat that the combustion gases produced by the boiler begin to condense back into a liquid. Upon condensing, combustion gases become highly corrosive. The corrosive condensate that forms inside a conventional boiler reduces its operational life and can result in damage to the flue as well. If a hydronic system is equipped with a conventional, noncondensing boiler, it must include thermostatic controls to ensure that the return water temperature stays above 140°F (60°C), **Figure 39-1**.

Thinking Green

Instantaneous Boilers

Instantaneous boilers are similar to instantaneous, tankless water heaters. In fact, some instantaneous boilers are designed to also provide for domestic hot water needs. These boilers have no tank and heat water only when heat is called for. Because there are no standby heat losses, these types of boilers are much more energy efficient than conventional boilers and may be suitable in certain applications.



PB Heat, LLC

Figure 39-1. Oil-fired conventional boiler with metal pipe for air intake and exhaust.

Copyright Goodheart-Willcox Co., Inc. 2017

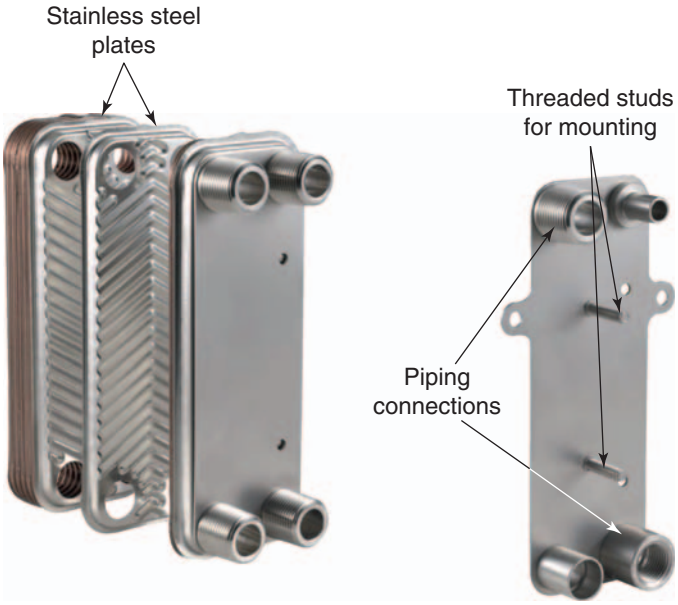
Condensing Boilers

Condensing boilers are designed to condense combustion gases and drain away the condensate. Corrosion caused by condensate is not a problem in condensing boilers because these boilers are designed to withstand the corrosive condensate and drain it away, **Figure 39-2**.

Condensing boilers are equipped with special secondary heat exchangers that remove additional heat from combustion gases, **Figure 39-3**. These secondary heat exchangers must be made of a material that can withstand the corrosive nature of the combustion condensate. These heat exchangers are primarily made of stainless steel. When additional heat is removed in the secondary heat exchanger, the combustion gases condense and release latent heat into the circulating water, further increasing the boiler's efficiency. Condensing boilers are over 90% efficient.

PB Heat, LLC

Figure 39-2. Gas-fired condensing boiler with a 93% efficiency rating. Note the plastic pipe connections for the exhaust vent.



Xylem Inc.

Figure 39-3. Cutaway of a plate heat exchanger made of stainless steel. The corrugated plates provide highly efficient heat transfer.

Condensing boilers may be gas-fired or oil-fired. Because condensing boilers are more efficient than conventional boilers, there is less unburned fuel in the exhaust. As a result, the condensate formed in a condensing boiler is less corrosive than any condensate that may form in a conventional boiler. Condensing boilers can be vented through a wall, roof, or unused chimney and are equipped with a drain connection for condensate removal.

Thinking Green

Condensing Boilers

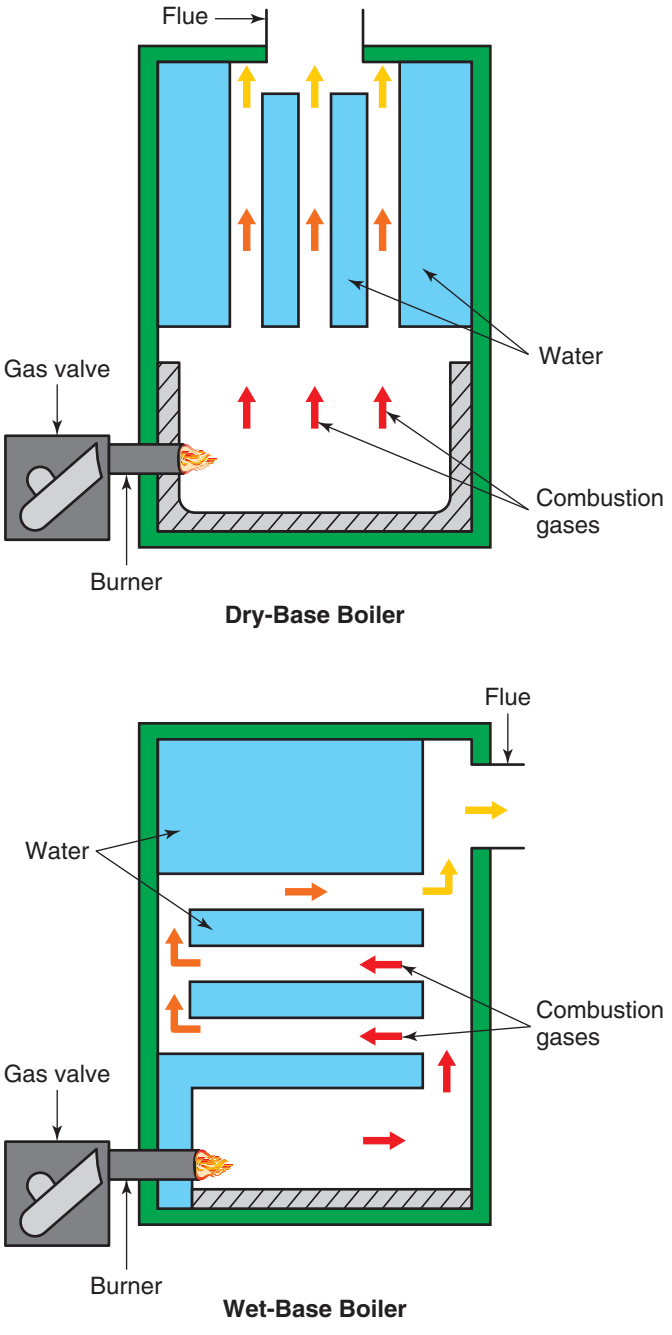
Condensing boilers are more efficient than conventional boilers. For every pound of combustion gas that is condensed, a condensing boiler produces 970 Btu more heat than a conventional boiler using the same amount of fuel.

Boiler Classifications

A boiler's heat exchanger is typically made of one of three types of material: cast iron, steel, or copper. Boilers are also classified as either wet base or dry base. In ***dry-base boilers***, the area under the combustion chamber is dry. The boiler water is contained in an area above the burner. In ***wet-base boilers***, the water surrounds the combustion area. See **Figure 39-4**.

Cast-iron boilers are frequently used in residential and light-commercial applications and usually hold 15 to 30 gallons of water. Although they require additional time to heat, they are able to maintain heat for extended periods of time.

Copyright Goodheart-Willcox Co., Inc. 2017



Goodheart-Willcox Publisher

Figure 39-4. The water in a dry-base boiler is contained in an area above the combustion area, whereas the water in a wet-base boiler surrounds the combustion area.

In steel boilers, water flows around a bundle of steel tubes containing combustion gases. Baffles inside the tubes increase heat transfer and slow combustion gases. This allows additional heat to be removed from the gases, increasing efficiency.

Copper-tube boilers use finned copper tubes as heat exchangers. Copper is a good heat conductor, which means these units heat quickly. Copper-tube boilers are classified as low-mass, low-volume boilers because they are much lighter than both cast-iron and steel boilers and typically contain only a few gallons of water.

Code Alert

Boiler Installation

The type of boiler that can be installed and the proper placement and work clearance of a boiler are dictated by local building codes. Building codes also address such issues as proper boiler connections, installation of safety and pressure-relief valves, and selection and installation of expansion tanks. The guidelines provided by the International Mechanical Code (IMC) are often required for commercial construction.

Water Treatment

Certain substances are often added to water in hydronic systems to lower the water's freezing point and raise its boiling point. Glycol is a common additive used to protect against water freezing within a system. There are two types of glycol: propylene and ethylene. The use of ethylene glycol often requires a special permit because it is toxic to humans and less environmentally friendly than propylene glycol.

To figure out how much glycol to add to a hydronic system, determine the system's lowest ambient water temperature and then follow the glycol manufacturer's instructions based on that temperature. In general, a 50% mixture of propylene glycol protects against freezing down to –30°F (–34°C), but also reduces the system's heating capacity to around 90% of its normal heating capacity. Never use glycol intended for automobile cooling systems or in hydronic systems with galvanized piping.

Since tap water has impurities that may cause scale, corrosion, or embrittlement, additional substances may also be added to prevent the formation of deposits in a system. Scale forms when salts in the water settle on metal surfaces as the water undergoes temperature changes. The salts that can be formed include calcium carbonate, magnesium sulfate, sodium hydroxide, silica oxide, and many more. Iron and manganese may also form deposits in the boiler. See **Figure 39-5**. These impurities must be removed before the water enters the boiler. Chemicals can be added to form a sludge with these salts, and boilers are equipped with valves that can be used to purge the sludge from the system.

Corrosion is a chemical degradation of metal. This can occur inside a hydronic system when the water is too acidic or when certain gases are dissolved in the water. Water can be contaminated by organic matter, oil, and dissolved gases, such as hydrogen sulfide, carbon dioxide, and oxygen. Corrosion resulting from

Copyright Goodheart-Willcox Co., Inc. 2017

Maximum Allowable Impurities in Boiler Water

Sodium chloride	NaCl	10.0
Sodium phosphate	Na_3PO_4	25.0
Sodium sulfate	Na_2SO_4	25.0
Silica oxide	SiO_2	0.2
Total dissolved solids		50.0

Goodheart-Willcox Publisher

Figure 39-5. Maximum levels of certain impurities in boiler water, listed in parts per million (ppm).

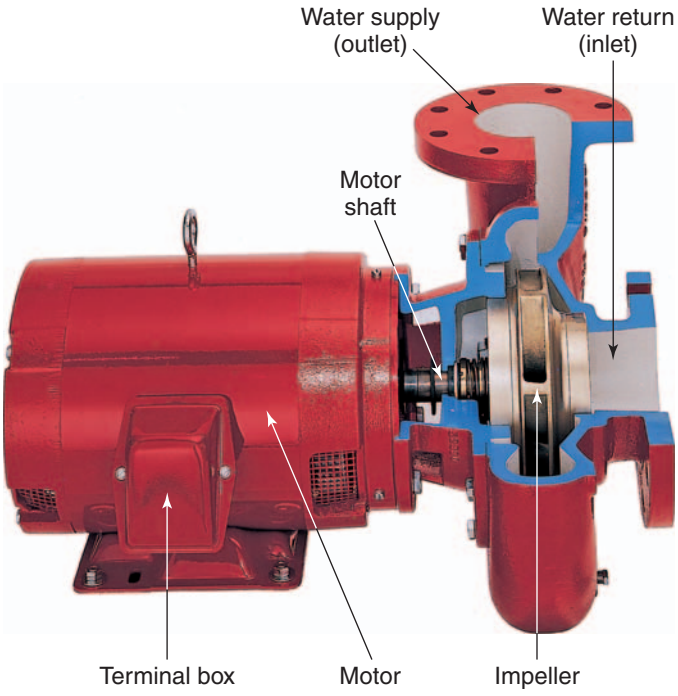
these contaminants can be reduced by neutralizing the acidic water with an alkali or by removing the gases through deaeration. ***Deaeration*** is the release of gases dissolved in a liquid. Chemical scavengers and corrosion inhibitors can also be added to the water to help prevent corrosion. Chemical scavengers are chemicals that interact chemically with the contaminants, rendering them inert. Corrosion inhibitors are chemicals that form a protective coating on the surface of the metal. Both types of additives are widely available at contracting supply houses, and some companies even specialize in the treatment of boiler water.

Long-term corrosion can cause embrittlement of system parts. ***Embrittlement*** is a weakening of the metal, which can cause structural failure along seams, under rivets, and at tube ends. Water may flash to steam through small leaks in these highly stressed areas. This allows any sodium hydroxide in the water to concentrate, which in turn speeds up further corrosion. Embrittlement can be slowed by maintaining a low acidity in the water, repairing leaks, and adding special inhibiting agents to the water. The water in a hydronic system should have a pH level between 7 and 10.

39.1.2 Circulating Pumps

Although some older hydronic systems circulate hot water through natural convection, the majority of systems use a circulating pump to circulate heated water throughout the system. A ***circulating pump*** is a motor-driven pump that controls water flow through hydronic system piping, **Figure 39-6**.

Circulating pumps consist of a motor section (containing the rotor, motor windings, and terminal box) and a pump housing (containing the impeller, seal ring, and water passages). An ***impeller*** is the part



Xylem Inc.

Figure 39-6. Cross section of a circulating pump used in a residential hydronic system.

of the pump that spins and forces water through the system. Circulating pumps are often wet-rotor centrifugal pumps. A ***wet-rotor centrifugal pump*** has bearings that are lubricated by the circulating water in the hydronic system rather than a petroleum-based lubricant. The wet-rotor design eliminates the need for a shaft seal and reduces noise and maintenance requirements. Many types of circulating pumps are used in hydronic systems, and some systems have more than one pump.

39.1.3 Expansion Tanks

To cope with the heat-related expansion of water, hydronic systems include an ***expansion tank***, sometimes referred to as a *compression tank*. In an expansion tank, one side of the tank is filled with water and connected to the hydronic system piping. The other side of the tank is filled with air, **Figure 39-7**.

The two sides of the tank may be separated by a rubber diaphragm, or the water may be contained in a rubber bladder inside the tank and the air stored in the space between the bladder and the shell of the tank. As the water in the system heats up and expands, excess water is forced into the expansion tank, where it applies pressure to the diaphragm or bladder and compresses the air. When the temperature of the water drops, the water contracts. This allows the air surrounding the

Figure 39-8. An expansion tank provides room for the expansion of circulating water as the system heats up. As the water cools down again, air pressure forces the water back into the system.

bladder or on the other side of the diaphragm to exert pressure to expel some of the water back into the system. See **Figure 39-8**. In this way, an expansion tank helps to maintain a stable system pressure under varying operating conditions.

Many bladder and diaphragm expansion tanks are equipped with an air fitting that can be used to pump air into the tank to adjust the system pressure. Others are precharged to 12 psi at the factory and cannot be recharged or adjusted.

Caution

Charging an Expansion Tank

Extreme care should be used if air is added to a diaphragm or bladder expansion tank. Excessive air pressure can rupture the diaphragm or bladder. Never use an air compressor or compressed air tank to add air to an expansion tank. Use only a bicycle pump and check the pressure in the expansion tank frequently during the procedure.

In older expansion tank designs, there is no physical barrier between the water and the air. These older expansion tanks are horizontally oriented to provide a larger air space above the water reservoir. They are also considerably larger than diaphragm or bladder expansion tanks. The older-style expansion tanks are always mounted above the boiler, such as in the attic or between floor joists, **Figure 39-9**.

Older expansion tanks are typically equipped with a combination valve at the bottom of the tank. The combination valve allows water to be drained from the tank and allows air to enter the tank at the same time.

An expansion tank can be mounted on either the supply or the return side of the system. However, it is vitally important that the circulating pump circulates water away from the expansion tank rather than toward the tank. See **Figure 39-10**.

39.1.4 Valves

A hydronic system requires numerous valves to function properly. These valves control the flow of

Figure 39-11. Mixing valves may be used to ensure that water is returned to the boiler at the proper temperature.

water through the system. Some of the valves commonly found in hydronic systems include mixing valves, flow control valves, pressure-reducing valves, and backflow preventers.

Mixing Valves

A ***mixing valve*** is a valve that blends hot water from one inlet with cooler water from another inlet so that the water leaving the valve is at the desired temperature. See **Figure 39-11**.

Mixing valves can be used to adjust the water temperature in a hydronic system. The valve reacts to changes in the temperature of the water by opening and closing its internal passages, which changes the ratio of hot water and cold water flowing through the valve. This constant adjustment ensures that the water leaving the valve is the correct temperature.

Most mixing valves are thermostatically or electronically operated. A ***thermostatic mixing valve (TMV)*** has a built-in thermostatic element that reacts mechanically to changes in the temperature at the valve outlet,

Copyright Goodheart-Willcox Co., Inc. 2017

adjusting the mixture ratio as needed to maintain the desired temperature, **Figure 39-12**.

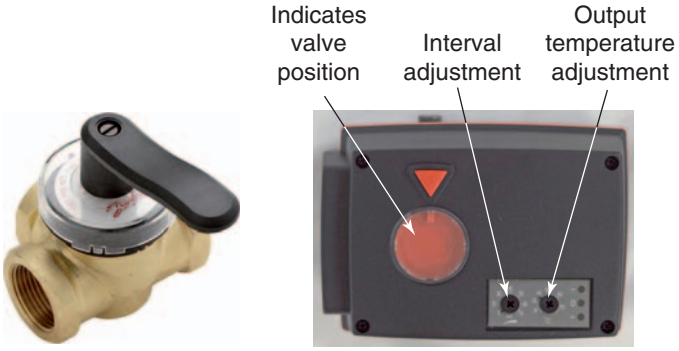
A ***motorized mixing valve*** accomplishes the same task, but has an electronic sensor that monitors the water temperature and a built-in electric motor that adjusts the valve as needed based on sensor feedback.

Some mixing valves are rotary valves that have handles for manually adjusting the mixture of hot and cold water. A motor actuator can also be used to adjust the valve position. The motor actuator is mounted on the manually operated rotary valve so that the valve's shaft engages a drive sleeve on the actuator. When the actuator receives a signal to adjust the valve, the motor and drive sleeve rotate, which in turn operates the valve shaft, **Figure 39-13**.

Mixing valves can be installed at the boiler inlet to monitor the return water temperature or at the boiler outlet to monitor the supply water temperature. Mixing valves are typically used with conventional boilers to keep the return water above a certain temperature to prevent combustion gases from condensing, **Figure 39-14**.

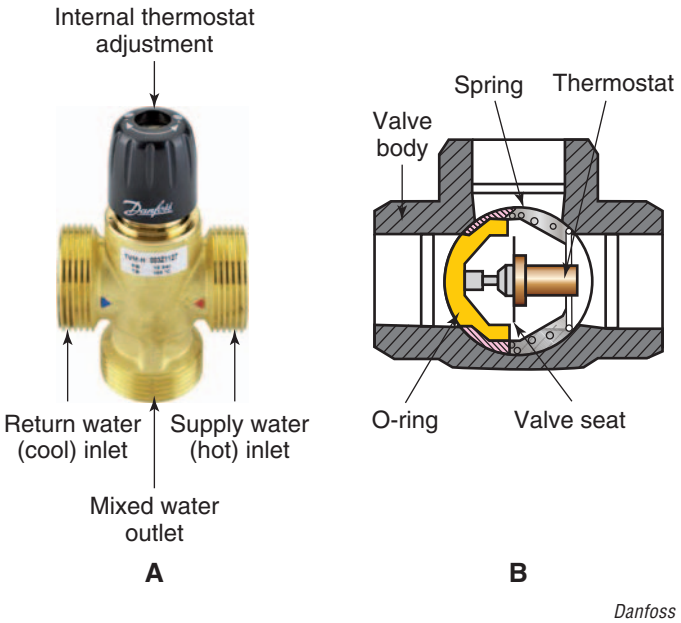
For a return water installation, if the water returning to the boiler is below the set temperature, the mixing valve will allow some of the hot supply water leaving the boiler to flow with the return water. Mixing the hot supply water with the cool return water raises the temperature of the return water above the combustion gas condensing point.

For a supply water installation, if the water leaving the boiler is not yet hot enough to flow through the lines and maintain a temperature above the combustion gas condensing temperature, the mixing valve recirculates the water through the boiler. When the supply water is above the set temperature, the mixing valve allows it to flow through the system. Some common settings for mixing valves are 140°F (60°C) for return water installations and 160°F (71°C) for supply water installations.



Danfoss

Figure 39-13. A rotary mixing valve and motor actuator designed for use with the valve. A sensor placed downstream triggers the actuator to open or close the valve in response to variations in water temperature.



Danfoss

A—The hot and cold water supplied at the valve's inlets are mixed inside the valve to provide a steady flow of water at the desired temperature. B—Cutaway showing the internal construction of a TMV. As the temperature of the water in the valve changes, the thermostatic element opens and closes the valve, changing the ratio of return water to supply water.

Balancing Valves

A hydronic system may deliver hot water to more than one terminal unit. If there are two or more terminal units, the water flow must be balanced to help distribute the heat equally through the system. Otherwise, the terminal units closest to the circulating pump will "steal" most of the heat, and those farther away will not receive their designed quantity of heated water. To address this problem, ***balancing valves*** are installed in the system. These valves adjust the water flow to each terminal unit or zone in the system so that heat is evenly distributed throughout the system, **Figure 39-15**.

Balancing valves are commonly built using globe valves or ball valves. Which type of valve is used may depend on system capacity, size, and other factors. A flow indication device may be used to observe balancing of the flow, **Figure 39-16**.

Pressure-Reducing Valves

Proper operating pressure must be maintained in a hydronic system. If a system starts to run low on water, makeup water is supplied by a connection to a water main. The pressure in the water main is typically much higher than is required for the hydronic system.

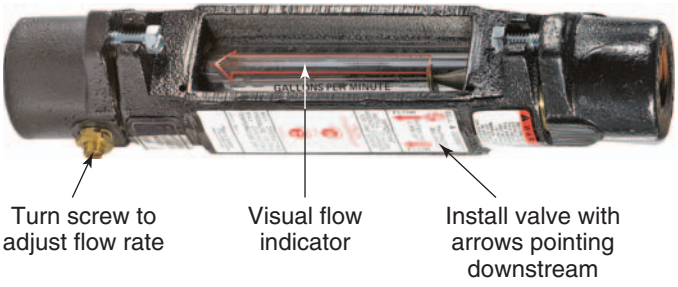
Figure 39-15. With a balancing valve installed in a hydronic system, the system can be balanced so that heated water flows evenly to every terminal unit. This balancing valve has two access ports that allow a technician to measure the valve's pressure drop.



Xylem Inc.

Figure 39-16. A flow indication device that may be used with a balancing valve in a hydronic system.

A ***pressure-reducing valve (PRV)*** is installed in the makeup water line to the boiler to reduce the pressure of the water supplied by the water main to the operating pressure needed by the hydronic system. It acts as a feed valve and also reduces pressure as needed, **Figure 39-17**.

11

Pro Tip

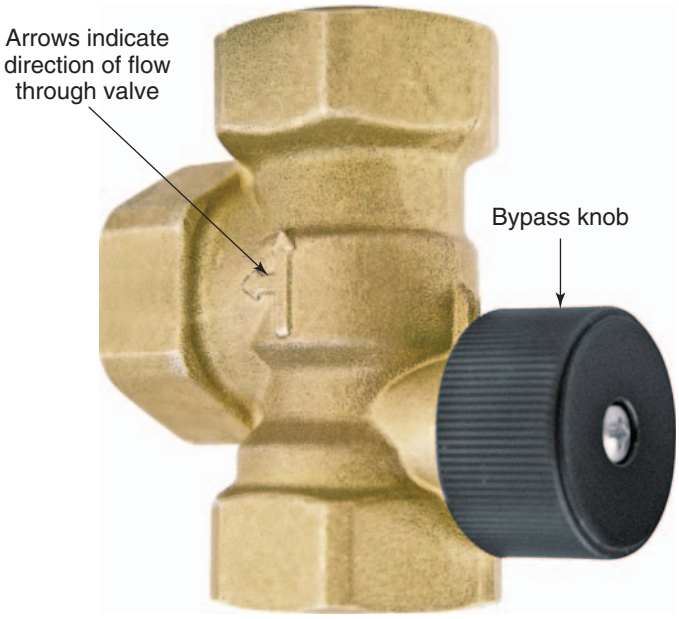
Valve Names

Like the rest of the HVACR industry, the hydronic industry can have multiple names for a single system component. The phrase *pressure-reducing valve* describes the action that the valve has on incoming water. However, since that is only part of its purpose, it may also be known as a *boiler feed valve*, a *boiler fill valve*, and other names. Always clarify what you mean and ask others for clarification.

Copyright Goodheart-Willcox Co., Inc. 2017

Xylem Inc.

Figure 39-17. A pressure-reducing valve helps a hydronic system maintain a preset pressure by allowing makeup water from a water main into the system as needed. Some valves have a handle that facilitates fast filling when a substantial amount of water must be added to a system.



Xylem Inc.

Figure 39-18. A flow-control valve prevents gravity circulation in a hydronic system, which occurs when heated water migrates to higher points in the system, causing rooms or zones located at those higher points to become overheated.

Flow-Control Valves and Backflow Preventers

A typical hydronic system includes a variety of ***flow-control valves*** to ensure that water flows in the proper direction through the system. When the circulating pump quits operating, hot water tends to migrate to higher points in the system, and cold water tends to fall to lower points in the system. Flow-control valves prevent this from happening. Flow-control valves are essentially weighted check valves. Some flow-control valves have a bypass knob or lever on the valve that can be used to open the valve to allow gravity circulation in an emergency, **Figure 39-18**.

Pro Tip

Flow-Control Valve Sizing

Usually flow-control valves are matched to piping size. However, if a system is equipped with a boiler that heats up very quickly, it may be necessary to use oversized flow-control valves to compensate for thermal expansion.

A ***backflow preventer*** is a specialized check valve installed in the makeup water line to prevent water in the hydronic system from flowing back into the water main. This can occur if the pressure in the water main drops below the pressure in the hydronic system. Since fluids flow from a higher pressure to a lower pressure, water will try to flow out of the higher-pressure hydronic system into the lower-pressure water main. In addition to backflow preventers, many pressure-reducing valves, which are also installed in the makeup water line, contain a check valve that prevents water from flowing back into the water main.

39.1.5 Terminal Units

Terminal units, also referred to as *heat emitters*, are the heat exchangers that transfer heat from the circulating water in a hydronic system to the air in the conditioned spaces. A variety of terminal units are used in hydronic systems. The terminal units that transfer heat through a combination of conduction and convection are covered in this section. Hydronic systems can also transfer heat through a combination of conduction and radiation. These systems are referred to as radiant heating systems and are discussed later in this chapter.

Convection-based terminal units all work the same way. The hot water inside the hydronic system transfers some of its heat to air passing over the heating element within the terminal unit. This warmed air circulates throughout the conditioned space, raising the temperature in the space. Convection heating elements are generally constructed of materials with a high

Copyright Goodheart-Willcox Co., Inc. 2017

thermal conductivity, such as copper and aluminum. A typical heating element consists of copper tubing to which aluminum cooling fins have been attached. The cooling fins increase the surface area over which the heat transfer takes place.

Radiators

In hydronic systems, a ***radiator*** is a heat exchanger that hot water or steam flows through. The radiator absorbs heat from the water or steam and then transfers that heat to the conditioned space. Despite its name, this type of terminal unit provides the majority of its heat to the conditioned space through natural convection rather than radiation. Radiators are available for both steam and hot-water hydronic systems and come in a variety of shapes and sizes. See **Figure 39-19**.

Pro Tip

Radiator Selection

Radiators that are designed specifically for hot-water hydronic systems typically cannot be used in a steam system. However, most radiators designed for steam systems can also be used in hot-water systems.

Fan Convectors

Another option for effective and economical hydronic heating is the ***fan convector***. A fan convector is very similar to a radiator. However, it is equipped with a fan that blows air across the surface of the heating element, which increases the rate of heat transfer and improves convection. Because of the high volume of air that passes over its surface, a fan convector is able

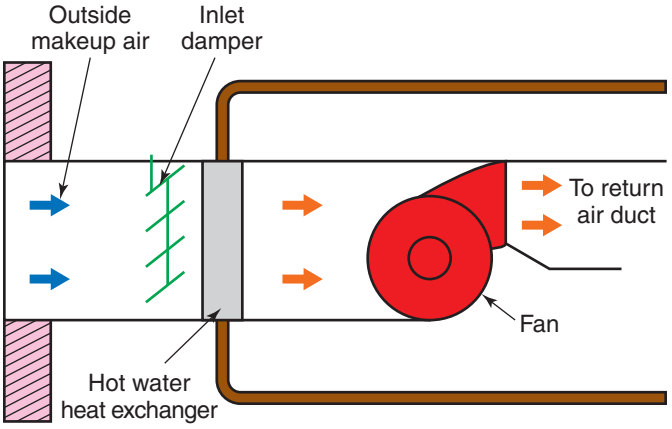
Copyright Goodheart-Willcox Co., Inc. 2017

to extract heat from lower-temperature water than a radiator, which relies on natural convection.

Fan convectors are available in many sizes and shapes. ***Kickspace fan convectors*** are designed to fit into very tight places, such as in the small space under kitchen and bathroom cabinets, in stair risers, and in between floor joists. Kickspace fan convectors work well in zoned applications and in combination with radiant heating systems, **Figure 39-20**.

Fan convectors may also be used in some forced-air applications. For instance, a fan convector can use hot water from a hydronic system to preheat makeup air before it is drawn in and heated by a forced-air furnace, **Figure 39-21**.



Goodheart-Willcox Publisher

Figure 39-21. A hydronic system can feed hot water to a fan convector to preheat makeup air before it is circulated through a forced-air furnace.

39.1.6 Air-Removal Components

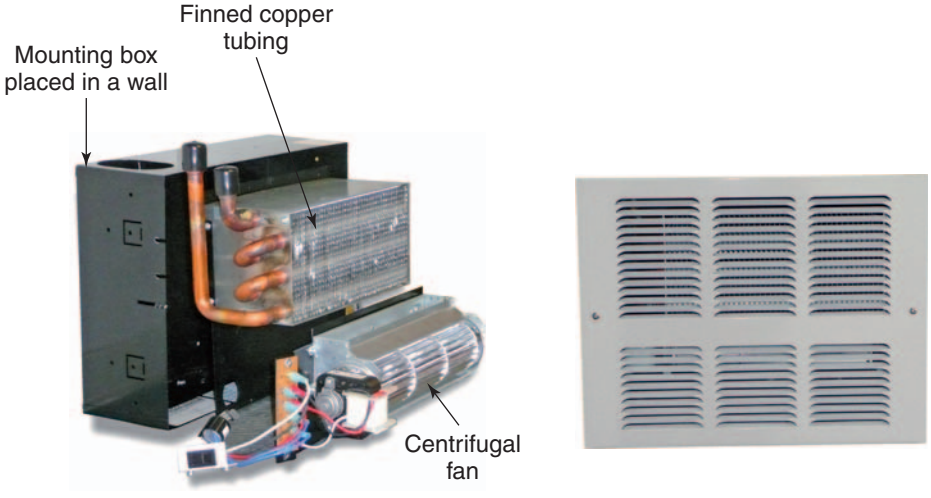
Air must be removed from the circulating water in a hydronic system. If it is not removed, air in the system can result in noisy operation or prevent the proper flow of water through the piping. Also, oxygen in the air can cause corrosion within the piping and other parts of the hydronic system. Corrosion can block pipes or valves and clog pumps, rendering the system inefficient or even inoperative.

The air in a hydronic system falls into three categories. The first type is called ***free air***. Free air consists of bubbles of air that collect at the high points in a hydronic system. One-way valves called air vents are used to release any free air trapped in a system.

The second type of air that can be trapped in a hydronic system is called ***dissolved air***. This is air that is trapped between molecules of the circulating water. Air scoops or air separators can be installed to reduce the amount of dissolved air in a system.

The third type of air that can be trapped is called ***entrained air***, which consists of small air bubbles that travel along with the circulating water. Entrained air can be removed with air scoops and air separators as well.

Water's ability to hold dissolved oxygen is inversely proportional to its temperature and directly proportional to its pressure. In other words, water at a colder temperature or a higher pressure can hold more dissolved oxygen than water at a warmer temperature or



King Electrical Mfg. Co.

Figure 39-20. A kickspace fan convector is typically mounted in a wall just above floor level and covered with a grille to look like a regular vent.

Copyright Goodheart-Willcox Co., Inc. 2017

lower pressure. As the temperature of water is increased or as the water pressure is reduced, dissolved oxygen in the water bubbles out and becomes free or entrained air. Air separators and air scoops are typically placed downstream from the boiler and upstream from the circulating pump. At this location, the circulating water has a relatively high temperature and low pressure, improving the ability of an air separator or air scoop to remove dissolved oxygen.

Air vents are float-operated valves that allow air to escape from a system while preventing water from leaking out and outside air from coming in. As air collects in the float chamber, the float drops, opening the valve and allowing air to escape out of the system. As the air escapes, water refills the float chamber, closing the valve. See **Figure 39-22**.

Air vents are installed at high points in a hydronic system where large pockets of air are likely to form, such as at the top of vertical piping. They are also installed on top of air scoops and air separators to vent the air separated by those devices.

Air scoops have a series of deflectors that create turbulence in the flow of water. This turbulence causes oxygen in the water to form tiny bubbles, which adhere to the deflectors. As more and more bubbles are formed, they begin to merge, forming larger bubbles that rise to the top of the chamber. The deflectors also catch any entrained air in the water flow and deflect it upward to the top of the chamber. See **Figure 39-23**.

Air separators work on essentially the same principle as air scoops. Air separators typically contain a wire mesh element, which creates a swirling motion in the circulating water. This agitation causes oxygen in the water to form tiny bubbles, which cling to the wire mesh. As more bubbles are collected, they merge together and form larger bubbles, which break free of the mesh and rise to the top of the chamber, where they are vented. See **Figure 39-24**.

When air is removed from a hydronic system, makeup water is added to the system to fill the space. This water contains dissolved oxygen plus some corrosive chemicals. Most hydronic systems are set up so that the makeup water passes through an air separator before it is circulated through the system.

39.2 Hydronic System Designs

Hydronic systems can be designed in a variety of ways to meet specific heating needs. A system can use heated water or steam as the convection medium, and boilers can be operated using gas or oil as the heat source. In addition, hydronic systems can vary in the way piping is configured. Most hydronic systems are closed loops, meaning that water in the system flows from the boiler, through the terminal units, and back to the boiler through a loop of piping that is completely sealed from atmospheric pressure. If the system is open to atmospheric pressure at any point, it is considered an open-loop system.

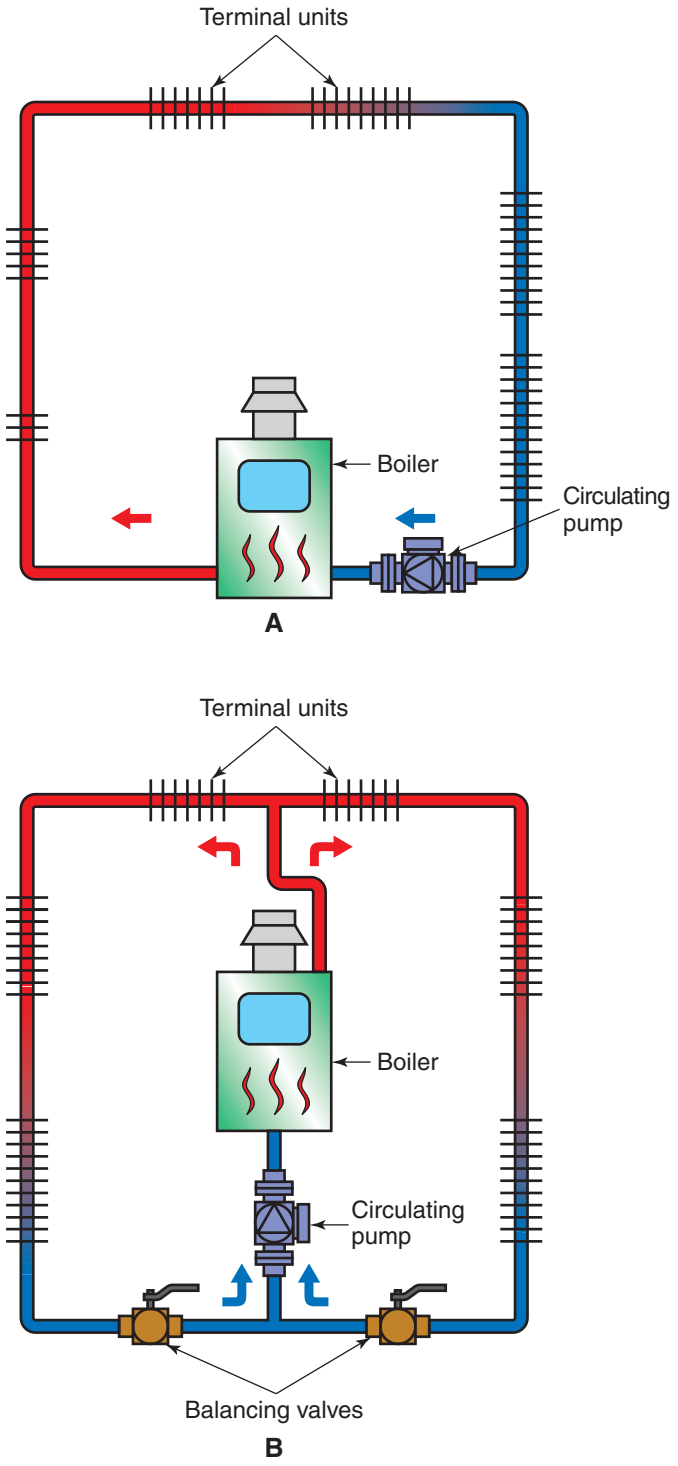
39.2.1 Series Loop Systems

A ***series loop hydronic system*** is designed so that all of the circulating water passes through each component in the system before returning to the boiler. Series loop systems are typically equipped with baseboard terminal units. As the water passes through each terminal unit in the system, the water's temperature is reduced. In order to compensate for the dropping temperature of the water, each successive terminal unit in the system must be larger than the previous unit, **Figure 39-25A**.

Large systems can be divided into two loops for improved efficiency. Splitting a large, single loop into two smaller loops reduces the overall distance that the circulating water must travel and the number of components it passes through. As a result, the overall temperature drop in the circulating water is reduced. In a split series loop, each loop receives some of the hot water from the boiler. Balancing valves in the return piping for each loop can be adjusted to change the ratio at which water is distributed between the two loops, **Figure 39-25B**.



Goodheart-Willcox Publisher

Figure 39-25. In a series loop system, all of the circulating water must pass through each of the terminal units in the loop. A—Single series loop. B—Split series loop.

39.2.2 One-Pipe Systems

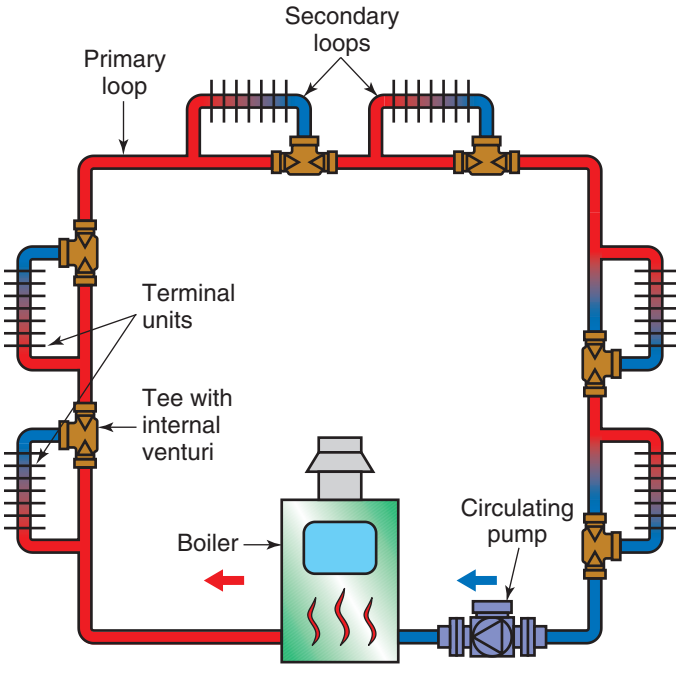
In a ***one-pipe hydronic system***, as in a series loop system, a single pipe supplies hot water from the boiler and carries the return water back to the boiler. However,

Copyright Goodheart-Willcox Co., Inc. 2017

unlike a series loop system, the terminal units in a one-pipe system are on branch circuits, called secondary loops. This means that all of the water flows through the primary loop, but not all of the water flows through each terminal unit, **Figure 39-26**.

A low pressure created in each secondary loop allows a portion of the circulating water to be diverted from the primary loop (also called the main loop). This diverted water flows through the secondary loop and then back to the primary loop. Low pressure is created in each secondary loop by connecting the return side of each terminal unit to the primary loop with a tee that has an internal venturi. The venturi restricts flow through the primary loop at that point, which creates a low pressure on the return side of the terminal unit. As a result, some of the water flows straight through the primary loop while the remainder is diverted through the secondary loop and terminal unit. The supply side of each terminal unit is connected to the primary loop by a standard tee fitting.

Since each successive terminal unit is receiving a portion of the return water from the previous terminal unit, the water supplied to each successive terminal unit is slightly cooler than the water supplied to the previous one. However, since not all of the circulating water passes through every terminal unit, the progressive temperature drop in the water is less than it would be in a series loop system.



Goodheart-Willcox Publisher

Figure 39-26. In a one-pipe system, tees equipped with an internal venturi create a low pressure on the return side of each terminal unit. This causes some of the water to be diverted through the terminal unit while the rest flows through the primary loop.

39.2.3 Two-Pipe Systems

Most hydronic systems are two-pipe systems. In a ***two-pipe hydronic system***, one pipe supplies hot water from the boiler to the terminal units. Another pipe carries return water from the terminal units back to the boiler. Since the supply and return pipes are completely separate, the temperature of the water supplied to all terminal units is essentially the same. This design eliminates the progressive temperature drop that occurs in series loop and one-pipe systems. A more consistent heat is available at the terminal units of a two-pipe system than the other arrangements available.

There are two types of two-pipe systems: direct return and reverse return. In a ***direct return hydronic system***, the water is returned to the boiler along essentially the same path it followed when it was supplied to the terminal unit. The terminal unit that is closest to the boiler has the shortest length of supply piping and also the shortest length of return piping. The terminal unit that is farthest away from the boiler has the longest length of supply piping and the longest length of return piping. See **Figure 39-27A**.

Due to friction, the pressure drop is greater in the longer branches. As a result, water flows at a different rate through each branch. This requires the system to be balanced.

In a ***reverse return hydronic system***, the terminal unit that is closest to the boiler has the shortest length of supply piping but the longest length of return piping. The terminal unit that is farthest from the boiler has the longest length of supply piping, but the shortest length of return piping. As a result, all branches of the system are approximately the same length. Because all branches are equal lengths, they have approximately equal pressure drops, and water flows at the same rate through each branch. Very little adjustment is needed to balance such a system, **Figure 39-27B**.

39.2.4 Zoned Systems

In many commercial and industrial buildings, it is desirable to maintain different temperatures in different rooms or areas. This is also desirable in some homes. For instance, the bedrooms may be kept at a different temperature than the living room, or the laundry room may be kept at a different temperature than the kitchen. Individual temperature control in different spaces is made possible by splitting a hydronic system into different zones. Each zone has its own piping branch, terminal units, zone valve, and room thermostat, **Figure 39-28**.

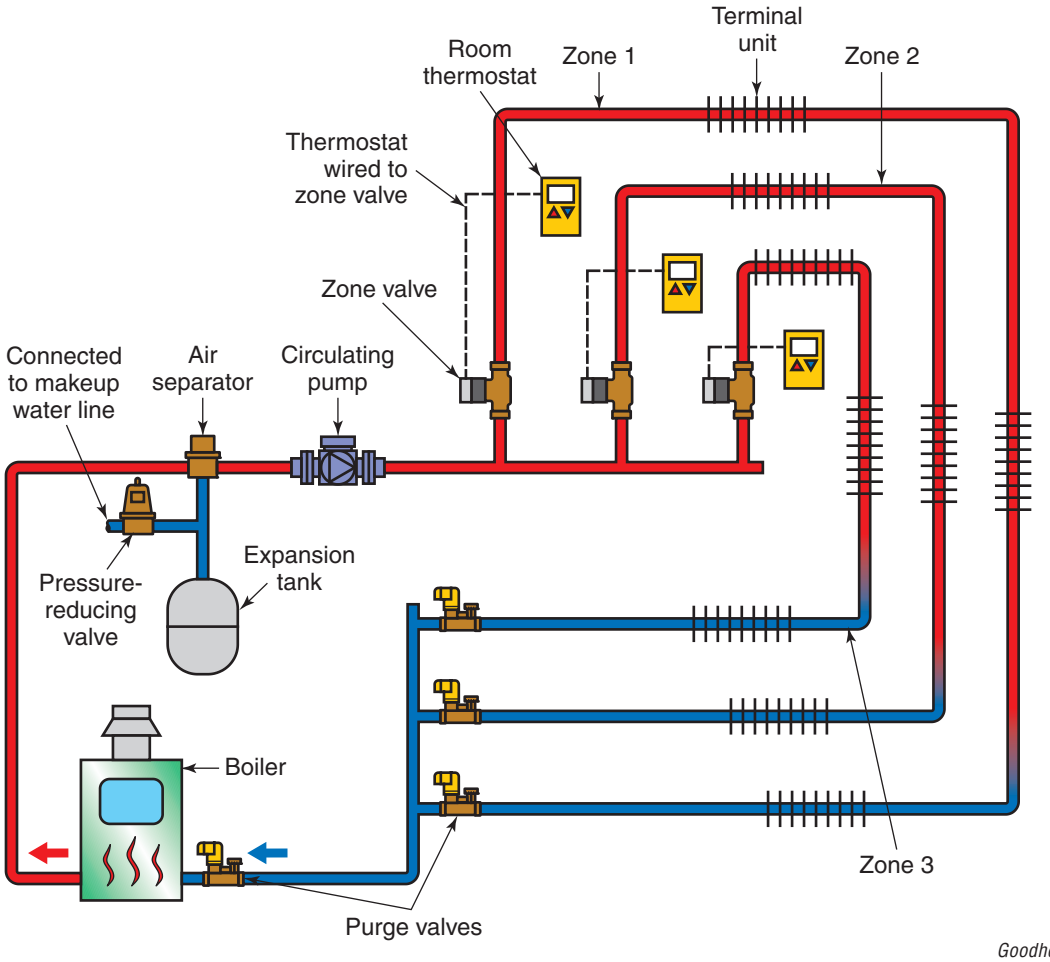
Goodheart-Willcox Publisher

Figure 39-27. A two-pipe system has a supply pipe and a return pipe. The water delivered to each terminal unit is approximately the same temperature. A—Direct return hydronic system. B—Reverse return hydronic system.



Goodheart-Willcox Publisher

Figure 39-28. A hydronic system with three zones, each of which has its own zone valve, terminal unit, and room thermostat.

Copyright Goodheart-Willcox Co., Inc. 2017

The temperature in each zone can be adjusted using a room thermostat and a zone valve. A ***zone valve***, also called a *zone control valve*, is a thermostatically operated valve that regulates the flow of heated water through a zone based on the voltage signal applied to it. A zone valve's actuator has wiring that connects to a room thermostat, **Figure 39-29**.

When the thermostat senses that a zone's control point is below its set point, it sends a signal for heat that causes the actuator to open a solenoid or plunger inside the valve body, allowing heated water to flow through the zone. If a zone has its own circulating pump, the zone valve may also close a switch that starts the pump to circulate heated water through the zone. After the zone's temperature rises above the set point, the thermostat closes the zone valve or slows down the circulating pump to reduce water flow through the zone. The result is that the appropriate amount of hot water enters the terminal units to maintain the set point temperature in each zone, **Figure 39-30**.

39.2.5 Radiant Hydronic Systems

Radiant hydronic systems are similar to standard hot-water hydronic systems in that hot water is circulated through a network of pipes. However, the piping in a radiant hydronic system is typically enclosed in walls or floors, completely out of sight. The piping in a traditional hydronic system connects to external terminal units in the conditioned spaces. Radiant hydronic systems also circulate water at a lower temperature than traditional hydronic systems.

Figure 39-29. The actuator on a zone valve opens and closes the valve when it receives a voltage signal from a room thermostat.

Bosch Thermotechnology Corp.

Figure 39-30. Modern, smart, programmable room thermostats can display indoor temperature, outdoor temperature, desired set point, system status, and energy consumption levels.

Whereas traditional hydronic systems use copper water tubing, radiant hydronic systems often use different types of tubing. This tubing may be made from cross-linked polyethylene (PEX), other plastics, and composite material, **Figure 39-31**.

Tubing made from plastic or composite material must have an oxygen barrier to be used in a radiant hydronic system. The barrier prevents oxygen from being absorbed through the tubing, which can rapidly corrode the boiler. Red PEX tubing is typically used

Composite Tubing **Plastic Tubing**

Danfoss

Figure 39-31. Radiant heating system tubing can be made from plastic or composite material.

Copyright Goodheart-Willcox Co., Inc. 2017

for hot water, and blue PEX tubing is typically used for cold water. There are no physical differences between the different colors. They are only used to indicate the temperature of the water in the tubing.

In radiant hydronic systems, a boiler heats up water, and a pump circulates the hot water through a network of plastic tubing. Separate radiant heat zones are fed by a manifold that distributes the flow of warm water to the individual loops of tubing that comprise each zone. The loops of tubing warm the surfaces adjacent to them, usually floors or walls, by conduction. The warmed floors or walls then radiate the heat into the conditioned space, **Figure 39-32**.

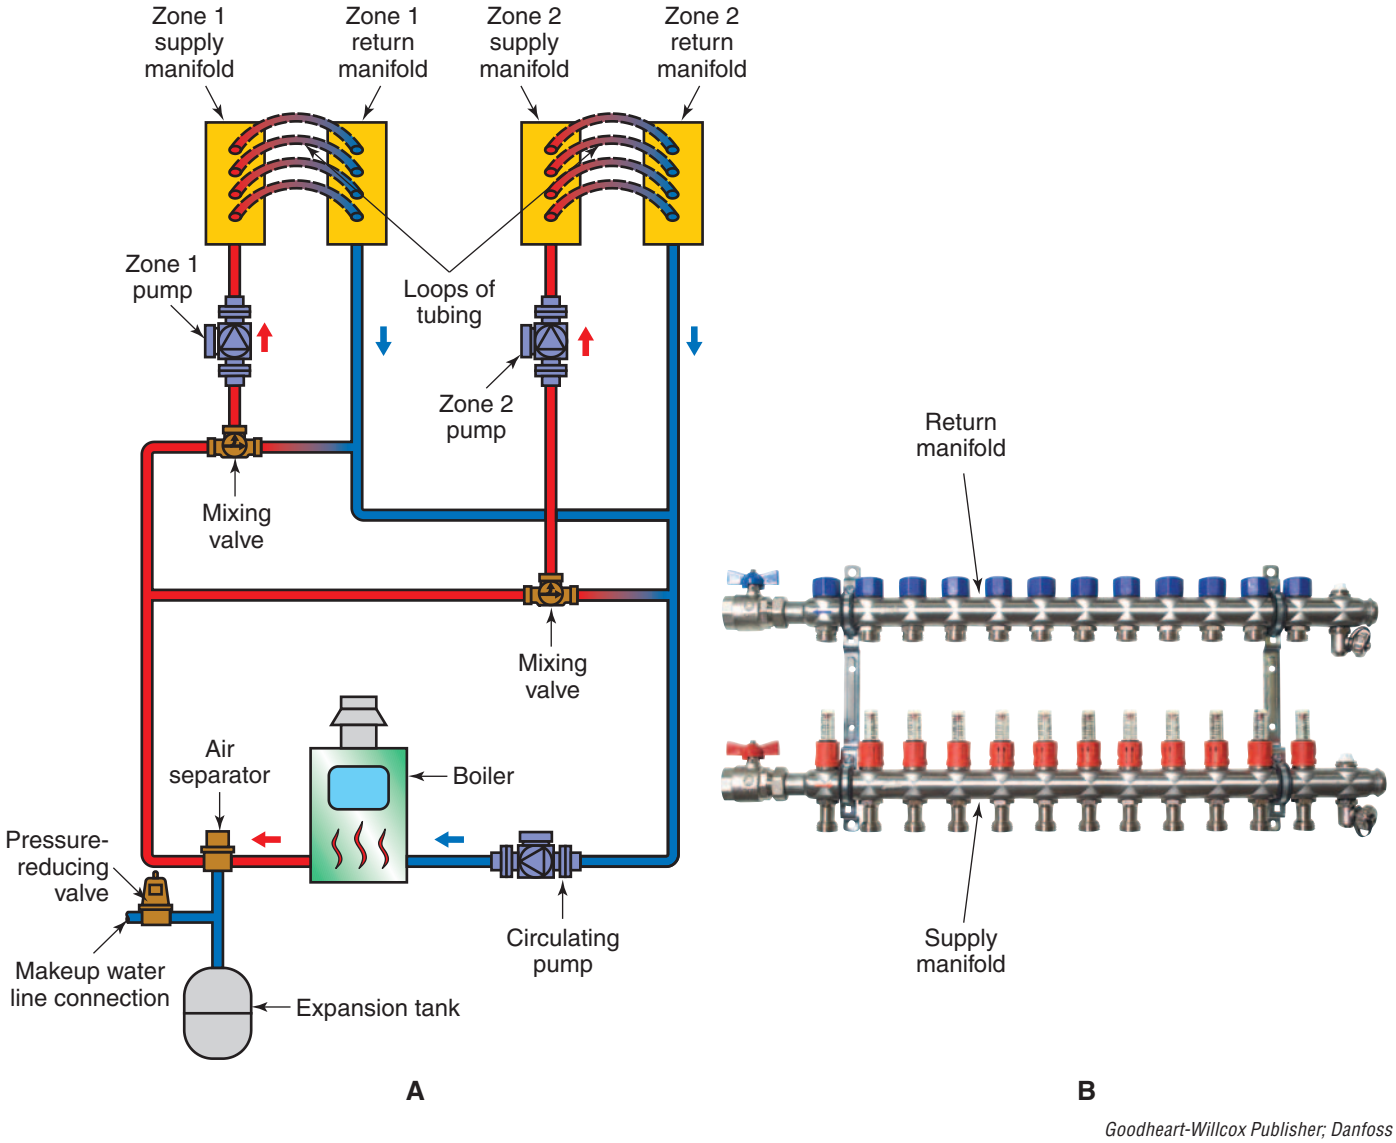
Code Alert

Radiant Hydronic Systems

The installation of radiant hydronic systems is typically regulated by local building codes. The codes specify proper installation methods for metal framing, wood framing, and concrete.

Underfloor Radiant Hydronic Systems

Underfloor radiant hydronic systems can be classified as wet or dry. ***Dry underfloor radiant hydronic systems*** consist of tubing attached to a wood floor or subfloor. ***Wet underfloor radiant hydronic systems*** consist



Goodheart-Willcox Publisher; Danfoss

Figure 39-32. Radiant hydronic systems have a supply manifold that divides water flow evenly among the loops of tubing. A return manifold recombines the return flows from the loops into a single return flow. A—A radiant hydronic system with two zones. The loops in the drawing have been shortened for illustrative effect. B—A supply manifold and return manifold.

of tubing embedded in concrete. Because a wet underfloor radiant heating system is embedded in a concrete slab, it must be installed before the slab is poured.

Techniques used to install these two types of underfloor radiant hydronic systems include the following:

- Tubing is installed over wood subfloor and covered with floor underlayment and flooring, which is a dry method of installation known as the *sleeper method*, **Figure 39-33**.
- Tubing is attached or suspended to the underside of the subfloor and, in some cases, placed in heat transfer plates, which is another dry method of installation, **Figure 39-34**.
- Special grooved panels are installed on top of the subfloor, and the tubing is fitted into the grooves in the panels. The flooring can be installed directly over the top of the panels. See **Figure 39-35**.
- Tubing is tied to a reinforcing wire mesh before a concrete slab is poured, which is a method of wet installation, **Figure 39-36**.
- Tubing is attached to a guide panel on top of the subfloor or slab and then covered with a relatively thin layer of concrete, which is another method of wet installation, **Figure 39-37**.

Thinking Green

Heating Large Spaces

If heating must be provided outdoors or in a large, open space, radiant heat is the most efficient and effective heating method. Since radiant heating warms occupants and objects directly, less energy is required than would be required to heat a similar space with convection heating.

39.2.6 Combined Heating and Cooling Systems

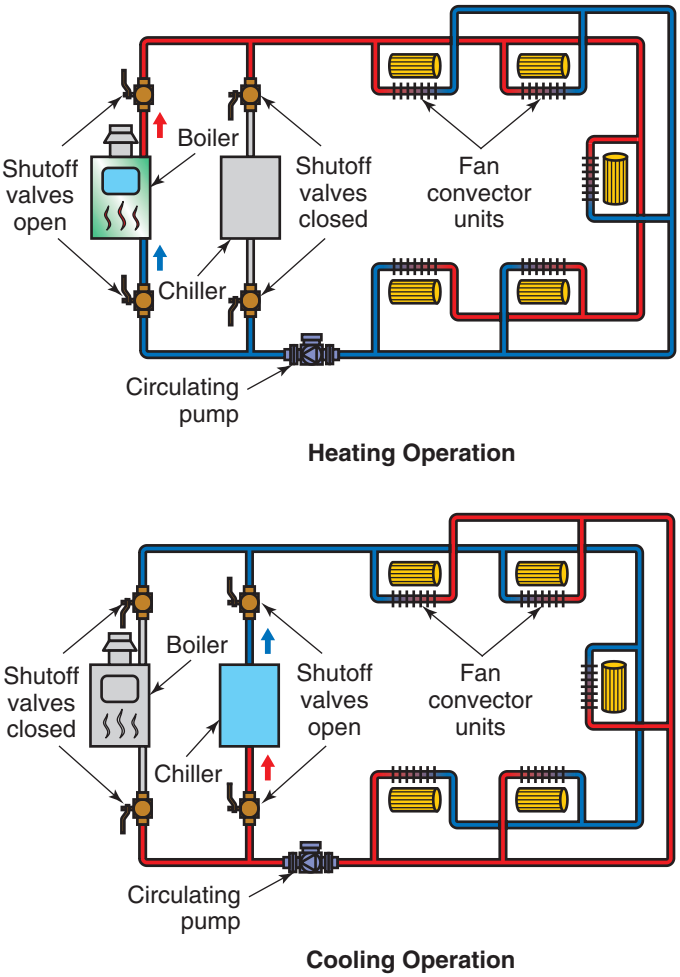
Many hydronic systems in commercial buildings have both boilers and chillers. Depending on the system design and the heating and cooling demands, these systems can provide either hot water or cool water to the terminal units. The heating and cooling systems may be integrated, or they may be essentially separate systems.

A two-pipe system uses the same supply pipe to provide hot water from the boiler and cool water from the chiller to the terminal units. Because of the shared piping, the heating and cooling systems cannot function simultaneously. Shutoff valves are used to isolate the chiller before the boiler is put into operation or to isolate the boiler before the chiller is put into operation. See **Figure 39-38**.

Terminal units used in a two-pipe system with a boiler and a chiller must be designed for both heating and cooling applications. These units are typically fan convectors with provisions for trapping and draining condensate.

A three-pipe system has separate supply pipes for carrying hot and cold water to the terminal units. The third pipe is a return pipe for either. Three-pipe hydronic systems are no longer widely used.

A four-pipe system has separate supply pipes for hot and cold water and also separate return pipes for hot and cold water. This arrangement allows the heating and cooling systems to operate simultaneously, which is useful in fall and spring when certain spaces may need to be warmed and others may need to be cooled, **Figure 39-39**.



Goodheart-Willcox Publisher

Figure 39-38. A two-pipe heating and cooling system must be changed over between heating and cooling operations. Isolating either the boiler or chiller may be done manually or automatically.

In some four-pipe systems, a single terminal unit is used rather than two separate units. The terminal units in these systems contain both heating and cooling coils. In other four-pipe systems, separate terminal units are used for heating and cooling. See **Figure 39-40**.

39.2.7 Steam Heating Systems

A ***steam heating system*** is a type of hydronic system in which water is heated into steam and piped to radiators in conditioned spaces. The steam releases heat as it condenses back into a liquid inside the radiator and returns to the boiler for reheating.

A boiler heats the steam to 212°F (100°C) or higher, except in vacuum systems, which are rare. As steam releases its heat to the conditioned space, the steam condenses. The condensed water, being heavier, returns

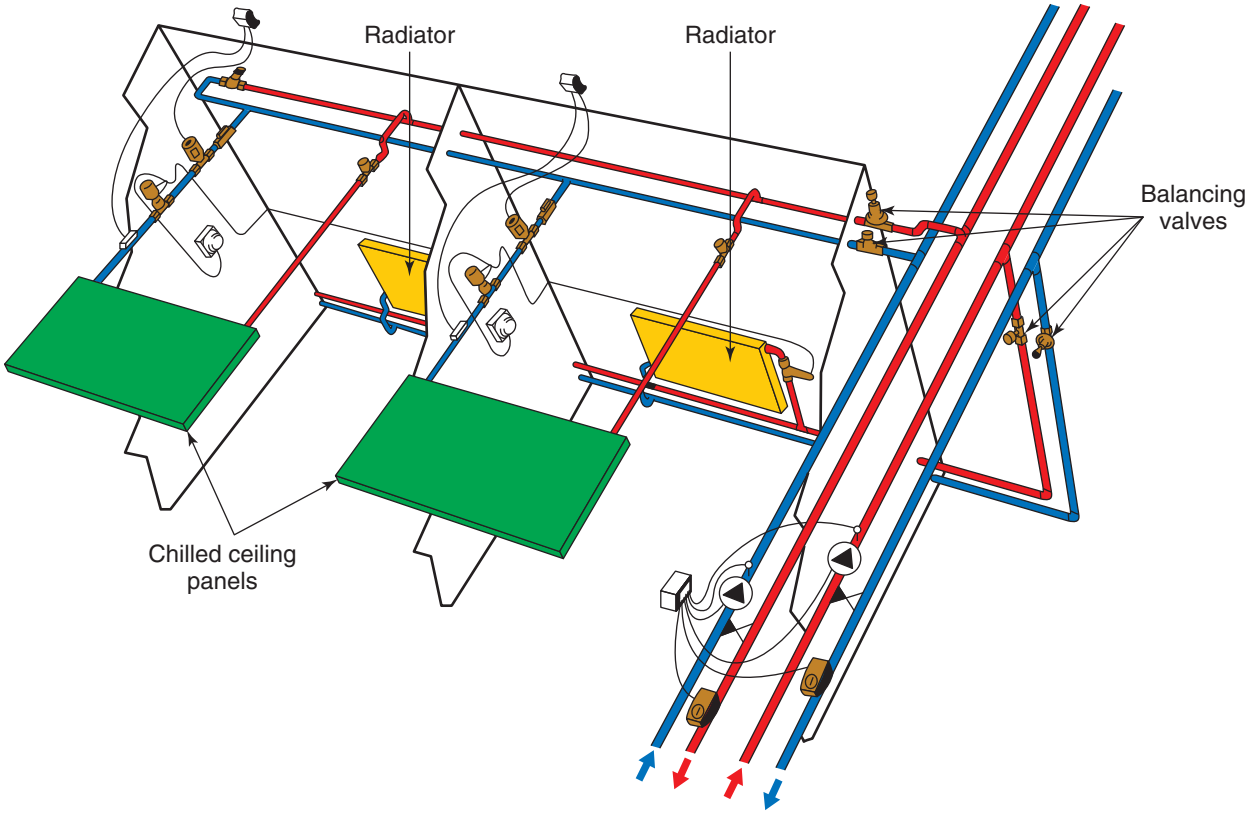
Goodheart-Willcox Publisher

Figure 39-39. In a four-pipe heating and cooling system, no changeover is needed because the hot water and cold water are supplied and returned in separate pipes. This design allows the heating and cooling portions of the system to run simultaneously.



Danfoss

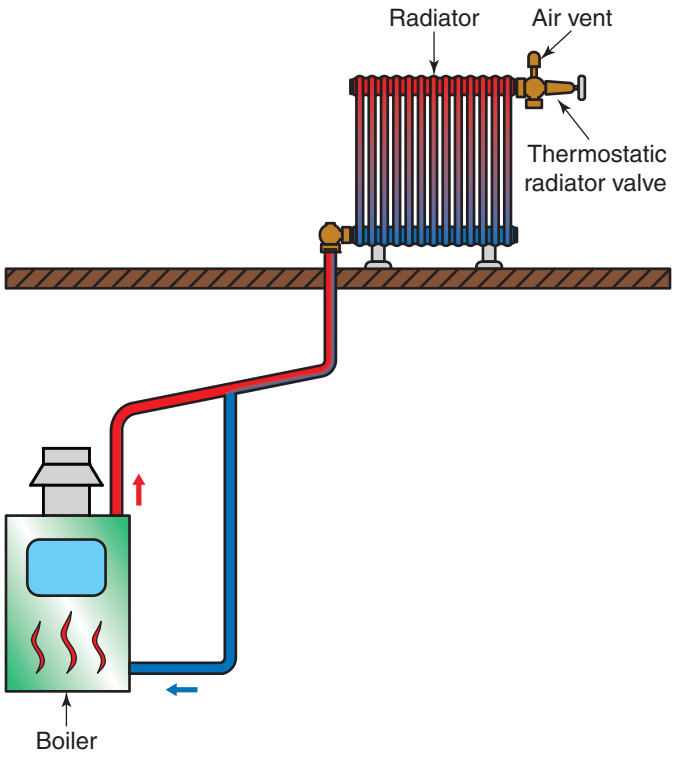
Figure 39-40. A four-pipe system with chilled ceiling panels that provide cooling and wall panel radiators that provide heat.

Copyright Goodheart-Willcox Co., Inc. 2017

to the boiler. The steam releases around 1000 Btu for each pound that condenses. Two basic steam heating systems in use are the one-pipe system and the two-pipe system.

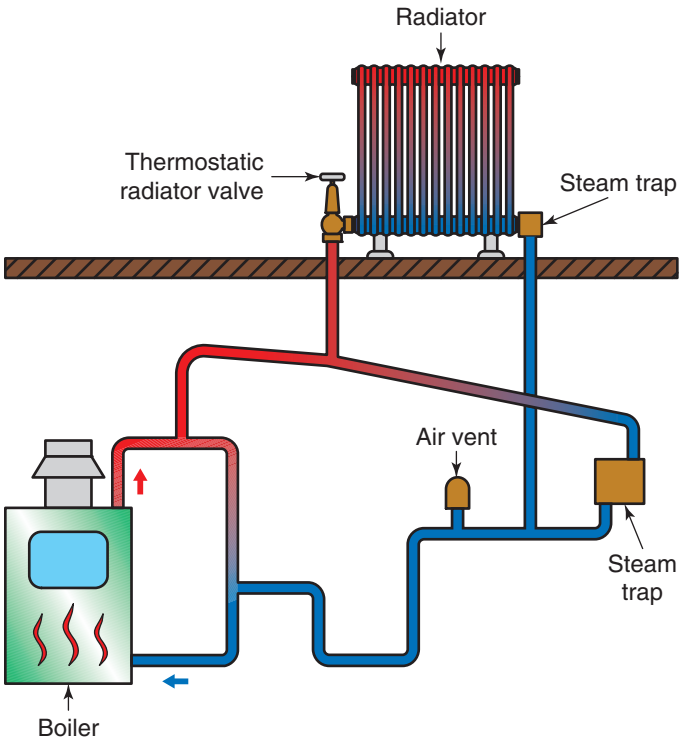
The one-pipe steam system uses a single pipe to carry steam to the radiators and return the condensed water to the boiler. In a one-pipe steam system, air vents are placed at the high points in the system and other places where air pockets are likely to form. The air vents allow air to escape the system so steam can travel to the upper parts of the piping. When steam reaches the vents, they heat up and close, preventing the steam from escaping. As the steam in the radiator gives off its heat, it condenses back to liquid water. The water flows back through the piping to the boiler due to gravity. See **Figure 39-41**.

A two-pipe steam system uses one pipe to carry steam to the radiator and another pipe to return the condensed water to the boiler. A two-pipe steam system has steam traps in the return pipe that block the flow of steam but allow condensed water to pass. See **Figure 39-42**. For some systems in which the boiler is located above some of the piping, a pump must be used to return the water to the boiler.



Goodheart-Willcox Publisher

Figure 39-41. In a one-pipe steam heating system, the condensed water drains back to the boiler through the same pipe that supplies the steam. Note that the piping slopes toward the boiler.



Goodheart-Willcox Publisher

Figure 39-42. In a two-pipe steam heating system, steam is supplied in one pipe, and the condensed water returns to the boiler through a different pipe. The steam supply pipe slopes toward the return pipe, and steam traps prevent steam from passing, but allow water to drain back.

For domestic applications, steam heating systems operate at low pressures or at a partial vacuum. The units are tested at 50 psig (345 kPa) for safety purposes. Commercial and industrial systems operate at progressively higher pressures that approach 1000 psig (7000 kPa). Steam boilers are typically equipped with pressure-relief valves, a water level sight glass, a pressure gauge, and a temperature gauge, **Figure 39-43**.

39.2.8 Oil-Fired Boilers

An oil-fired boiler has a combustion chamber that is lined with material that is unaffected by high temperatures, called refractory material. Fuel oil is stored in a tank, which may be located outdoors, underground, or in the basement of a building. Fuel oil is burned in a gun-type burner, **Figure 39-44**.

When the boiler receives the signal to fire, fuel oil is pumped into the burner nozzle under a pressure of about 100 psig (700 kPa). This atomizes the fuel and causes it to spray out of the nozzle. At the same time, power is supplied to a high-voltage transformer connected to two electrodes in the burner nozzle. Sparks

PB Heat, LLC

Figure 39-43. A typical steam boiler is equipped with a variety of safety, limit, and operational controls.

jump across the spark gap just at the edge of the burner nozzle outlet. The sparks ignite the atomized fuel spray, creating a flame in the combustion chamber, **Figure 39-45**.

Heat from the combustion chamber is conducted through the boiler wall into the water. The combustion gases from the burning fuel flow through the stack into the flue. A stack thermostat senses the temperature of the gases leaving the furnace. If the atomized fuel is not ignited after a few seconds of fuel pump operation, the pump will stop, and a manual reset will have to be operated before it will cycle again. An automatic draft regulator helps maintain a constant pressure in the combustion chamber.

A room thermostat controls the circulating pump. The pump circulates the warm water through the terminal units and returns it to the boiler. The boiler's water temperature is controlled by a device on top of the boiler called a tridicator, which can sense both temperature and pressure. A tridicator indicates both pressure and temperature of the water or steam in a boiler. When the water temperature in a boiler drops below

Figure 39-45. Diagram of an oil-fired boiler in operation.

the required level, the tridicator signals the burner to turn on. It also shuts the burner off when the water temperature reaches the desired level.

All boilers have a ***high-limit control***. This control is often attached to the boiler's combustion chamber. However, it may also be installed in the boiler's warm-water outlet. The high-limit control automatically shuts off the fuel if the water temperature or pressure gets too high. A pressure-relief valve is also mounted on the boiler, which opens automatically if the pressure inside the boiler exceeds the safe limit. An expansion tank is used to hold expanding (warm) and contracting (cool) water.

39.2.9 Gas-Fired Boilers

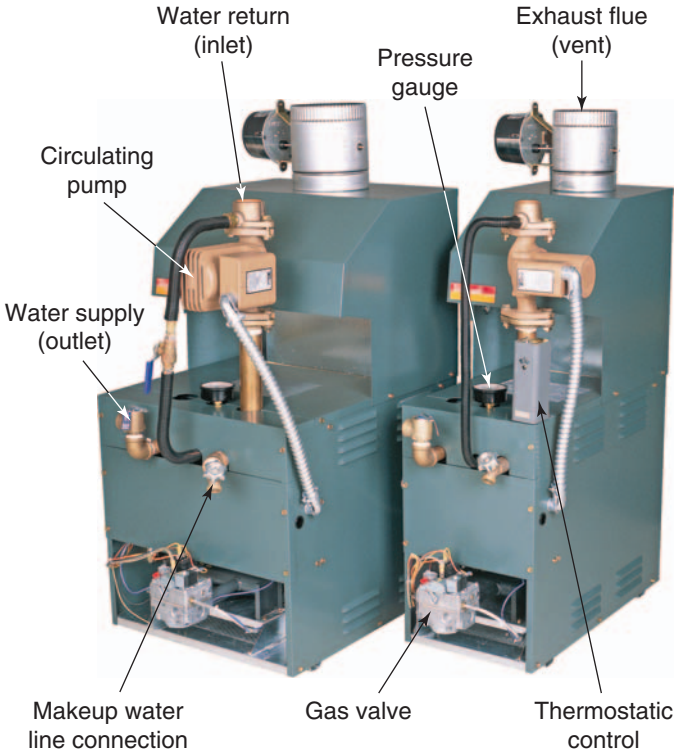
A gas-fired boiler burns fuel gas as a means of producing heat for boiling water. Older models used a low, constant pressure gas and an atmospheric burner. Newer, high-efficiency models are condensing boilers that extract as much heat out of combustion gas as possible. Gas-fired boilers can be identified by their connection to a gas line and the presence of gas burning components. A gas valve and manifold are good indicators of a gas-fired boiler, **Figure 39-46**.

A pressure regulator ensures that the gas supplied to the burner flows at a constant, preset pressure. When

Copyright Goodheart-Willcox Co., Inc. 2017

gas is supplied to the burner, a pilot light or electronic ignition system ignites the burner. The heat generated in the combustion chamber is conducted through the boiler wall and into the water, and the combustion gases flow through the stack into the flue. An air break or draft diverter installed in the stack helps maintain a constant pressure in the combustion chamber, **Figure 39-47**.

Water temperature in the boiler is controlled by a tridicator located at the top of the boiler. The tridicator turns the burner on when the water temperature drops below the required level and also turns the burner off when the temperature rises to the proper level. A high-limit control is attached to the warm-water outlet of the boiler. The high-limit control automatically shuts off the gas if the water temperature or pressure gets too high. The system also has a pressure-relief valve. This valve prevents the buildup of dangerously high pressure in the boiler. An expansion tank is used to hold expanding (warm) and contracting (cool) water.



Raypak, Inc.

Figure 39-46. Two conventional gas-fired boilers that can operate with return water temperatures as low as 105°F before combustion gases start condensing.

39.3 Hydronic System Controls

Water level, temperature, and flow are three variables that are regulated by a hydronic system's controls. Floats or sensors monitor the volume of water in a hydronic system and feed more water to the system when the water level is too low. Thermostatic controls are used to maintain the proper water temperature in the system and to adjust water temperature or flow to keep the conditioned space at the desired temperature. Flow switches monitor flow through the system. Control valves shut down or bypass parts of the system to stop water flow.

39.3.1 Low-Water Cutoff

A ***low-water cutoff (LWCO)*** is a control that ensures that a hydronic system operates only when it contains the proper amount of water. A low-water cutoff may operate a makeup water valve to add more water to the system if the water level gets low. Low-water cutoffs also shut down the system if the water level drops too low.

A low-water cutoff is generally a switch that is turned on and off by a float device or is triggered by sensor probes. A float-type LWCO operates in two stages. As the water level drops, the float also drops. When the water level drops below a specific level, the float switch turns on the makeup water pump or opens the makeup water valve to add more water to the system. When the float rises back up to the correct level, the switch turns off, and no more water is added. However, if the float drops to an even lower point, the float switch cuts off the fuel supply to the boiler and deactivates the pumps, **Figure 39-48**.

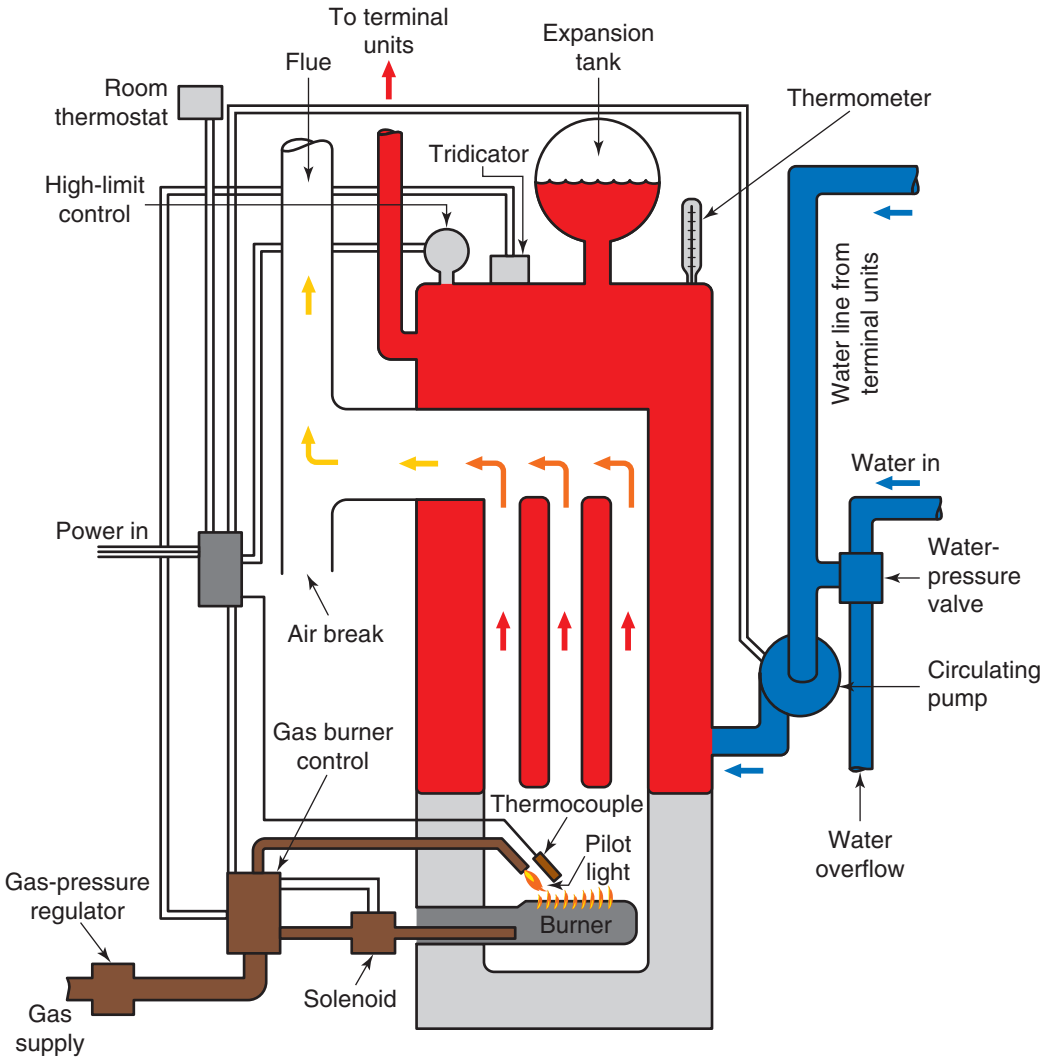
Some low-water cutoffs use probes instead of a float. This type of LWCO has two electrodes that are immersed in the water. A small current flowing in the water between the two electrodes energizes a holding relay, allowing the boiler to run. If the water level falls below the upper electrode, the current flow between the electrodes stops, which causes the relay to open and the system to shut down. Some probe-type LWCOs have a third electrode so that the control can be used to add makeup water to the system or to shut down the system, depending on the water level.

Caution

Low-Water Cutoffs

Excessive air or contaminants in boiler water can result in foaming, which can cause a low-water cutoff to malfunction. For this reason, a technician should ensure that a hydronic system is cleaned properly before putting it into service and that as much air is removed from the water as possible.

Copyright Goodheart-Willcox Co., Inc. 2017



Goodheart-Willcox Publisher

Figure 39-47. A gas-fired boiler uses an atmospheric gas burner as the source of heat.

39.3.2 Flow Switch

In order for a hydronic system to function efficiently, proper water flow must be maintained. ***Flow switches*** are used to shut down a hydronic system or bypass parts of it when there is inadequate flow. A hot-water system equipped with a flow switch is shown in **Figure 39-49**. If the water flow ceases, the flow switch opens the electrical circuit and shuts off the burner. Some boilers have a recirculation circuit that helps to maintain a more constant water temperature in the boiler. If water flow stops in this circuit, the flow switch will also shut down the system.

39.3.3 Aquastat

An ***aquastat*** measures the temperature of the boiler water and turns the burner or heating element on and off as needed to maintain the preset temperature. Many aquastats have a built-in safety function that shuts off the burner or heating element if the water temperature in the boiler exceeds the safe operating limit. The aquastat may need to be reset manually before the boiler can be operated again.

An aquastat also sets a boiler's low operating temperature and differential. These settings determine a boiler's operating temperature range. The aquastat turns on the burner or heating element if the boiler's water temperature drops below the operating temperature range and turns it off again when the temperature exceeds the operating temperature range, **Figure 39-50**.

39.3.4 Zone Controls

While an aquastat maintains the proper water temperature in a boiler, a variety of thermostatic controls

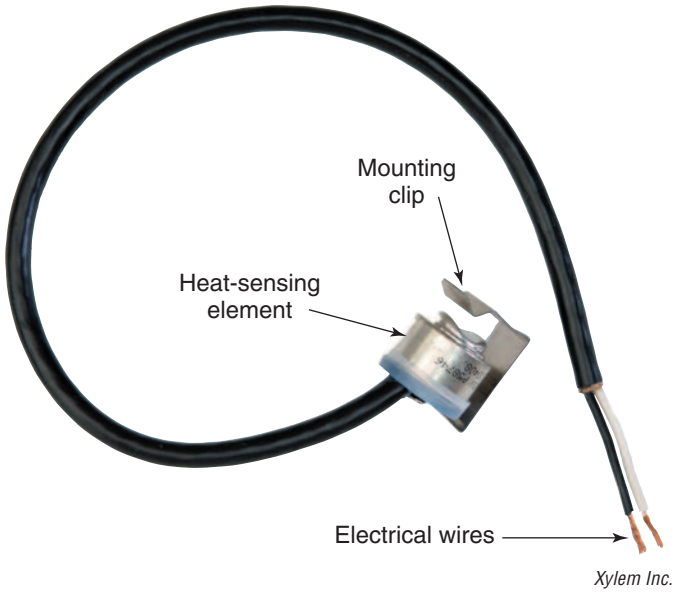
Figure 39-49. A flow switch located in the return line is wired to the mixing valve and the burner to shut down the system if flow stops. The dashed lines indicate where a flow switch would be located in a boiler with a recirculation circuit.



Xylem Inc.

Figure 39-50. An aquastat's heat sensing element opens and closes an electrical contact used to control boiler system operation.

can be used to maintain the desired temperature in a certain area of a conditioned space. One type of thermostatic control, called a room thermostat, adjusts room temperature by regulating the flow of heated water through a single zone of a system's tubing. In a series loop system, the room thermostat turns the circulating pump on and off as needed to maintain the desired temperature in a single-zone conditioned space.

Copyright Goodheart-Willcox Co., Inc. 2017

In one-pipe and two-pipe systems, reduced flow through one terminal unit does not result in reduced flow through the other terminal units, as would be the case in a series loop. This means that while a main room thermostat can be used to set an overall heat level for the building, individual thermostatic radiator valves should be installed to control flow through each individual terminal unit for zone control. This allows greater control of heat in specific areas, **Figure 39-51**.

For zoned systems, separate room thermostats can be installed in each zone. Each thermostat provides an input to a temperature controller, which in turn controls the operation of the circulating pumps and zone valves to regulate water flow through the individual zones. The system can also be set up so that the circulating pump operates continuously and the zone valves open and close as needed.

Figure 39-51. Thermostatic radiator valves. A—Thermostatic radiator valve installed on a radiator. B—Thermostatic radiator valve with a remote sensor for wall mounting.

39.3.5 Outdoor Reset Control

The temperature of the boiler water is normally set by an aquastat and remains constant unless the boiler temperature set point is changed. The temperature of the water in the boiler is typically set to provide efficient heating on the coldest days of the season. However, on relatively warm days, far less heat is lost from the conditioned spaces. As a result, the system cycles on and off relatively quickly. Fuel is wasted maintaining a higher boiler temperature than is needed for efficient heating, and wear and tear on the system increases because of short cycling.

An ***outdoor reset control*** is an auxiliary control that modifies the operating temperature range of a hydronic system based on the difference between outdoor and indoor temperatures. As the difference between indoor and outdoor temperatures decreases, the outdoor reset control lowers the operating temperature of the system. This provides more gradual heating on relatively warm days and prevents short cycling of the system.

Pro Tip

Outdoor Reset Controls

The maximum temperature setting on an outdoor reset control must be set lower than the temperature setting on the boiler's high-limit control. This prevents the high-limit control from interfering with the normal operation of the outdoor reset control.

39.3.6 Indoor Reset Control

An ***indoor reset control*** adjusts boiler temperature to match the heating load. It does this by monitoring the cycle time required to satisfy a call for heat. If the system runs an excessively long time to satisfy a call for heat, the indoor reset control increases the boiler water temperature. If the system is short cycling, the indoor reset control lowers the boiler water temperature.

Caution

Indoor and Outdoor Reset Controls

Never wire an indoor or outdoor reset control in such a way that it bypasses the boiler's high-limit control.

Copyright Goodheart-Willcox Co., Inc. 2017

39.3.7 Hydronic System Operating Sequences

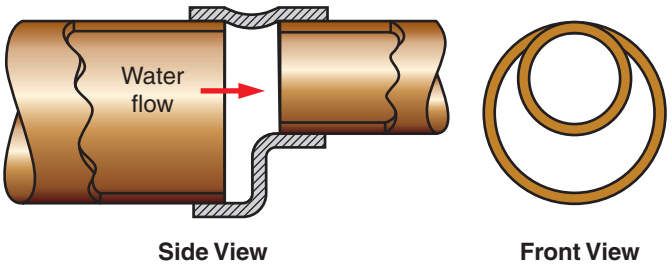
Hydronic system operation can be controlled in four basic ways:

- Burner and circulating pump turn on at the same time.
- Burner remains on continuously, and the pump cycles on to move the water when heat is called for.
- Circulating pump operates continuously, and the zone valves open and close to allow water access to zones based on calls for heat.
- Zone valves and circulating pump are cycled on at the same time.

39.4 Hydronic System Installation

All local code requirements must be checked and followed when installing a hydronic system. The boiler for a hydronic system must be mounted level. The top of all sections of tubing must be aligned to prevent air from being trapped at the junctions between tubing of different sizes. Eccentric reducer fittings should be used to join tubing of different sizes. In hot-water hydronic systems, eccentric reducer fittings reduce the danger of air pockets forming where differently sized tubes are joined. An ***eccentric reducer fitting*** is a reducer fitting in which the centerlines of the tubes are offset, **Figure 39-52**.

When installing hydronic systems, be sure to allow for tubing or pipe expansion. A 100′ length of steel pipe lengthens by 3/4″ with every 100°F increase in temperature. A 100′ length of copper tubing lengthens by 1 1/16″ with every 100°F increase in temperature. Where riser (vertical) pipes connect to a horizontal run, install a flexible joint. Also, install an expansion joint at the boiler.



Goodheart-Willcox Publisher

Figure 39-52. By keeping the top of two differently sized tubes aligned, an eccentric reducer fitting eliminates any pockets where air might get trapped.

Code Alert

Hydronic System Tubing and Piping

The acceptable materials, joining methods, and designs for hydronic tubing and piping are specified by local building codes. Codes address such topics as the types of tubing and pipe that can be installed, valve requirements, drainage, pipe support, and installation of embedded piping.

In closed-loop hydronic systems, the hot water coming from the boiler is above atmospheric pressure, which means smaller pipes can be used. The heat load can be based on a 20°F (11°C) temperature differential between the supply water and return water. Typically, water returning to a boiler should be 20°F (11°C) lower in temperature than water leaving the boiler. After installation, hydronic systems must be flushed to remove all dirt. The system must also be tested for leaks as specified by code before it may be operated.

Code Alert

Hydronic System Testing

The International Mechanical Code (IMC) specifies that hydronic piping (excluding that which is used by ground-source heat pumps) must be tested hydrostatically at one-and-one-half times the maximum system design pressure. This test pressure must not be less than 100 psi (689 kPa). This test pressure must be maintained for at least 15 minutes.

Safety Note

Pressure-Relief Valve

A boiler's pressure-relief valve should have a drainpipe attached to it to prevent the boiler from releasing an uncontrolled spray of hot water in the event that the valve opens. Cut the outlet end of the drainpipe at an angle to prevent someone from plugging it or capping it.

39.4.1 Preparing a System for Initial Start-Up

After a hydronic system is installed, it should be checked before it is put into service. The procedure used to check a new boiler is commonly referred to as *boiling out*. The water to be used in the system should be analyzed for hardness, contaminants, and proper pH level. If the water is excessively hard, contains contaminants, or has an improper pH level, it must be properly conditioned for use. Filtering and conditioning the water can reduce particulates and minerals,

Copyright Goodheart-Willcox Co., Inc. 2017

and solutions can be added to the water to adjust the pH level and reduce corrosion.

Fluxes, pipe joint compounds, and cutting oils left over from the installation process can sometimes form gases in a system. Dirt, sand, steel thread chips, solder bits, or sawing and filing chips can erode the system. These contaminants can also clog screens and ruin valves and pump seals.

To prepare a system for its initial start-up, begin by filling the system with water. Add about one pound of trisodium phosphate for every 50 gallons of water. Circulate the solution for about four hours and then drain it out. Clean the screens and refill the system with water. It is then ready to operate. A card should be attached to the boiler so a history of all maintenance and service performed on the system can be recorded. A list of future treatment procedures should be included on the card.

Unless the pump seals leak, avoid treating the water with chemicals. The chemicals may damage seals and valves. Do not use over 300 ppm of chromates or over 500 ppm of nitrites. Organic growth can be controlled using sodium pentachlorophenate; however, it is best to consult a water treatment expert before attempting boiler water treatment.

39.4.2 Balancing a Hydronic System

During the initial start-up of a system, pressure gauges or flow meters are used to determine the rate of water flow, in gallons per minute (gpm), through each balancing valve. Some balancing valves have access ports on either side that allow a technician to check the valve's pressure drop with a pressure gauge. Other balancing valves might have a built-in flowmeter, **Figure 39-53**.

A manufacturer of a balancing valve typically provides a chart that equates the valve's pressure drop to water flow in gallons per minute. A technician should then compare the valve's measured rate of water flow to system specifications and adjust the balancing valve as needed to achieve the correct flow rate. Balancing valves with a memory stop feature make it easy to reestablish the system balance after a seasonal shutdown.

39.4.3 Steam Heating System Installation

Steam heating systems vary with each installation. When radiators are used as the terminal units, the system does not add humidity to the air in the room or filter air in any way. Air circulation results entirely from natural convection, which means separate systems for controlling the humidity and filtering air must be used.

© 2012 Caleffi North America, Inc.

Figure 39-53. Balancing valves with built-in flowmeters.

All steam heating systems must be installed according to applicable codes. As with hot-water boilers, a steam boiler must be mounted level. Radiators must be pitched to ensure that the condensed water drains from the radiator, and the return piping must slope down to the boiler. The piping must be designed to provide for expansion, and air vents must be located at the high points of the system. Each radiator should have an air vent and a steam trap.

Steam traps operate thermostatically based on the temperature difference of fluids passing through them. They open for cool fluid (condensed water) and close for hot fluid (steam). Thus, a steam trap keeps the steam in the radiator but allows condensed water to return to the boiler. There are three types of thermostatic steam traps:

- ***Expansion steam traps*** have an internal material that expands and contracts with temperature change, triggering the steam trap's valve.
- ***Balanced pressure steam traps*** are filled with a mixture of water and mineral spirits. This mixture vaporizes and condenses just below the temperature of steam to trigger the valve.
- ***Bimetal steam traps*** contain two dissimilar metal strips that are bonded together. Temperature changes cause movement in one direction or the other to trigger the valve.

To help maintain a constant temperature within a room and increase the comfort and efficiency of the system, a thermostatic radiator valve should be installed at each radiator. In a two-pipe system, a thermostatic radiator valve should be installed on the supply

Copyright Goodheart-Willcox Co., Inc. 2017

side of the radiator, allowing the valve to regulate the amount of steam that enters the radiator. Refer back to **Figure 39-42**.

For a one-pipe system, the air vent should be installed on the thermostatic radiator valve. By regulating the amount of air leaving the radiator, the valve allows only a certain amount of steam to enter, providing the appropriate amount of heat to the room. Refer back to **Figure 39-41**.

39.5 Troubleshooting and Servicing Hydronic Systems

When properly designed and maintained, hydronic systems can provide many years of reliable heat. However, hydronic systems are more maintenance intensive and more sensitive to neglect than forced-air heating systems. Over time, contaminants and air can get into the system and cause corrosion and problems with valves and other components. Hydronic systems also have many electrical and electronic components, such as circulating pumps and zone valves, that can fail and cause the system to malfunction.

The first step in troubleshooting a hydronic system is to get the facts. Ascertain the history of a system by asking the owner if this is a new problem, a recurring problem, or an old problem and by asking if the system has been serviced recently. Most hydronic system problems fall into one of three areas: electrical, venting, or water circulation. The following sections describe some of the maintenance, troubleshooting, and repair procedures needed to keep a hydronic system operating properly.

39.5.1 Boiler Problems

Electrical problems in a boiler may be the most troublesome because the boiler is part of a larger system and is wired in the field by a technician during installation. Begin by checking for power at the boiler. A multimeter can be used to determine if the service switch has power and if the wiring is correct. The black lead should be the ungrounded (hot) wire, and the white lead should be the grounded (neutral) wire.

If the boiler will not fire, check the vent pipes and dampers. In order to function properly, a gas-fired or oil-fired boiler must also be able to take in fresh combustion air and vent exhaust gases. Any blockage in the intake and exhaust passages can cause incomplete combustion or boiler failure. Venting problems are often caused by vent restriction or deteriorating vent piping. Visually check the rotation of the damper shaft. If the damper appears operational and the vent piping is unobstructed and in good condition, check the limit and operating controls.

Observe the boiler's start-up sequence. How far into the sequence the boiler gets will be a guide in isolating the source of the problem. Use a multimeter to determine if the rollout and blocked-vent switches are operational. A rollout switch is a safety control that shuts down the boiler if the burner flames "roll out" or travel beyond the combustion chamber. This can happen if the exhaust passages are blocked with soot or if the burner is receiving its combustion air from a source other than the combustion blower. A blocked-vent switch is a safety control that shuts down the boiler if a backdraft condition is detected. If these switches are tripped, look for flue blockages and sources of combustion air. Thermostats are another common source of heating problems. Thermostats may malfunction due to vibration, oxidized contacts, broken wires, or improper temperature settings.

Safety Note

Rollout and Blocked-Vent Switches

If a rollout or blocked-vent switch interrupts boiler operation, it is extremely important that the cause of the interruption be found and corrected before the boiler is put back into operation. The conditions that trip a rollout or blocked-vent switch can result in fatal levels of carbon monoxide entering the building. Never bypass a rollout or blocked-vent switch to put a boiler back into service.

39.5.2 Water Circulation Problems

Water circulation problems affect the transfer of heat. To check the circulation of water through a system, supply power to one of the circulating pumps to establish flow through the boiler. Use a contact thermometer to compare supply and return water temperatures. With the boiler firing and at operating temperature, there should be at least a 20°F (11°C) temperature difference between the supply and return water temperatures at the boiler.

Most water circulation problems result from air trapped in the system. Air in a hydronic system can compress and expand, causing problems with pressure controls and pumps. Excessive air or pressure problems can form bubbles that disrupt water flow through the pump. The implosion of bubbles causes damage to circulator pumps and is referred to as ***cavitation***. If enough air gathers at one location in a hydronic system, it can completely block the flow of water. A section or component with this condition is

Copyright Goodheart-Willcox Co., Inc. 2017

said to be ***air-bound***. Air in a hydronic system will also cause noise.

Hydronic systems are equipped with a variety of air-removal components, such as air scoops, air separators, and air vents. When these components are operating properly, they automatically vent air from the system. Manual bleed valves may be installed on some systems. These valves trap air like an air separator or air scoop, but they must be manually opened to allow the air to vent out.

Drain hoses are sometimes attached to the outlets of air vents to drain away any water that leaks from the vent. If the air vents or drainage hoses become clogged, the vents can malfunction. In addition, many air vents are equipped with valve caps that keep dust and debris from entering the valve. These caps should be loose enough for air to escape through the cap. If the cap is tightened completely, it will block the escape of air, causing the air vent to fail.

Pro Tip

Air Vent Failure

Air vents in living spaces frequently get painted during remodeling projects. The paint can clog the air vents and cause them to malfunction.

Common symptoms of excessive air in a hydronic system include the following:

- Pump motor failure and water leaks around the pump packing.
- Noise in wet-rotor centrifugal pumps resulting from a lack of lubrication.
- Cavitation causing noise in pipes.
- Turbulence causing noise in pipes.
- Poor heat transfer at the terminal units.
- Accelerated corrosion.

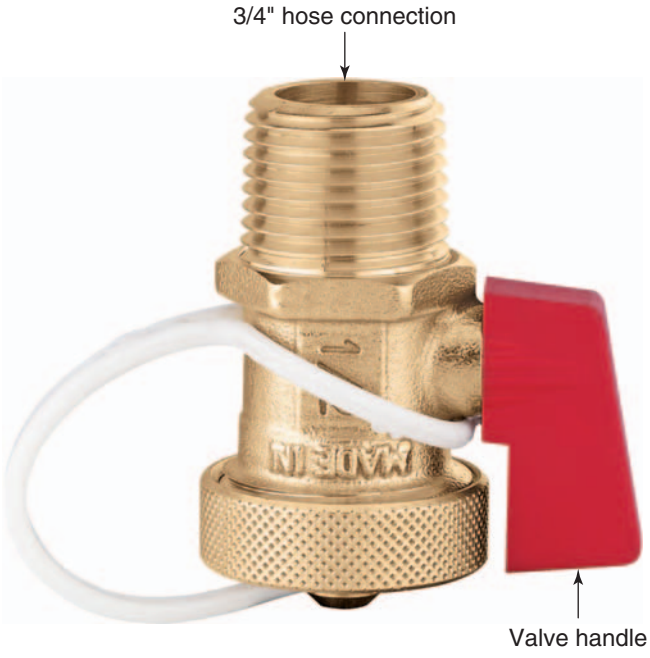
39.5.3 Bleeding a Hydronic System

If a hydronic system shows signs of having excessive trapped air, purge the system or bleed off the air and look for the source of the air buildup. In a system equipped with air vents, a buildup of air indicates that one or more of the air vents is malfunctioning or that the system is improperly designed. The faulty vents must be located and cleaned or replaced. If all the air vents are working properly but there is still excessive air, additional air vents may need to be added where the air is collecting.

Systems equipped with manual bleed valves can be bled by opening each bleed valve until only water emerges from the valve. If possible, connect a hose to the valve outlet and place the other end in a bucket filled with several inches of water before opening the valve. This not only prevents water spillage from the valve, but also provides a good way of visually determining when all the air has been removed. Once the valve is opened, any air that escapes from the system will form bubbles as it leaves the end of the hose. When no more bubbles emerge from the hose, all of the air has been removed, and the manual bleed valve can be closed. The process is then repeated at each manual bleed valve in the system.

39.5.4 Purging a Hydronic System

If a hydronic system has been recently installed, has been drained for service, or contains a large amount of trapped air, it should be purged. Purging is similar to bleeding, except that it removes air from the entire system rather than a localized area served by a manual bleed valve or air vent. During purging, water from the makeup water line gradually fills the system and, because the water enters the system at a relatively high pressure, pushes any trapped air out through a drain valve or purge valve, **Figure 39-54**.



© 2012 Caleffi North America, Inc.

Figure 39-54. A drain valve designed to be connected to a balancing valve to drain a hydronic system.

Copyright Goodheart-Willcox Co., Inc. 2017

Safety Note

Purging a Hydronic System

Use caution when bleeding or purging a hydronic system since the water may be hot. When purging a system, take precautions to prevent an electrocution hazard by making sure the boiler's electrical components do not come into contact with water.

Pro Tip

Purge Valves

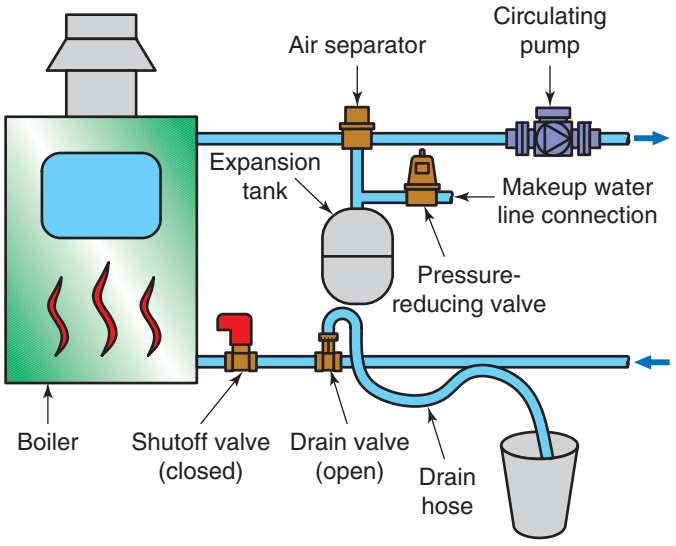
Purge valves combine the function of a shutoff valve and drain valve in a single valve body. Rather than using a single purge valve, some systems have separate shutoff valves and drain valves. The shutoff valve downstream from the drain valve must be closed while these systems are being purged.

Systems that use only water can be purged using the makeup water supply and purge valves. For series loop systems, this is a simple, single-stage operation. For systems with a primary loop and secondary loops, the individual loops should be purged separately. If the system uses a glycol solution, an auxiliary pump is used to purge the system and recycle the glycol solution.

Purging a Series Loop System

If a series loop system uses only water (not glycol or other substances), it can be purged using the following procedure. Refer to **Figure 39-55** as you follow this procedure.

1. Turn off the boiler and allow it to cool down. If the system is purged while it is still hot, the sudden rush of cold makeup water can cause the boiler to crack.
2. Attach a hose to the drain valve. Run the other end of the hose to a drain. Rather than purging directly to a drain, you can also put the end of the hose in a bucket. The advantage of this method is that bubbles can be clearly seen coming out of the end of the hose.
3. Open the bypass at the pressure-reducing valve in the makeup water line. Also, engage the fast-fill handle on the pressure-reducing valve. This allows makeup water to enter the system at full pressure.
4. Make sure the drain hose is securely positioned at the drain so water will not spill. Then, close the shutoff valve downstream from the drain valve and open the drain valve so all of the water is diverted through the hose. As air is forced out of the system, the discharge from the hose will hiss and spit.
5. When a solid stream of water free of bubbles comes out of the hose, shut off the bypass at the pressure-reducing valve and disable the valve's fast-fill handle.
6. Close the boiler drain valve and open the shutoff valve.
7. Check the cold boiler pressure. If the pressure is incorrect, check the setting on the pressure-reducing valve and adjust it as necessary. If the pressure is still high, open the drain valve after adjusting the pressure-reducing valve setting. When the pressure drops to the proper level, the makeup water line should maintain the proper pressure.
8. Turn on the boiler. As the boiler heats up, check the drain valve and piping around the boiler for leaks.
9. When the system has warmed up to operating temperature, check the boiler pressure. Also, make sure the terminal units are heating up properly.



Goodheart-Willcox Publisher

Figure 39-55. Setup for purging a series loop system.

Purging a One-Pipe System with Primary and Secondary Loops

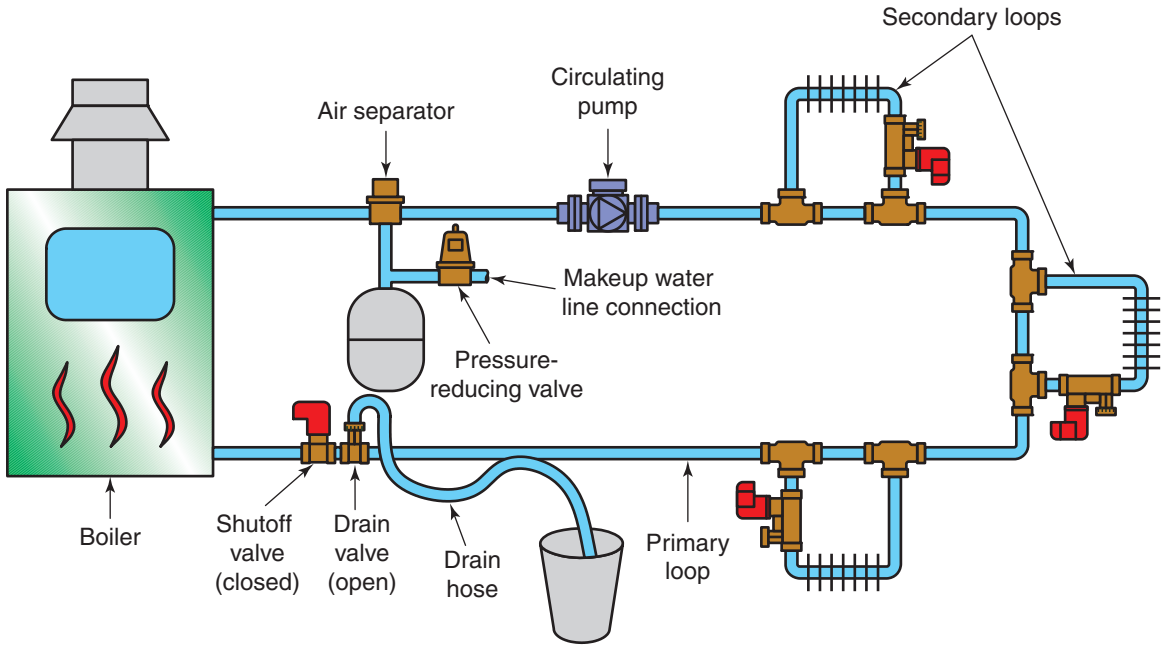
A one-pipe system with primary and secondary loops is purged in a manner similar to a series loop system. However, extra steps are required to ensure that all the loops are properly

11

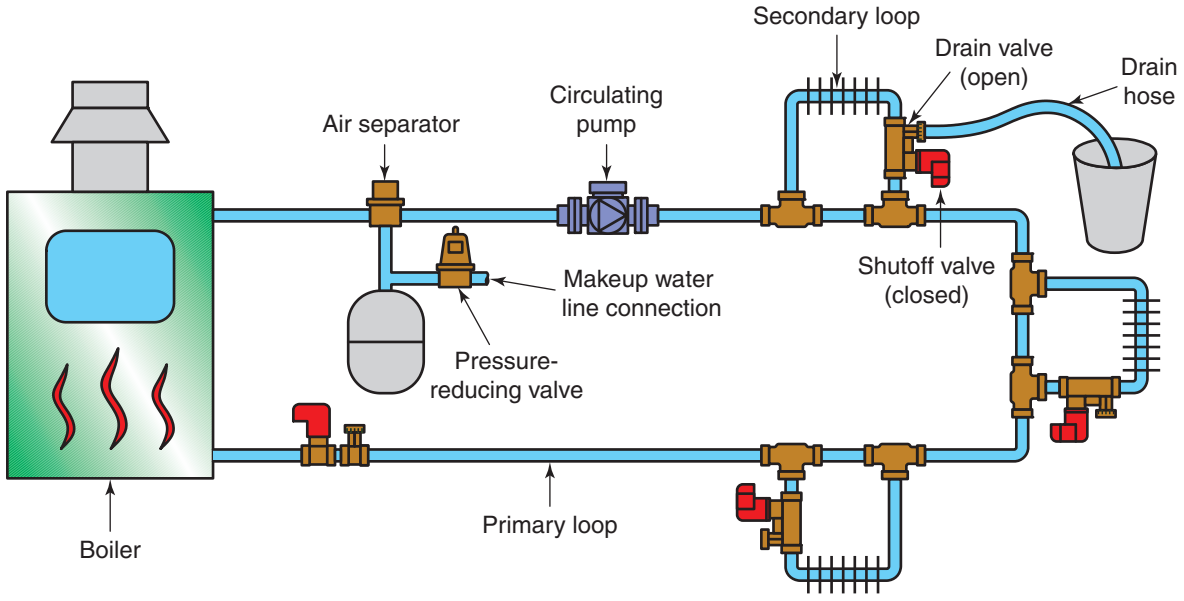
Copyright Goodheart-Willcox Co., Inc. 2017

purged. Refer to **Figure 39-56** as you follow this procedure.

1. Turn off the boiler and allow it to cool down.
2. Isolate the secondary loops so that only the primary loop will be purged.
3. Purge the primary loop as described in the previous procedure.
4. When the primary loop has been properly purged, close the drain valve on the primary loop and move the hose to the drain valve on the first secondary loop. Open the drain valve on the secondary loop and allow water to run through the loop until the water is free of bubbles.
5. When no more bubbles appear, close the drain valve and move the hose to the drain valve



Purging Primary Loop



Purging Secondary Loop

Goodheart-Willcox Publisher

Figure 39-56. Setup for purging a one-pipe system with primary and secondary loops.

Copyright Goodheart-Willcox Co., Inc. 2017

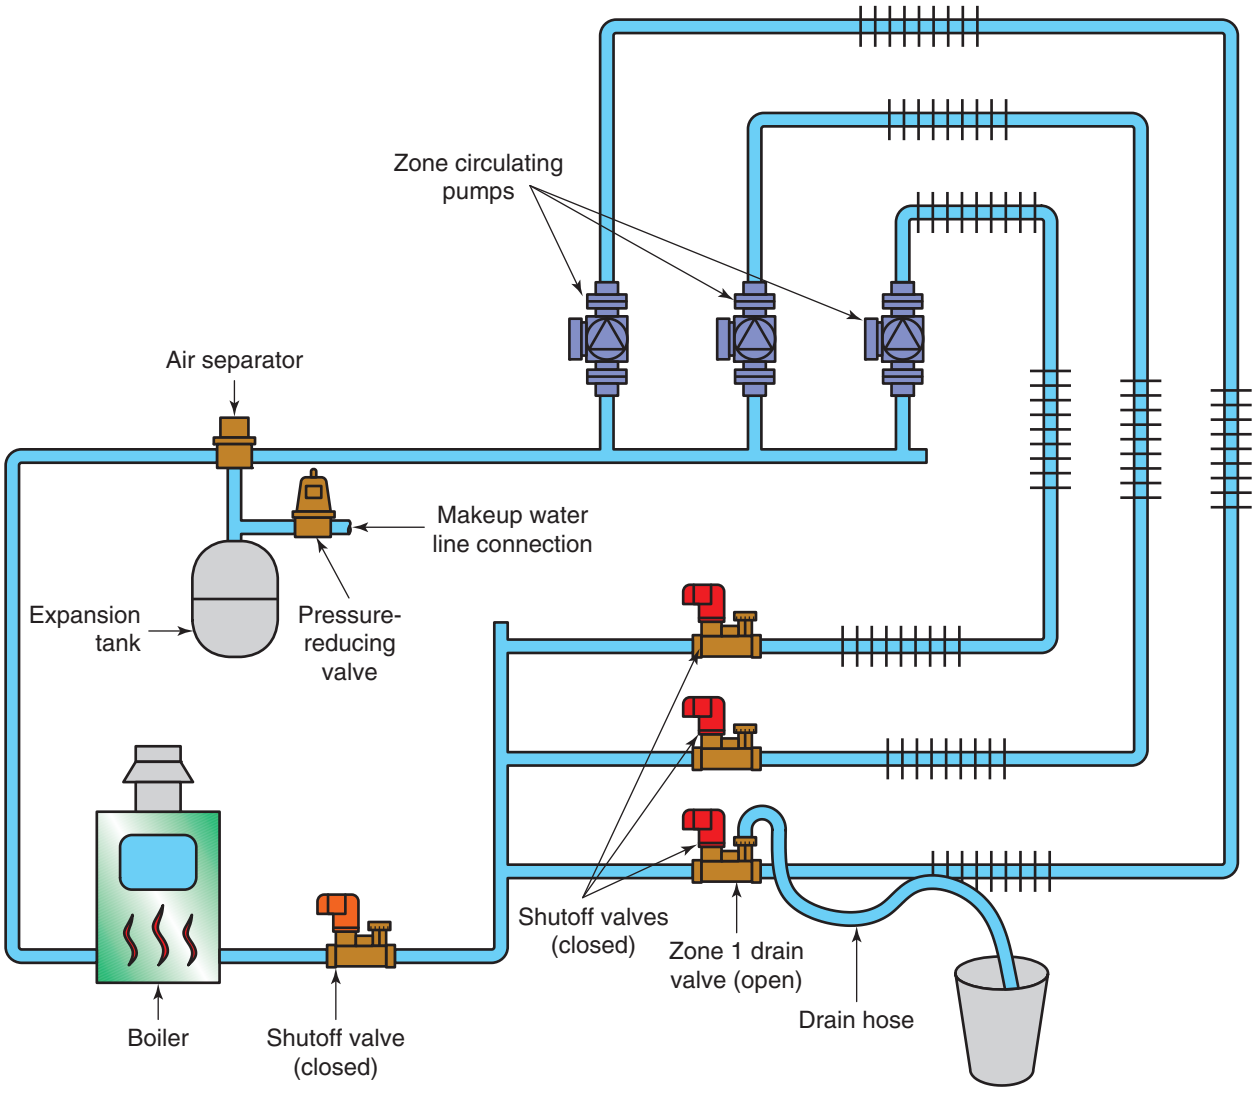
on the next secondary loop. Purge the second secondary loop as described in the previous step. Repeat this step for each secondary loop in the system.

6. When the primary loop and all secondary loops have been purged, shut off the bypass at the pressure-reducing valve and disable the valve's fast-fill handle. Remove the hose and open all shutoff valves.
7. Double check the system to ensure that all shutoff valves have been reopened. Check the cold boiler pressure and adjust the pressure-reducing valve as needed.
8. Start the boiler and check for leaks. When the boiler reaches proper operating temperature, check the boiler pressure and make sure the terminal units are heating up properly.

Purging a Two-Pipe Zoned System with Zone Circulating Pumps

Two-pipe zoned systems typically control flow through the zones using zone valves or separate circulating pumps for each zone. The following procedure describes how to purge a zoned system equipped with zone circulating pumps. Refer to **Figure 39-57** as you follow this procedure.

1. Turn off the boiler and allow it to cool down.



Goodheart-Willcox Publisher

Figure 39-57. Setup for purging a two-pipe zoned system with zone circulating pumps.

Copyright Goodheart-Willcox Co., Inc. 2017

2. Close the shutoff valves in the return lines of every zone.
3. Close the shutoff valve in the boiler return line.
4. Attach a hose to the drain valve in the return line of the first zone. Run the other end of the hose to a drain or bucket.
5. Open the bypass at the pressure-reducing valve in the makeup water line. Also, engage the fast-fill handle on the pressure-reducing valve.
6. Open the drain valve in the return line of the first zone until no bubbles are visible in the water. Then, close the drain valve and move the hose and bucket to the next zone.
7. Repeat the previous step for every zone in the system.
8. When the last zone has been purged, open all of the shutoff valves for the zones.
9. Move the hose to the drain valve in the boiler return line.
10. Open the drain valve in the boiler return line and keep it open until there are no bubbles in the water.
11. After closing the drain valve, remove the hose and open the shutoff valve in the boiler return line.
12. Shut off the bypass at the pressure-reducing valve and disable the valve's fast-fill handle.
13. Double check the system to ensure that all shutoff valves have been reopened. Check the cold boiler pressure and adjust the pressure-reducing valve as needed.
14. Start the boiler and check for leaks. When the boiler reaches proper operating temperature, check the boiler pressure and make sure the terminal units are heating up properly.

Purging a Two-Pipe Zoned System with Zone Valves

The following procedure describes the steps used to purge a two-pipe zoned system equipped with zone valves rather than zone circulating pumps. Refer to **Figure 39-58** as you follow this procedure.

1. Turn off the boiler and allow it to cool down.
2. Close the shutoff valves in the return lines of every zone.
3. Close the differential pressure bypass valve in between the main water supply and water return lines.
4. Close the shutoff valve in the boiler return line.
5. Open the bypass at the pressure-reducing valve in the makeup water line. Also, engage the fast-fill handle on the pressure-reducing valve.
6. Manually open the zone valve for the first zone.
7. Connect a hose to the drain valve in the first zone. Open the drain valve and keep it open until there are no more bubbles in the stream of water coming from the hose directed into the bucket. Then, close the drain valve.
8. Manually close the zone valve for the first zone.
9. Repeat Steps 6 through 8 for each zone in the system.
10. When every zone has been purged, move the hose to the drain valve in the boiler return line.
11. Open the shutoff valves and zone valves for each of the zones. Also, open the differential pressure bypass valve.
12. Open the drain valve in the boiler return line and keep it open until there are no more bubbles in the water coming from the hose. Then, close the drain valve.
13. Remove the drain hose and open the shutoff valve in the boiler return line.
14. Shut off the bypass at the pressure-reducing valve and disable the valve's fast-fill handle.
15. Double check the system to ensure that all shutoff valves have been reopened. Check the cold boiler pressure and adjust the pressure-reducing valve as needed.
16. Start the boiler and check for leaks. When the boiler reaches proper operating temperature, check the boiler pressure and make sure the terminal units are heating up properly.

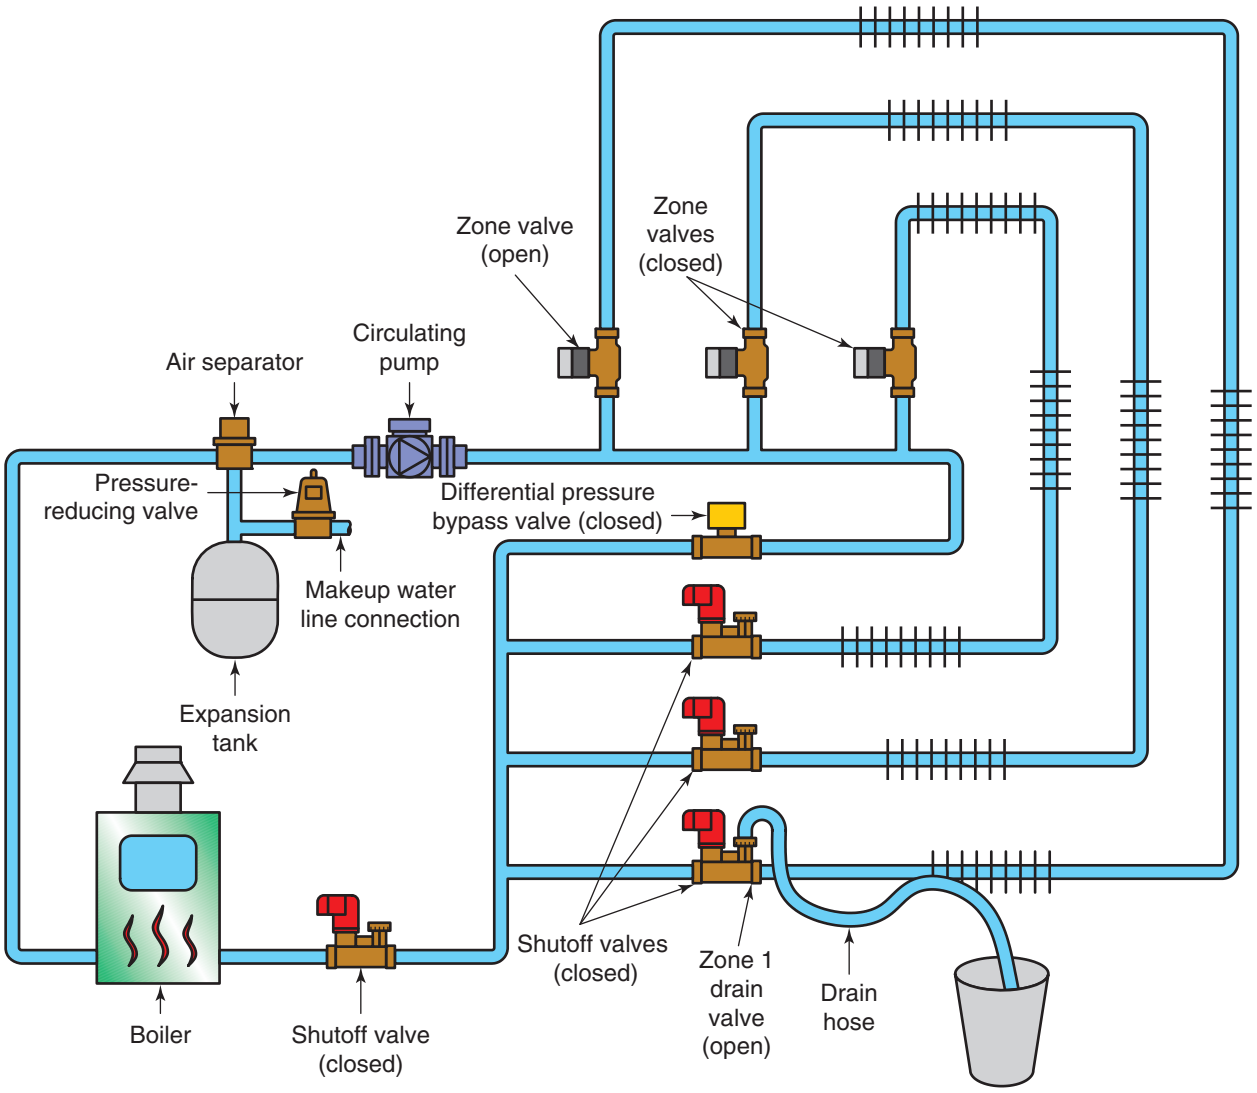
Purging a Hydronic System Filled with Glycol Solution

If a hydronic system is filled with a glycol solution, the system should be purged using a technique that reclaims the solution. This

Copyright Goodheart-Willcox Co., Inc. 2017

is accomplished by using a transfer pump to recirculate the solution that is drained from the system. A variation of this technique can be used to add glycol solution to a system. Refer to **Figure 39-59** as you follow this procedure.

1. Turn the boiler off and let it cool down.
2. Attach a hose to the drain valve in the boiler return line and place the other end of the hose in a bucket. Close the shutoff valve in the boiler return line.
3. Attach a hose to the inlet of a transfer pump and place the other end of the hose in the bucket.
4. Attach a hose to the outlet of the transfer pump and attach the other end to the drain valve in the water supply line.
5. Open the drain valve in the boiler return line.
6. When water has covered the ends of both hoses in the bucket, open the drain valve in the water supply line and turn on the transfer pump.
7. Allow the water to circulate and the pump to run until there are no more bubbles appearing in the bucket. Be sure to keep the ends of both hoses at the bottom of the bucket and completely submerged during this process.



Goodheart-Willcox Publisher

Goodheart-Willcox Publisher

Figure 39-59. If a hydronic system is filled with a glycol solution, the fluid drained from the system is captured in a bucket during the purging process. A transfer pump then circulates the drained fluid back into the system.

8. When no more bubbles appear in the bucket, turn off the transfer pump and close both drain valves.
9. Disconnect the hoses and the transfer pump.
10. Double check the system to ensure that all shutoff valves have been reopened. Check the cold boiler pressure and adjust the pressure-reducing valve as needed.
11. Start the boiler and check for leaks. When the boiler reaches proper operating temperature, check the boiler pressure and make sure the terminal units are heating up properly.

39.5.5 Expansion Tank Problems

The expansion tank in a hydronic system provides space for water expansion and helps to maintain a consistent pressure in the system. If the tank becomes waterlogged, it fails to function properly. This can lead to a variety of symptoms, including increased system pressure and the potential release of water through the pressure-relief valve.

If the expansion tank is waterlogged, the water in the system has nowhere to go as it heats up and expands. As a result, system pressure builds up until it exceeds the pressure limit of the pressure-relief valve. The valve opens and releases water to lower the system pressure. When the boiler cycles off, the water in the system cools and contracts, lowering the system pressure further. The pressure-reducing valve then allows more fresh water (containing more air) into the system. If this continues, the inside of the system will become corroded from the minerals and chemicals that are commonly found in untreated tap water.

One method of checking for a waterlogged expansion tank is to compare the temperature at the bottom

Copyright Goodheart-Willcox Co., Inc. 2017

of the tank with the temperature at the top of the tank. If the tank is hot from top to bottom, it is waterlogged. The portion of the tank containing air should remain relatively cool, even if warm water enters the other half of the tank. Water leaking from the pressure-relief valve every time the boiler cycles on is another indication that the expansion tank may be waterlogged or undersized and should be recharged or replaced.

Recharging a Horizontal Expansion Tank

If an older-style, horizontal expansion tank becomes waterlogged, the excess water can be drained from the tank to restore proper function.

1. Turn off the boiler and allow the system to cool down.
2. Close the shutoff valve to isolate the expansion tank or shut off the makeup water line.
3. Connect a hose to the combination valve at the bottom of the tank.
4. Open the combination valve and allow several gallons of water to drain from the tank. As the water drains, air is drawn in through the combination valve to replace it.
5. Close the combination valve and remove the hose.
6. Open the shutoff valve to the expansion tank or reopen the makeup water line.
7. Turn on the boiler and let it run for one to two hours to check for proper operation of the expansion tank.

Recharging a Diaphragm Expansion Tank

Some diaphragm expansion tanks can be recharged if they become waterlogged. The following procedure explains how to add an air charge to these tanks. If the tank will not hold an air charge, the diaphragm is likely ruptured and the tank needs to be replaced.

1. Turn off the boiler and allow the system to cool down.
2. Shut off the makeup water line.
3. Remove the cap from the air valve on the expansion tank and use a pressure gauge to measure the air pressure in the tank.
4. Use a bicycle pump to increase air pressure if necessary. Recheck the pressure after every two or three strokes of the pump to avoid overcharging the tank.
5. Replace the cap on the expansion tank air valve and reopen the makeup water line.
6. Turn on the boiler and allow it to run for one to two hours to check for proper operation of the expansion tank.

39.5.6 Other Hydronic System Problems

If a hydronic system is providing uneven heating, begin by making sure there are no air blockages. Check for the proper operation of circulating pumps, zone valves, and thermostatic controls. If the system components are functioning properly, but the system is still providing uneven heating, it may be necessary to perform a room-by-room heat loss calculation and adjust the balancing valves to bring the system into balance.

Unusual noises in the system can be caused by a number of things. Air in the system can cause noises in the piping. Broken or poorly lubricated pumps can also be the source of unusual noises in the system. The pipes themselves can cause noise as they expand and contract, especially if they are tightly clamped to their hangers or are in contact with the edges of the openings they pass through. Expansion joints help eliminate this problem. When looking for the source of unusual noises, work systematically to eliminate potential causes until the source of the noise is found.

39.5.7 Servicing a Steam Heating System

A steam heating system should be checked once each month during the heating season. Start by checking the water level sight glass and the pressure gauge. The water level sight glass must show the boiler water level at one-third to one-half full.

If the water level is high, drain the system to the correct lower level. If the water level is low but still shows in the sight glass, add water. Water should be added until the level is correct. After filling the boiler to the correct level, close the fill valve completely. If no water shows in the water level sight glass or if the pressure gauge is above normal, shut the system off at once. Allow the boiler to completely cool before adding water.

Operating the system with a low water level can result in short cycling. Brief cycling periods cause rapid temperature changes in the boiler. After several thousand cycles, the boiler walls or tubes may crack.

Copyright Goodheart-Willcox Co., Inc. 2017

For this reason, it is important to ensure that the proper level is maintained during operation.

When checking water level, note that the water level sight glass may trap water if its openings are clogged. This could make it appear that the water level is higher than it really is. Trust the reading only if the system is clean and the sight glass and its connections have been cleaned recently. Some systems are equipped with petcocks (small drain valves) that can be used to verify the boiler water level.

After checking the water level in the boiler, check the boiler's safety and control components. When checking the pressure-relief valve, make sure it is equipped with a discharge tube to safely divert the discharge away from people and equipment. Pull the lever open briefly to verify that it is not stuck closed. Water or steam should immediately flow from the valve. If no steam or water comes out, shut off the system at once. Allow the system to cool down and then replace the pressure-relief valve. Also, check the low-water cutoff by opening the boiler drain valve. The low-water cutoff should operate right away by cutting off all fuel and electrical power. If it does not operate, shut down the unit and service the low-water cutoff.

Safety Note

Steam Heating System Safety

A steam heating system should be serviced with great care. Escaping steam or hot water can cause severe burns. A boiler can explode if the steam pressure is permitted to exceed the boiler safe pressure limit. Wear goggles when opening petcocks and valves. Stand to one side to prevent burns from steam or hot water, and do not allow the escaping steam or hot water to spill on anyone.

Continue steam heating system service by inspecting the terminal units. If one radiator is cool while the others are hot, it is not receiving steam. This problem may be caused by one of the following component malfunctions:

- The radiator valve is closed. Either the thermostat for the valve or the valve itself is not working.
- The radiator is air-bound. This indicates the air vent is not working.
- The radiator is filled with condensed water. This indicates the steam trap is not working.

Lightly tapping the suspected component with a rubber mallet may jar the component so that it begins functioning again momentarily. Once the faulty component is identified, shut down the system and allow it to cool down. Reduce the system pressure to atmospheric pressure through purging and replace the faulty component. Restart the system and keep a close eye on the system pressure while the system heats up. Check the system for proper operation.

39.6 Preparing a Boiler for the Heating Season

Before a boiler is put into service for the heating season, it requires preventive maintenance and a thorough inspection. The annual inspection can reveal developing problems, such as leaks and corrosion, that could cause the system to perform unreliably if left unattended. Proper maintenance and operational practices can help to ensure optimal performance, reducing operating costs and increasing equipment life.

Boiler Inspection and Maintenance

Use the following steps to prepare a boiler for operation before the heating season begins.

1. Clean the burner (gas or oil).
2. If the boiler is an oil-fired unit, clean the nozzle. Use a cloth and solvent. Do not use a wire brush, as the bristles may scratch the orifice.
3. Clean and adjust the ignition electrodes.
4. Inspect the insulation and replace it if it is cracked or damaged.
5. Clean the flame detector lens. Operate the detector controls by closing the fuel valve. The detector controls should lock out (lock in the off position).
6. If the unit is gas-fired, clean the pilot light if the boiler has one.
7. Check and tighten all electrical and fuel connections.
8. Oil the blower motors.
9. Check motor temperatures. If warmer than normal, cleaning or new bearings may be necessary.
10. Inspect heat exchanger tubes for soot or fly ash and clean as needed.
11. Inspect and clean the breeching (top of the boiler flue).
12. Cycle the controls. Shut off the makeup water line and open the boiler drain valve to check for proper operation of the low-water cutoff.

Copyright Goodheart-Willcox Co., Inc. 2017

13. Operate all safety and pressure-relief valves and petcocks to check for proper operating condition.

Boiler operation is compromised if there are signs of overheating, excessive scale, excessive corrosion, or damaged pressure vessel components, such as the boiler's heat exchanger. A boiler must also pass a pressure test. Prior to draining the boiler for cleaning, fill it with water. With the boiler at operating pressure, close the water supply and return valves to isolate the boiler from the system. If the boiler pressure drops, the boiler has leaks and will fail inspection. The leaks need to be identified and repaired if possible. Start by checking the valves because they are most susceptible to small leaks that can cause the boiler to fail the pressure test.

Code Alert

Boiler Test

Local building codes typically require boiler systems to pass a post-installation pressure test before they can be put into service. Refer to your local building codes for specific requirements.

Before putting a boiler back in service, crack the valves and check for unusual noises or vibrations prior to fully opening them. If a boiler is operated in conjunction with other boilers, make sure its operating temperature and pressure are the same as the other boilers before opening the water supply and return valves. For steam boilers, be sure to drain condensed water from the steam supply line prior to opening the steam supply valve to avoid slugging condensate into the steam main.

Chapter Review

Summary

- Hydronic systems use conditioned water or steam to distribute heat. Compared to forced-air heating systems, hydronic heating systems are more efficient at heat transfer, require less room for fluid piping than air ducts require, provide more consistent heating, and do not introduce dust or allergens into the conditioned spaces.
- The basic components of a hydronic system include a boiler, circulating pump, expansion tank, terminal units, and air-removal components. Various valves, such as mixing valves and balancing valves, are used to control the flow of water through the system.
- Impurities in boiler water can cause corrosion and embrittlement in a hydronic system. Chemical scavengers, corrosion inhibiters, and air-removal components can be used to help prevent corrosion caused by contaminants and dissolved gases.
- Series loop and one-pipe hydronic systems supply water to the terminal units and return water to the boiler through a single pipe. Two-pipe hydronic systems supply water to the terminal units through one pipe and return the water to the boiler through a separate pipe. Zoned hydronic systems are split into different zones, each with its own piping, terminals units, zone valve, and room thermostat. A room thermostat maintains each zone's set point temperature by controlling a zone valve or zone circulator pump, which regulates the flow of water through that zone.
- Radiant hydronic systems use plastic or composite tubing directly in contact with a floor, wall, or panel to heat a conditioned space. The water circulating through the tubing warms the surfaces adjacent to it by conduction. Underfloor radiant heating systems can be classified as wet or dry, depending on the installation and use of concrete.
- Combined heating and cooling hydronic systems have both boilers and chillers. In two-pipe systems, the boiler and chiller use the same pipes to supply water to the terminal units. A four-pipe system uses separate pipes to carry water to and from the boiler and to and from the chiller, allowing the boiler and chiller to be operated simultaneously.
- A steam heating system supplies steam to radiators in conditioned spaces. Air vents and steam traps allow air and condensed water to leave the radiators, but not steam. As the steam heats the room, it cools down and condenses, and the condensed water returns to the boiler to be reheated.
- A low-water cutoff automatically shuts down a boiler if the water level gets too low. A flow switch shuts down the system or bypasses part of it when there is inadequate water circulation. An aquastat maintains proper water temperature in the boiler, while a room thermostat controls the temperature in the conditioned space.
- To prepare a hydronic system for initial start-up, circulate a solution of water and the proper chemical treatment through the system, drain it out, and then refill the system with conditioned water. Once the system is operating, balance the system by using a pressure gauge to measure the rate of water flow through each balancing valve.
- Most hydronic system problems fall into one of three categories: electrical, venting, or water circulation. Electrical problems commonly affect system controls. Venting problems affect boiler combustion and may cause the system's rollout switch or blocked-vent switch to shut down the boiler. Most water circulation problems are caused by trapped air. If a system has a significant amount of trapped air in it, it should be purged.
- A steam heating system should be checked once each month during the heating season. Inspection and service of a steam heating system involves checking the boiler's water level, checking the boiler's safety and control components, and inspecting the system's terminal units.
- Before each heating season, a boiler should be carefully checked, and preventive maintenance should be performed on it. Preventive maintenance involves cleaning and inspecting the burner, checking the boiler controls, and testing the safety and pressure-relief valves for proper operation. Boilers and their piping must also pass a pressure test.

Review Questions

Answer the following questions using the information in this chapter.

1. Which of the following is *not* an advantage of hydronic heating systems compared to forced-air heating systems?
   A. Do not introduce dust or allergens into the conditioned space.
   B. Greater efficiency of heat transfer.
   C. Less sensitive to neglect and require less maintenance.
   D. Provide a more consistent temperature level.
2. Which of the following statements comparing steam and hot-water hydronic systems is *not* true?
   A. Hot-water systems are more efficient than steam systems.
   B. Hot-water systems are now more commonly used than steam systems.
   C. Hot-water systems can adjust water temperature to meet heating demands, which is not possible with steam systems.
   D. Steam systems can be more easily modified to provide chilled water for cooling.
3. What is the reason that conventional boilers operate with a water temperature above 140°F (60°C)?
   A. Most boiler controls can only function at temperatures above 140°F (60°C).
   B. A temperature above 140°F (60°C) swells seals in the circulating pumps, preventing leaks.
   C. A temperature of 140°F (60°C) is required to kill any biological contaminants that might be in the water.
   D. A temperature of 140°F (60°C) is required to prevent combustion gases from condensing.
4. Boiler heat exchangers are typically made out of _____.
   A. aluminum, manganese, or cast iron
   B. cast iron, brass, or molybdenum
   C. cast iron, copper, or steel
   D. steel, brass, or aluminum
5. Which of the following types of water treatment forms a protective coating on the surfaces of a hydronic system?
   A. Alkali treatments.
   B. Chemical scavengers.
   C. Corrosion inhibitors.
   D. All of the above.
6. The release of dissolved gasses from water in a hydronic system is known as _____.
   A. cavitation
   B. deaeration
   C. gas entrainment
   D. liquefaction
7. The purpose of an expansion tank is to _____.
   A. provide space for water to expand as the system heats up
   B. return water to the system as the system cools down
   C. maintain a stable system pressure under varying conditions
   D. All of the above.
8. Which type of hydronic system valve prevents hot water from migrating to higher points in the system when the circulating pump quits operating?
   A. Balancing valve.
   B. Flow-control valve.
   C. Mixing valve.
   D. Pressure-reducing valve.
9. Which type of hydronic system valve helps to distribute heat equally throughout the system?
   A. Backflow preventer.
   B. Balancing valve.
   C. Pressure-reducing valve.
   D. All of the above.
10. Which of the following statements about terminal units is *not* true?
    A. Fan convectors can extract heat from lower-temperature water than a radiator can.
    B. Radiators are available in baseboard, column, and panel styles.
    C. Radiators can be used as terminal units in both steam and hot-water hydronic systems.
    D. Radiators provide the majority of their heating through radiation rather than through convection.

Copyright Goodheart-Willcox Co., Inc. 2017

11. Air vents are designed to _____ from a hydronic system.
    A. capture and release entrained air
    B. release free air
    C. release makeup water
    D. separate and release dissolved air

12. A _____ hydronic system is similar to a series loop system, except that its terminal units are on branch circuits, called secondary loops.
    A. one-pipe
    B. parallel loop
    C. two-pipe
    D. zoned

13. Which of the following hydronic system designs provides the most consistent heat at the terminal units?
    A. One-pipe.
    B. Primary loop.
    C. Series loop.
    D. Two-pipe.

14. Why is a reverse return hydronic system the design that is the easiest to balance?
    A. All supply and return branches are approximately the same length.
    B. All terminal units must have the same capacity.
    C. The circulator simply reverses flow when the call for heat is met, so no balancing is required.
    D. Water flows in both directions through the same length of pipe.

15. In a zoned hydronic system, each zone has its own _____.
    A. room thermostat
    B. terminal units
    C. zone valve
    D. All of the above.

16. Which of the following statements about radiant hydronic systems is *not* true?
    A. They typically use PEX, other plastics, or composite material for tubing.
    B. System tubing is completely enclosed in walls or floors.
    C. Radiant hydronic systems typically circulate water at a cooler temperature than hot-water hydronic systems do.
    D. Radiant hydronic systems typically use radiators as terminal units.

17. A _____ hydronic system has separate supply and return pipes for hot and cold water.
    A. one-pipe
    B. two-pipe
    C. three-pipe
    D. four-pipe

18. A two-pipe steam heating system has _____ that allow condensed water to return to the boiler, but prevent steam from passing.
    A. air vents
    B. condensing traps
    C. low-water cutoffs
    D. steam traps

19. Which of the following best describes the function of an air vent in a steam heating system?
    A. It allows air to exit the system, but prevents steam from exiting.
    B. It allows a small amount of air to enter the system to promote steam generation.
    C. It allows small amounts of steam to escape from the radiator to reduce system pressure.
    D. It opens when the system reaches operating temperature, allowing increased airflow through the radiator.

20. All boilers have a(n) _____ that automatically shuts off the fuel supply if the water temperature or pressure gets too high.
    A. atmospheric burner
    B. gun-type burner
    C. high-limit control
    D. low-water cutoff

21. If a hydronic system is operating with a reduced water level, the _____ may open the makeup water valve to add water to the system.
    A. aquastat
    B. flow switch
    C. low-water cutoff
    D. None of the above.

22. Which hydronic system control monitors the cycle time required to satisfy a call for heat?
    A. Flow switch.
    B. Indoor reset control.
    C. Outdoor reset control.
    D. Room thermostat.

23. When joining tubing of different sizes, a technician should use a(n) _____.
    A. eccentric reducer fitting
    B. expansion joint
    C. flexible joint
    D. riser pipe

Copyright Goodheart-Willcox Co., Inc. 2017

24. Where should an air vent be installed on a one-pipe steam heating system?
    A. About half way up the radiator.
    B. At the inlet of the radiator.
    C. An air vent is not needed on a one-pipe steam system.
    D. On the thermostatic radiator valve.

25. Which of the following is *not* a step in preparing a hydronic system for initial start-up?
    A. Clean the filter screen and refill the system with water.
    B. Fill the boiler with a mixture of water and the proper chemical treatment.
    C. Treat the water with 500 ppm of vinegar.
    D. Use a pressure gauge to determine the proper setting for each balancing valve.

26. Which of the following can prevent a boiler from firing?
    A. A blocked vent.
    B. An inoperative vent damper.
    C. A tripped rollout switch.
    D. All of the above.

27. Which of the following best explains the difference between system purging and system bleeding?
    A. Bleeding removes air from the entire system, and purging removes air from a localized part of the system.
    B. Bleeding removes excess water from the entire system, and purging removes excess water from a localized part of the system.
    C. Purging removes air from the entire system, and bleeding removes air from a localized part of the system.
    D. Purging removes excess water from the entire system, and bleeding removes excess water from a localized part of the system.

28. A waterlogged expansion tank may cause the _____ valve to release water every time the boiler cycles on.
    A. balancing
    B. mixing
    C. pressure-reducing
    D. pressure-relief

29. A steam boiler's water level sight glass should be _____ to one-half full.
    A. one-tenth
    B. one-eighth
    C. one-quarter
    D. one-third

30. Which of the following is *not* a step in preparing a boiler for operation before the heating season begins?
    A. Check for proper operation of the low-water cutoff.
    B. Clean and adjust ignition electrodes.
    C. Operate all pressure-relief valves to check for proper operating condition.
    D. Purge the entire system of excess air.

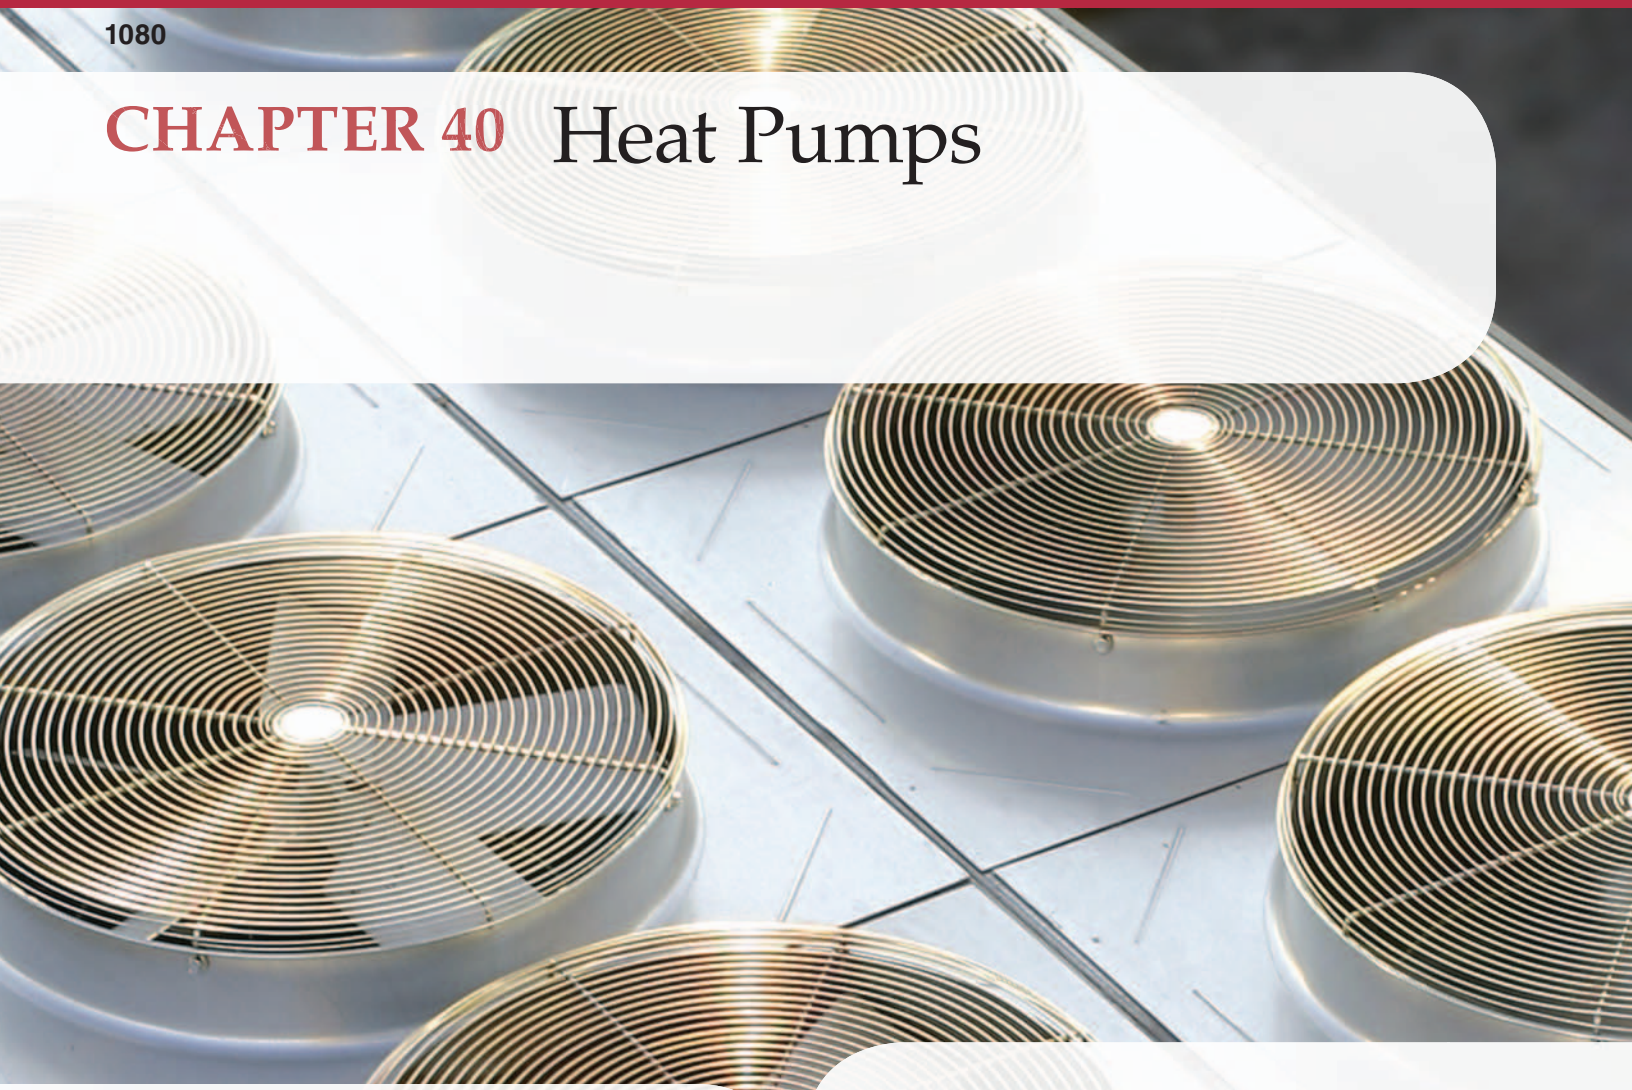
CHAPTER 40 Heat Pumps



Chapter Outline

40.1 Heat Pump Basics
40.2 Types of Heat Pumps
- 40.2.1 Air-Source Heat Pumps
- 40.2.2 Ground-Source Heat Pumps

40.3 Heat Pump Efficiency
40.4 Heat Pump System Components
- 40.4.1 Accumulators
- 40.4.2 Compressors
- 40.4.3 Metering Devices
- 40.4.4 Reversing Valves
- 40.4.5 Coils and Loops

40.5 Heat Pump Controls
- 40.5.1 Temperature Controls
- 40.5.2 Defrost Controls
- 40.5.3 Auxiliary Heat

40.6 Heat Pumps and Solar Heating Systems
40.7 Heat Pump System Service
- 40.7.1 Heat Pump Installation
- 40.7.2 Heat Pump Maintenance
- 40.7.3 Troubleshooting Heat Pumps

Learning Objectives

Information in this chapter will enable you to:

- Describe the basic operation of a heat pump in heating mode and in cooling mode.
- Summarize the difference between ground-source heat pumps and air-source heat pumps.
- Identify a heat pump system's principal components.
- Explain how a reversing valve operates and how it controls the direction of refrigerant flow through a heat pump.
- Compare and contrast different types of coils and loops used in heat pump systems.
- List two common methods used to defrost heat pumps.
- Understand how auxiliary heat is used in conjunction with heat pumps.
- Summarize how heat pumps can be combined with solar heating systems.
- Perform routine maintenance and service on heat pump systems.

Review of Key Concepts

Reviewing these concepts from earlier chapters will help you understand new concepts presented in this chapter:

- A compression refrigeration system uses mechanical energy to drive the refrigeration process. The four processes that make up a compression refrigeration system are compressing, condensing, metering, and evaporating. (Chapter 6)
- A heat sink is a surface or substance that absorbs heat transferred by a warmer surface or substance. (Chapter 27)
- An air handler uses a fan to distribute conditioned air to a building's conditioned space through a series of supply and return ducts. (Chapter 33)
- In electric heat defrost, electric heating elements are installed in an evaporator, around it, or within the refrigerant passages and energized to melt ice and frost buildup. Electric heating elements can be used for heating conditioned air or for defrosting purposes. (Chapter 21)

Introduction

A ***heat pump*** is a compression refrigeration system that can reverse the circulating flow of refrigerant in order to add heat or remove heat from a conditioned space, depending on its mode of operation. Heat is absorbed by one coil in one location and released by another coil in another location. In this way, heat pumps are similar to standard comfort cooling systems. However, unlike comfort cooling systems, heat pumps can reverse the flow of refrigerant in order to change their operation from cooling to heating. A reversing valve controls the direction of refrigerant flow through a heat pump's refrigerant circuit. The direction of refrigerant flow determines whether the heat pump heats or cools a conditioned space. When the refrigerant flow is reversed, the coil that previously functioned as an evaporator begins functioning as a condenser. The other coil, which functioned as a condenser, now begins functioning as an evaporator. Heat pumps can use a variety of system arrangements and distribution methods. These can be found in residential, commercial, and industrial applications.

40.1 Heat Pump Basics

Basic heat pump theory rests on the principle that heat moves from warmer substances to cooler substances. Thus, a coil that is cooler than its surroundings will absorb heat, and a coil that is warmer than its surroundings will release heat. For instance, if one refrigerant coil of a heat pump is mounted outdoors and maintains a refrigerant temperature of 0°F (–18°C), it removes heat from the air even if the outside temperature is only 10°F to 15°F (–12°C to –9°C). The low pressure applied to the refrigerant in the coil lowers its temperature and causes it to absorb heat from the outside air. This low-pressure vapor refrigerant is then compressed, causing its temperature to increase to 120°F to 140°F (49°C to 60°C). It is pumped to a coil mounted indoors where it releases heat to the cooler indoor space as the vapor condenses.

Pro Tip

Heat Pump Coil Names

Since a heat pump's two heat exchanger coils can switch functions depending on operational mode, neither coil is permanently called an evaporator or a condenser. The refrigerant coil that is located inside and warms or cools the air for the conditioned space is called the ***indoor coil***. The refrigerant coil that absorbs or expels heat for the indoor coil is called the ***outdoor coil***, whether it is located inside or outside a building. The exact location of an outdoor coil depends on the type of system.

When a heat pump is operating in heating mode, the outdoor coil functions as an evaporator by absorbing heat. The indoor coil functions as a condenser by releasing heat. Low-pressure liquid refrigerant enters the outdoor coil, picks up heat from the outdoor air, and vaporizes. The low-pressure refrigerant vapor is drawn into the compressor, compressed to a high temperature and pressure, and then pumped to the indoor coil. Since the refrigerant vapor's temperature is higher than the indoor air temperature, it releases heat indoors and condenses. As the refrigerant vapor becomes liquid and flows back to the outdoor coil, the cycle repeats. See **Figure 40-1A**.

When a heat pump is operating in cooling mode, a heat pump's reversing valve changes position, causing the refrigerant to flow through the system in the opposite direction. This switches the evaporator and condenser functions performed by the indoor and outdoor coils. The indoor coil now functions as an evaporator, and the outdoor coil functions as a condenser.

Liquid refrigerant flows through the indoor coil where it absorbs heat and boils into a vapor. The compressor compresses the refrigerant vapor to a high temperature and high pressure and pumps it to the outdoor coil. The air surrounding the outdoor coil is cooler than the high-temperature refrigerant in the coil, allowing the compressed refrigerant vapor to give up its heat to the outside air. The refrigerant condenses and subcools in the outdoor coil. From there, it

Figure 40-1. Both the heating and cooling modes of a heat pump. Heating Mode—When the heat pump is in heating mode, the reversing valve is set so that the outdoor coil acts as an evaporator, and heat is released by the indoor coil inside the building. Cooling Mode—When the heat pump is in cooling mode, the reversing valve is set so that the indoor coil acts as an evaporator, and heat is released by the outdoor coil outside the building.

Copyright Goodheart-Willcox Co., Inc. 2017

flows back to the indoor coil, repeating the cycle. See **Figure 40-1B**.

Although the direction of refrigerant flow through each coil changes depending on the reversing valve, the direction of refrigerant flow through the compressor is always in the same direction.

Self-contained (packaged) units with a capacity between 1/2 ton and 25 tons are common, and large systems with a capacity between 100 tons and 1000 tons are in use as well. Window units with a capacity between 1/2 ton and 2 tons are also available. In addition, heat pumps can be used for more than just conditioning a living space. Domestic water heating and heat recovery from industrial processes are two examples of alternative heat pump applications.

40.2 Types of Heat Pumps

The earth absorbs energy from the sun and stores it as heat energy in the ground or air. A heat pump can extract this energy by transferring the heat from the ground or air to a fluid medium, such as water or a refrigerant. Heat pumps can be classified according to their heat sources. If a heat pump transfers heat from the ground or a body of water to a conditioned space, it is referred to as a *ground-source* heat pump. If a heat pump transfers heat from the outside air to a conditioned space, it is referred to as an *air-source* heat pump.

40.2.1 Air-Source Heat Pumps

An ***air-source heat pump (ASHP)*** is a heat pump that uses the outside air as a heat source or a heat sink for producing the desired temperature in a conditioned space. Air-source heat pump installations are ideal where winter heating loads are almost the same as summer cooling loads. In general, these installations are most satisfactory when the outdoor air temperature in the winter remains above or only occasionally drops below 32°F (0°C). However, newer technology and systems can handle air temperatures below this level. Air-source heat pumps can be further divided into *air-to-air* heat pumps and *air-to-water* heat pumps.

Air-to-air heat pumps transfer heat between outside air and air inside a conditioned space using forced air as the indoor heat distribution method. Air-to-air heat pumps are a fairly popular type of heat pump and come in two styles: split systems and packaged systems.

Many split system heat pumps have an exterior appearance similar to that of a split air-conditioning system. They consist of an outdoor unit (containing the outdoor coil, a compressor, and a fan) and an indoor unit (containing the indoor coil and a blower). Occasionally, a split heat pump's indoor unit is incorporated with a gas or oil furnace, and the indoor coil is installed in the furnace's plenum, **Figure 40-2**.

Pro Tip

Liquid and Gas Lines

In a split air-conditioning system, the lines that connect the condenser and evaporator are called the *liquid line* and *suction line*. In a heat pump system, however, the larger refrigerant line that connects the indoor and outdoor units is called the *gas line*, because it always carries refrigerant gas. In the summer, the gas line carries cold gas from the indoor unit to the outdoor unit, and in the winter, it carries hot gas from the outdoor unit to the indoor unit. The smaller refrigerant line is still called the *liquid line* because it always carries liquid refrigerant, even though the liquid flows in different directions during summer and winter.

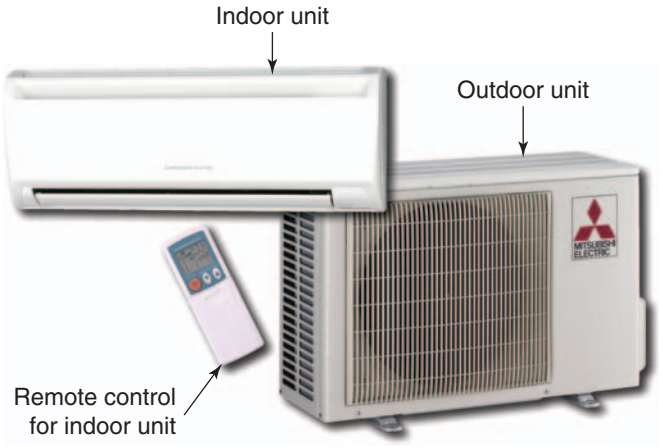
Similar to a packaged air-conditioning system, a packaged heat pump system contains all the heat pump components in a single housing. The packaged system is installed outdoors, which means supply and return ductwork must extend through an exterior wall or roof to and from the unit, **Figure 40-3**.

An air-to-air heat pump can also be used in a ductless system. This type of system uses a single outdoor unit installed on a pad or mounted on brackets. Tubing and wiring connect the outdoor unit to one or more indoor units, depending on the manufacturer. See **Figure 40-4**.

Motor-driven fans in both indoor and outdoor units improve heat transfer by blowing air across the coil surfaces. The location of the indoor unit varies, depending on the building's heating and cooling needs.

Rheem Manufacturing Company

Figure 40-3. Packaged heat pump systems have an exterior appearance similar to packaged air-conditioning systems. They make servicing easier because all the system components can be accessed from a central location outside a building.



Mitsubishi Electric, HVAC Advanced Products Division

Figure 40-4. A ductless heat pump system consists of a single outdoor unit, one or more indoor units, and individual controls for each indoor unit.

In a system with multiple indoor units, each unit has its own independent controls, and some systems even have remote controls. Ductless heat pump systems are often used in new and retrofitted offices, homes, and motels where conventional window or wall units are not desirable or applicable. The main advantage of a ductless heat pump system with multiple indoor units is that it can provide individual temperature control to multiple spaces using a single outdoor unit. For more information on ductless systems, see Chapter 31, *Ductless Air-Conditioning Systems*.

Air-to-water heat pumps transfer heat between outside air and air inside a conditioned space using a hydronic system for heat distribution. Water passes through a water coil heat exchanger and absorbs heat from the refrigerant when the heat pump is in heating mode. When the heat pump is in cooling mode, the water releases heat that is absorbed by the refrigerant in the water coil heat exchanger. Air-to-water heat pumps are often used for domestic water heating and in radiant hydronic systems.

40.2.2 Ground-Source Heat Pumps

A ***ground-source heat pump (GSHP)*** is a heat pump that uses the earth as a heat source or a heat sink for producing the desired temperature in a conditioned space. By circulating water or refrigerant through tubing placed underground or underwater, ground-source heat pumps use the earth's thermal energy to heat or cool a conditioned space. Although outdoor air temperatures may vary by season, the temperature underground or in a body of water remains relatively constant. This allows a ground-source heat

Copyright Goodheart-Willcox Co., Inc. 2017

pump to produce consistent heating and cooling temperatures year round.

Pro Tip

Geothermal Heat Pumps

Since ground-source heat pumps use heat from the earth (geothermal heat) as their source, they are also called *geothermal heat pumps*.

An air-source heat pump's efficiency relies heavily on outdoor air temperature. However, in certain climates, outdoor temperatures can vary drastically, even over the course of a single day. Ground-source heat pumps avoid this temperature variation because their outdoor coil is placed underground or underwater. By determining the range of temperatures to which the outdoor coil will be exposed, a technician can design a ground-source heat pump to function within these parameters with improved system efficiency.

Pro Tip

Outdoor Coil

The term *outdoor coil* is an all-encompassing term that includes the heat exchangers used in both air-source and ground-source heat pumps. In a ground-source heat pump system, the outdoor coil is often referred to as a *ground coil* if it circulates refrigerant underground. It is called a *ground loop* if it circulates water in tubing buried underground or a *water loop* if it circulates water in tubing placed underwater.

Thinking Green

Ground-Source Heat Pump Efficiency

Ground-source heat pumps are recognized by the Environmental Protection Agency as the most efficient heating and cooling systems. They have the highest cooling efficiency and lowest annual operating costs among heat pumps. In addition, ground-source heat pumps offer a renewable energy source that can be used anywhere in the United States and Canada.

Ground-source heat pumps use two different methods to exchange heat with the earth or a body of water: direct exchange and water source. ***Direct-exchange (DX) heat pumps*** are ground-source heat pumps that circulate refrigerant through an outdoor coil that is placed in direct contact with the earth. These heat pumps circulate refrigerant through tubing buried underground. A direct-exchange heat pump system consists of a sealed, underground outdoor coil (ground coil); an indoor coil; a compressor; a reversing valve; and a metering device, **Figure 40-5**.

The majority of ground-source heat pump systems in the United States are water-source systems. ***Water-source heat pumps (WSHP)*** circulate water through a separate, secondary circuit, called a ground loop placed underground or a water loop placed underwater. This water circuit is physically isolated from any refrigerant circuit. The ground or water loop uses the water as a heat-transfer medium to exchange heat with the earth or body of water. This water also flows through a water coil, which is essentially a water-to-refrigerant heat exchanger (often located indoors). This may be similar to water-cooled heat exchangers found in other types of refrigeration systems. Heat transfers in either direction between the water and the refrigerant in the heat pump system, **Figure 40-6**.

When water-source heat pumps are used in moderate and colder climates, it may be necessary to use a solution of water and glycol in the ground or water loop to prevent ice from forming in the heat pump's water coil.

When a water-source heat pump is in heating mode, low-pressure liquid refrigerant flows through the water coil. The liquid refrigerant boils into a low-pressure vapor as it absorbs heat from the water being circulated through the ground or water loop. The vaporized refrigerant is then compressed and discharged into the indoor coil. In this case, the indoor coil functions as a condenser because the vaporized refrigerant turns back into a liquid after giving up its heat to the air circulating to the conditioned space, **Figure 40-7**.

In the summer, the flow of refrigerant is reversed to remove heat from a building. In this case, the indoor coil acts as an evaporator, and the water coil acts as a condenser. The water circulating through the ground or water loop absorbs heat from the refrigerant in the water coil and releases it underground, **Figure 40-7**.

In each case, the refrigerant flow through the compressor is in the same direction. The change from heating mode to cooling mode is accomplished entirely by operation of the reversing valve.

Ground-source heat pump systems can be further classified as open-loop systems or closed-loop systems. ***Closed-loop ground-source heat pump systems*** continuously circulate the same water or refrigerant. Closed-loop systems are used where there is not enough water to support an open-loop system or where local codes prohibit open-loop systems, **Figure 40-8**.

On the other hand, ***open-loop ground-source heat pump systems*** use wells or lakes as their water source. The well or lake serves as both the supply (pump) and discharge (dump) source for the system. Because the water is used by the system and then returned back to the earth, open-loop heat pump systems require a large quantity of clean water.

Figure 40-5. In a direct-exchange heat pump system, the refrigerant exchanges heat directly with the earth by flowing through an outdoor coil that is buried underground.

Caution

Outdoor Coil Placement

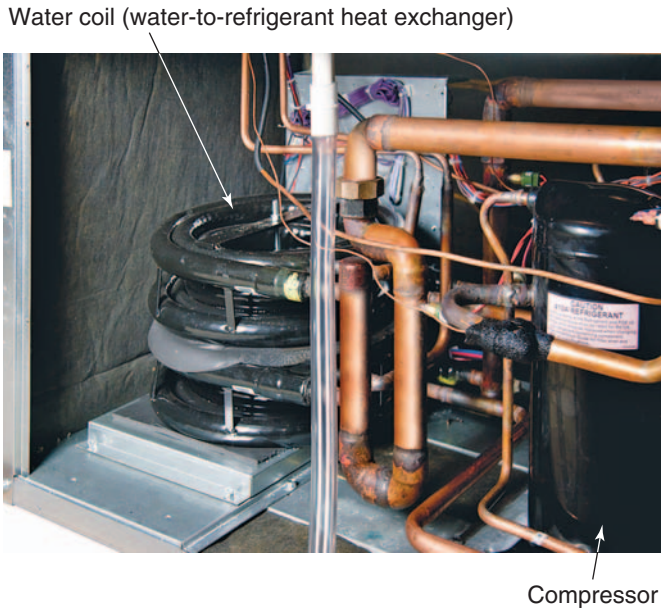
A ground-source heat pump's outdoor coil may be placed in still water, such as a pond or lake. However, an outdoor coil cannot be placed in a flowing body of water because of the risk that the coil could be struck by a moving piece of ice or debris.

40.3 Heat Pump Efficiency

A number of methods have been developed for gauging heat pump efficiency. These methods are often recognized by their acronyms:

- Energy efficiency ratio (EER).
- Seasonal energy efficiency ratio (SEER).

Copyright Goodheart-Willcox Co., Inc. 2017



ClimateMaster

Figure 40-6. In a water-source heat pump system, the water coil exchanges heat between the water that travels through the ground or water loop and the refrigerant that circulates through the system's outdoor coil. Even though this refrigerant coil is located indoors, it is considered the outdoor coil, as it is transferring heat between the refrigerant and outdoors through the water coil.

- Heating seasonal performance factor (HSPF).
- Coefficient of performance (COP).

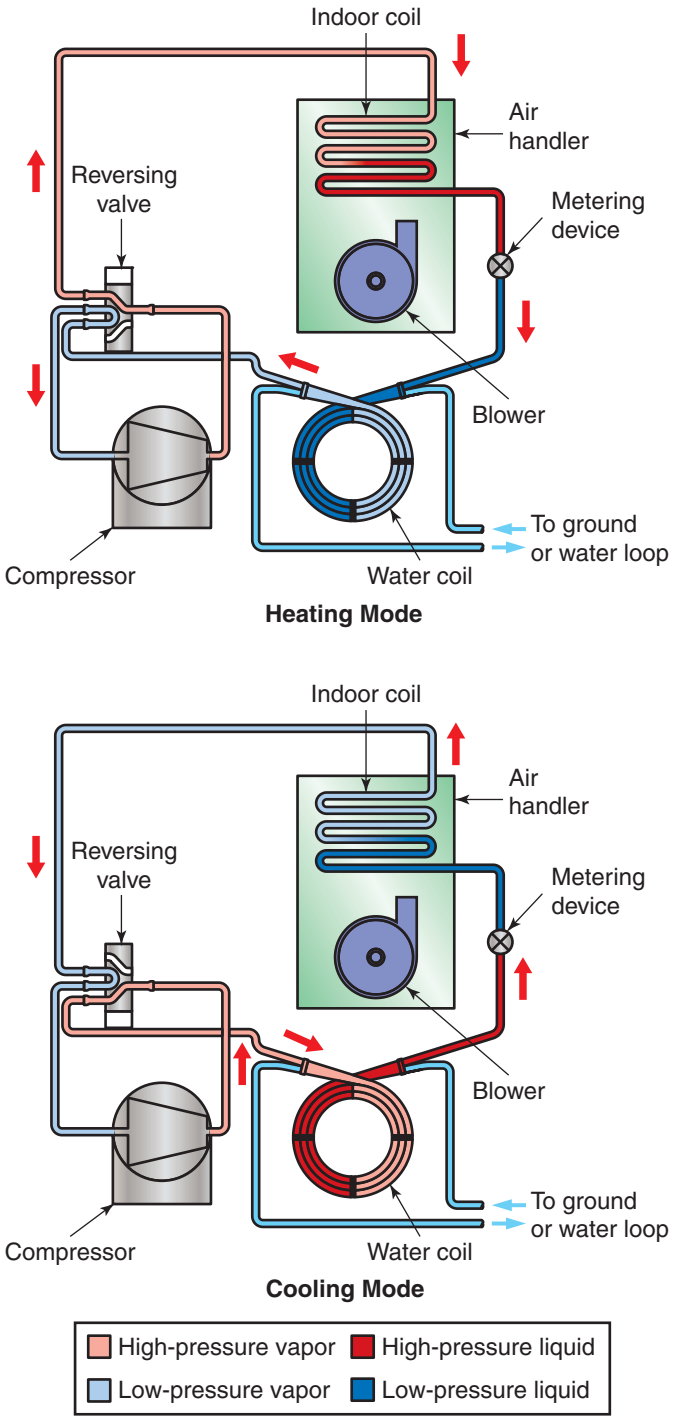
The higher the number rating on a heat pump, the more efficient the heat pump is. Thus, a 13-SEER heat pump is more efficient than a 12-SEER heat pump, and a 7-HSPF heat pump is more efficient than a 5-HSPF heat pump. For more information on how to calculate heat pump efficiency, see Chapter 46, *Energy Conservation*.

The Environmental Protection Agency (EPA) and the Department of Energy (DOE) have also developed a system called Energy Star for labeling energy-efficient, cost-saving products. Items meeting Energy Star guidelines can save consumers 10% to 40% on heating and cooling costs, **Figure 40-9**.

Thinking Green

Heating and Cooling Costs

Residential energy costs account for 20% of all US energy consumption, and nearly 50% of all energy used in the home is for heating and cooling. Purchasing energy-efficient heat pump systems can reduce energy use, save money, and benefit the environment. In an effort to promote energy efficiency, the federal government, state governments, and local municipalities may provide tax incentives to homeowners who replace older, less-efficient systems with high-efficiency units.



Goodheart-Willcox Publisher

Figure 40-7. Water-source heat pump systems use water circulating through a ground or water loop to exchange heat with the system's refrigerant.

The price of operating ground-source heat pumps is very cost-effective compared to electric heating systems and standard gas furnaces in milder climates. They are also cost-effective compared to air-source heat pumps. This is because an air-source heat pump's

Open-Loop Heat Pump Systems

ClimateMaster

Figure 40-8. Closed-loop heat pump systems continuously circulate the same refrigerant or water. Open-loop heat pump systems use water to absorb or release heat and then return that water back to the earth.

Energy Star Qualifying Specifications					
Type of Heat Pump		**SEER**	**EER**	**HSPF**	**COP**
Air-Source Heat Pumps	Split	14.5	12	8.2	
	Packaged	14	11	8	
Ground-Source Heat Pumps	Closed loop (water-to-air)		17.1		3.6
	Closed loop (water-to-water)		16.1		3.1
	Open loop (water-to-air)		21.1		4.1
	Open loop (water-to-water)		20.1		3.5
	Direct expansion		16		3.6

Goodheart-Willcox Publisher

Figure 40-9. Energy efficiency guidelines for heat pumps to qualify for the Energy Star label.

heating cycle becomes less efficient as the outdoor temperature drops. With a lower outdoor temperature, there is less heat available to transfer, which means more energy is used by an air-source heat pump to produce a given amount of heat than would be used by a ground-source heat pump.

Refrigerants evaporate in a heat pump's outdoor coil at a given temperature and pressure. As the outdoor temperature drops, the temperature difference between the air and the refrigerant in the outdoor coil decreases, making it more difficult for the refrigerant to absorb heat from the air. In colder climates, when outdoor air temperatures drop below the evaporation point of the refrigerant, an air-source heat pump cannot be used for heating. Most manufacturers provide a low-temperature value at which an air-source heat pump should not be used for heating.

40.4 Heat Pump System Components

Heat pumps have many of the same components as traditional compression refrigeration systems. However, a heat pump is unique in that it provides both heating and cooling. The principal parts of a heat pump system include a compressor, an accumulator, an outdoor coil, an indoor coil, a reversing valve, one or more metering devices, and one or more fans, **Figure 40-10**.

40.4.1 Accumulators

A heat pump system requires more refrigerant in cooling mode than in heating mode, which means excess refrigerant must be stored somewhere during heating. Due to liquid receiver designs and a heat pump's ability to reverse the direction of refrigerant flow, a liquid receiver placed in the liquid line is not a good way to store extra refrigerant.

The best way to store extra refrigerant in a heat pump system is to install an accumulator in the suction line between the reversing valve and the compressor. In this section of tubing, refrigerant flow does not change direction, as it does in much of the rest of the system. Installing an accumulator in this location

Copyright Goodheart-Willcox Co., Inc. 2017

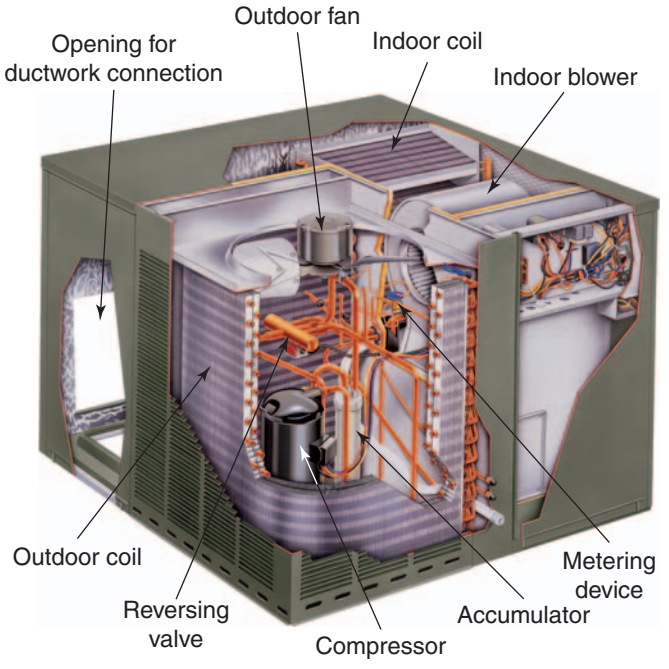
allows it to store extra refrigerant when the refrigerant is not needed and helps to protect the compressor from liquid slugging during the heating mode, **Figure 40-11**.

Some heat pumps use another refrigerant storage device called a charge compensator tank. Like an accumulator, a charge compensator tank is used during the heating mode to store extra liquid refrigerant. A ***charge compensator tank*** is a canister with the heat pump's gas line running through it. However, the gas line only passes through the tank. It does not open inside it. The smaller liquid line is connected to the tank and fills it with liquid refrigerant. During the heating mode, the gas line is colder than the liquid line, causing the warmer refrigerant from the liquid line to condense and flow into the charge compensator tank for storage. During the cooling mode, the gas line is warmer than the liquid line, which causes the liquid refrigerant in the tank to boil and circulate through the system as needed.

Pro Tip

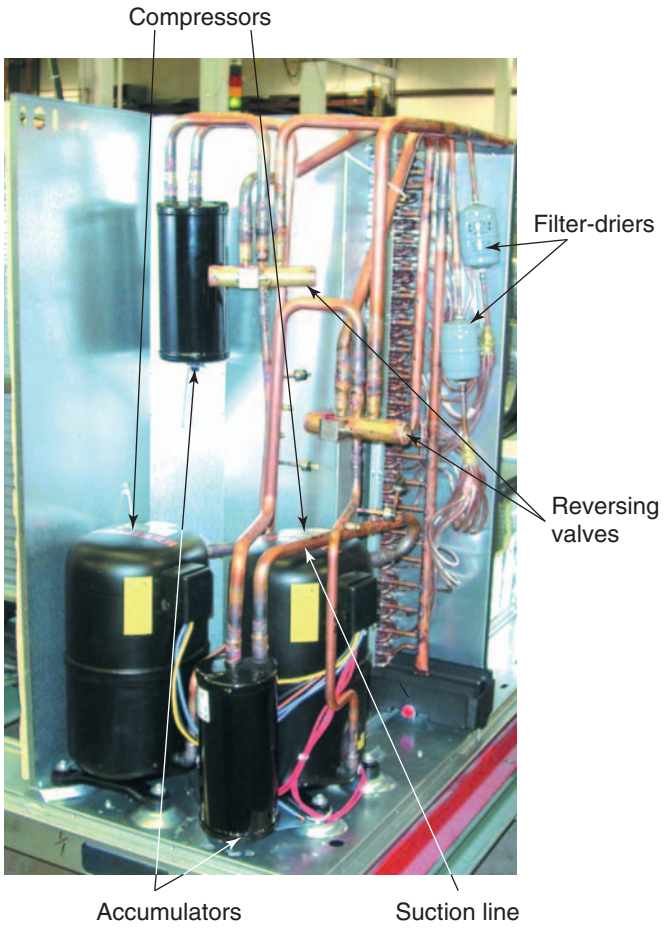
Accumulator Orifices

Heat pumps cannot use the same accumulators as other refrigeration systems. An accumulator used in a heat pump system must have smaller orifices to throttle liquid refrigerant going to the compressor. This is especially important during the winter when colder outdoor temperatures may increase the amount of liquid refrigerant in the accumulator.



Rheem Manufacturing Company

Figure 40-10. Cutaway of a packaged heat pump system showing the system's principal components.



York International Corp.

Figure 40-11. A commercial heat pump system equipped with two compressors and two accumulators. Note how each accumulator is placed in the suction line between the reversing valve and the compressor.

40.4.2 Compressors

Heat pump compressors are similar to compressors in standard air-conditioning units. However, heat pump compressors differ in that they are required to operate at lower ambient temperatures than most air-conditioning compressors. While air-conditioning compressors operate only during warm months, heat pump compressors must operate during both warm and cold seasons.

A heat pump compressor must be designed to handle some liquid slugging without damage. This is done by using slow start-up routines, stronger valves, and other internal component design features. In addition, suction line accumulators and two-way filter-driers are used in heat pump systems to protect the compressor from liquid slugging and contamination. Crankcase heaters also help protect a compressor from any refrigerant that may have migrated to the cold compressor dome and condensed into a liquid during the Off cycle. **Figure 40-12** shows a typical crankcase heater.

Copyright Goodheart-Willcox Co., Inc. 2017

York International Corp.

Figure 40-12. A crankcase heater strapped to the exterior of a compressor dome.

A crankcase heater is an electric resistance heater that warms the compressor dome prior to compressor start-up. This vaporizes any liquid refrigerant that may have entered the compressor during the Off cycle. A crankcase heater also warms up the compressor oil for adequate circulation during low-temperature operation. Crankcase heaters may be designed to fit inside the compressor or to be added to the exterior of the compressor if the unit is used in a cold ambient area.

A heat pump's load not only varies throughout the seasons, but it can also vary throughout a single day. As a result, variable speed compressors are being used with increased frequency to improve a heat pump system's efficiency. Heat pump compressors may be single speed, variable speed, or variable capacity. Single-speed compressors are typically used in residential applications as they are lower in cost than two-speed or variable speed compressors.

For normal heating or cooling loads, a two-speed compressor operates at low speed. When outdoor temperatures are extremely hot or extremely cold, a two-speed compressor operates at high speed for maximum cooling or heating. At high speeds, a two-speed compressor motor operates as a two-pole motor. At low speeds, it operates as a four-pole motor.

Some two-speed reciprocating compressors rotate their motor shaft in one direction for low capacity and rotate in the opposite direction for high capacity. Rotation in one direction engages all of the pistons, while rotation in the other direction engages only some of the pistons.

Variable speed compressors require a separate proportional controller, such as a variable frequency drive (VFD) to produce proper electrical signals to control compressor speed. Variable speed compressors achieve a higher seasonal energy efficiency rating (SEER) than their single-speed counterparts, as they can operate at the proper speed to match system capacity.

Commercial systems sometimes use compressors with a modulating internal unloader to vary capacity. These reciprocating compressors change capacity by operating valves. The valves unload one or more compressor cylinders into clearance pockets.

Outdoor and indoor coil fans may be operated by variable speed motors. This allows the system to match fan speed with the changing system capacities available through the use of two-speed or variable-speed compressors and other methods of variable capacity.

Heat pump compressors with a capacity from 1/3 ton to 1 ton use single-phase motors, often with a start capacitor. If they have dual-voltage settings, these single-phase motors should be operated at 240 V when possible. Using the higher of the two voltage settings permits the use of smaller wires, which cost less than larger wires. Three-phase motors are used in units with a capacity over 1 ton, mainly to improve their electrical performance.

Compressor motors in hermetic systems are usually well insulated to protect from line current voltage fluctuations. Temperature protectors are built into the motor windings and open during compressor overheating extremes.

40.4.3 Metering Devices

In order to circulate refrigerant in either direction, a heat pump must use two metering devices. Each metering device is placed close to the heat exchanger coil into which it meters low-pressure refrigerant. The most commonly used metering devices in heat pumps are thermostatic expansion valves (TXVs). One TXV is mounted at the inlet of the outdoor coil, and the other is mounted at the inlet of the indoor coil. Fixed-orifice metering devices and capillary tubes are also used in heat pumps. Some systems use a capillary tube for one mode of operation and a TXV for the other mode. Metering devices differ with system applications.

Fixed-Orifice Metering Devices and Capillary Tubes

Fixed-orifice metering devices and capillary tubes are not well suited for the changing conditions found

Copyright Goodheart-Willcox Co., Inc. 2017

in most heat pump applications. Because they cannot meter refrigerant flow based on evaporator outlet temperature (as does a TXV), these metering devices must be sized for a specific amount of refrigerant flow. One size fixed-orifice metering device or capillary tube is used for the indoor coil, and a different size is used for the outdoor coil. These types of metering devices may be used in low-volume systems that are designed for a specific outdoor temperature range, but in general, most heat pump systems use metering devices that can produce a variable rate of refrigerant flow.

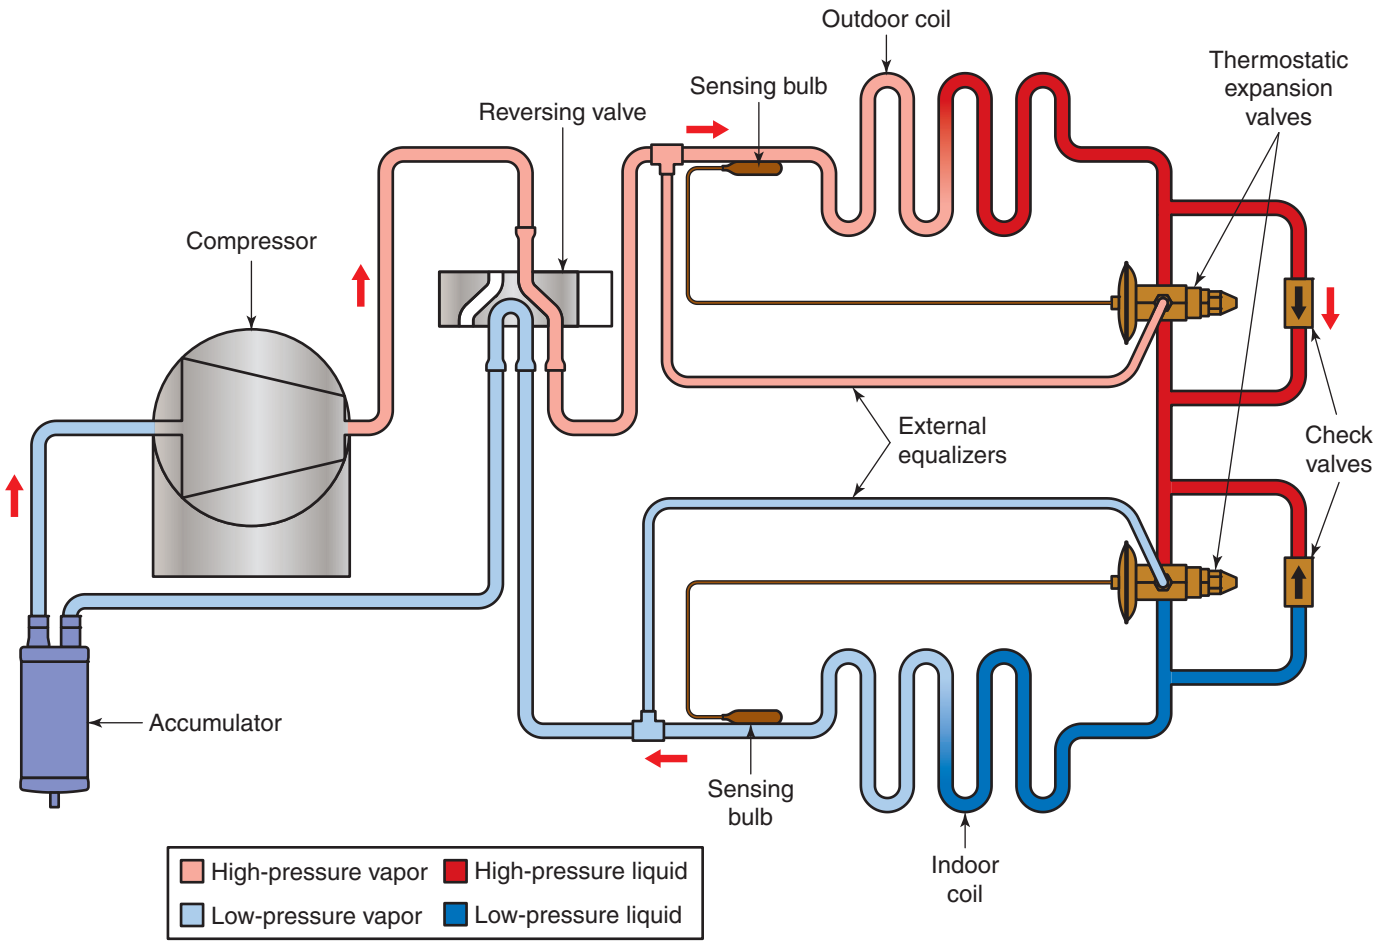
Thermostatic Expansion Valves

Standard TXVs allow refrigerant to flow in only one direction. This is a problem in heat pump systems, where refrigerant must be able to flow in either direction. Even if two TXVs are used facing opposite directions, one will always block refrigerant flow. One solution to allow proper refrigerant flow is to install a check valve in tubing that runs parallel with each TXV. This arrangement allows refrigerant to circulate through the proper TXV for a given mode of operation. When a TXV is not used for a given mode of operation, refrigerant flows through a check valve to bypass that TXV, **Figure 40-13**.

Each TXV is sized for the coil that it feeds. Heat pump TXVs usually have a cross-charged sensing bulb to accurately control the amount of refrigerant delivered to each coil across the heat pump's range of operating temperatures and pressures. For this reason, TXVs designed specifically for use in heat pumps may not be used in conventional air-conditioning systems.

A second solution to reversing refrigerant flow in a heat pump system equipped with TXVs is to use ***biflow thermostatic expansion valves***. These TXVs allow refrigerant flow in either direction. This eliminates the need for bypass lines and check valves around a TXV not in use for one of the modes of operation. However, there are two different types of biflow TXVs: biflow bypass TXV and biflow metering TXV.

A ***biflow bypass TXV*** has a built-in bypass passage regulated by a check valve. When refrigerant circulates



Goodheart-Willcox Publisher

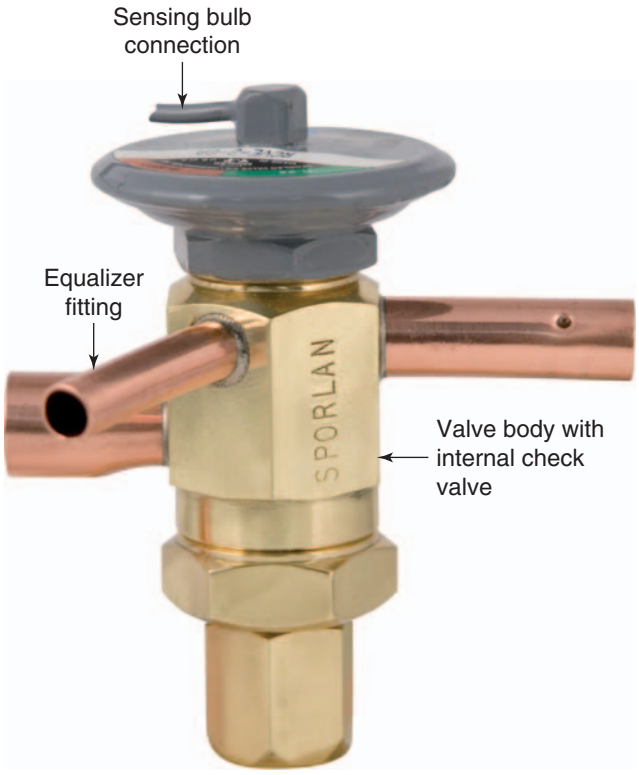
Figure 40-13. If a heat pump system uses thermostatic expansion valves, a check valve in parallel with each TXV provides a path for refrigerant to flow in either direction.

Copyright Goodheart-Willcox Co., Inc. 2017

in the opposite direction of a given TXV's normal flow, the refrigerant is bypassed through a check valve within the biflow bypass TXV. When using these TXVs, a heat pump requires two of these metering devices; however, it does not require external bypass lines with check valves. In this way, less labor and fewer parts are required, **Figure 40-14**.

A ***biflow metering TXV*** meters refrigerant flow in either direction. Whether the heat pump is in heating mode or cooling mode, this one TXV is metering the refrigerant. Biflow metering TXVs require special installation considerations and can only be used in certain systems. Typically, these are used in systems in which the two heat exchanger refrigerant coils are physically located close to each other. Examples of these include packaged air-source heat pumps or some water-source heat pumps.

The sensing bulb of a biflow metering TXV is mounted on the refrigerant line between the reversing valve and the compressor inlet. This setup allows the sensing bulb to always monitor superheat without regard to the system operating in heating or cooling mode. Its external equalizer line must be connected to this same refrigerant line. Since a biflow metering TXV meters refrigerant in either direction of flow, it eliminates the need for two metering devices and any parallel tubing and check valves normally required for a system with conventional TXVs. See **Figure 40-15**.



Courtesy of Sporlan Division - Parker Hannifin Corporation

Figure 40-14. A biflow bypass TXV appears similar to a conventional TXV, but it has an internal check valve that allows refrigerant to flow in either direction through the valve body. Refrigerant is metered in one direction and bypassed in the other direction.

In conventional air-conditioning systems, TXV sensing bulbs are only exposed to the cool temperatures in the suction line, but in a heat pump system, TXV sensing bulbs are exposed to much higher temperatures. For instance, when a heat pump is in cooling mode, hot compressor discharge gas flows through the gas line to which the idle TXV sensing bulb for the heating mode is attached. During the heat pump's heating mode, the TXV sensing bulb for the cooling mode is exposed to the compressor's high-temperature discharge gas in the gas line. These high temperatures may cause the pressure in the sensing bulb to increase enough to burst the bulb or the diaphragm or bellows to which it is attached.

To avoid this problem, heat pumps require TXVs to have a maximum operating pressure (MOP) compatible with the system's coils and compressor. These TXVs have a reduced vapor charge that can exert only a limited amount of pressure to control the TXV. Even when hot discharge gas increases the sensing bulb's temperature, the heat will not increase the pressure enough to burst the sensing bulb or its attached element in the TXV.

Flow Check Pistons

Instead of using TXVs or fixed metering devices, some heat pumps use flow check pistons. A ***flow check piston*** meters refrigerant passing through it in one direction and moves its piston to allow refrigerant to pass freely in the other direction. When refrigerant flows in one direction, the flow check piston meters it to low pressure. When refrigerant flows in the other direction, the flow check piston allows it to pass without a pressure drop. A flow check piston consists of a valve assembly and a piston with a hole in its center, **Figure 40-16**.

When a heat pump coil is acting as a condenser, liquid refrigerant flowing out of the coil is metered through a hole in the center of the piston and then passes into a distributor. With the refrigerant flowing in this direction, the flow check piston provides an even distribution of metered refrigerant into the coil acting as an evaporator. If the flow is reversed, the piston moves back, which permits a free flow of refrigerant without metering.

Depending on the system application, flow check pistons can be used for both cooling and heating modes or for just one mode in conjunction with another

Copyright Goodheart-Willcox Co., Inc. 2017

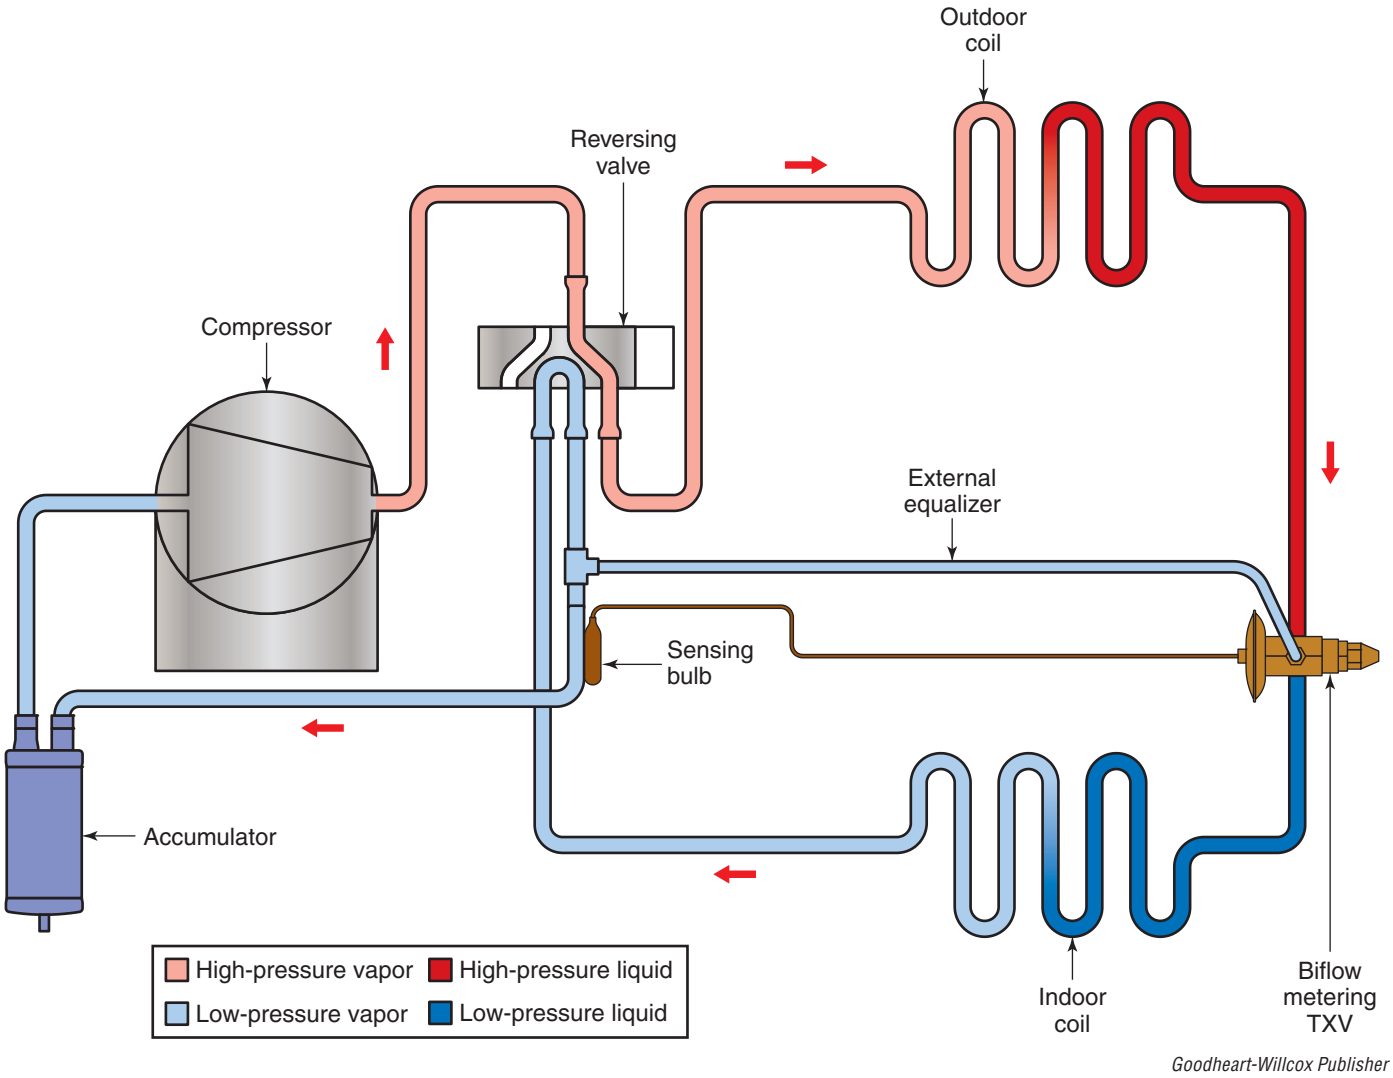


Figure 40-15. A biflow metering TXV eliminates the need for two metering valves in a heat pump.

metering device for the other mode. In some installations, two flow check pistons are used as metering devices between the indoor and outdoor coils. While one flow check piston acts as a metering device, the other opens to allow refrigerant to pass freely. When changing from one mode to the other, the flow check pistons switch functions.

40.4.4 Reversing Valves

A ***reversing valve*** is a four-way manifold controlled by a solenoid valve that can reverse the flow of refrigerant through a circuit, **Figure 40-17**. Inside a reversing valve is a movable section of tubing mounted on a piston. One position directs refrigerant flow for cooling mode, and the other position directs refrigerant flow for heating mode. A reversing valve allows a heat pump system to change from cooling to heating. For cooling, the reversing valve routes refrigerant from the indoor coil to the compressor and then to the outdoor coil. For heating, the reversing valve routes refrigerant from the outdoor coil to the compressor and then to the indoor coil.

Reversing Valve Connections

The four tubing stubs on a reversing valve connect to the suction line (compressor inlet), the discharge line (compressor outlet), the indoor coil, and the outdoor coil. The four tubing stubs are arranged so that a reversing valve has one side with only one stub, while the other side has three. The tubing stub on the side by itself always connects to the compressor discharge line. On the side with three tubing stubs, the middle stub always connects to the suction line. The suction line typically leads to an accumulator before going to the compressor inlet. Each of the two outer tubing stubs connects to either the indoor coil or the outdoor coil.

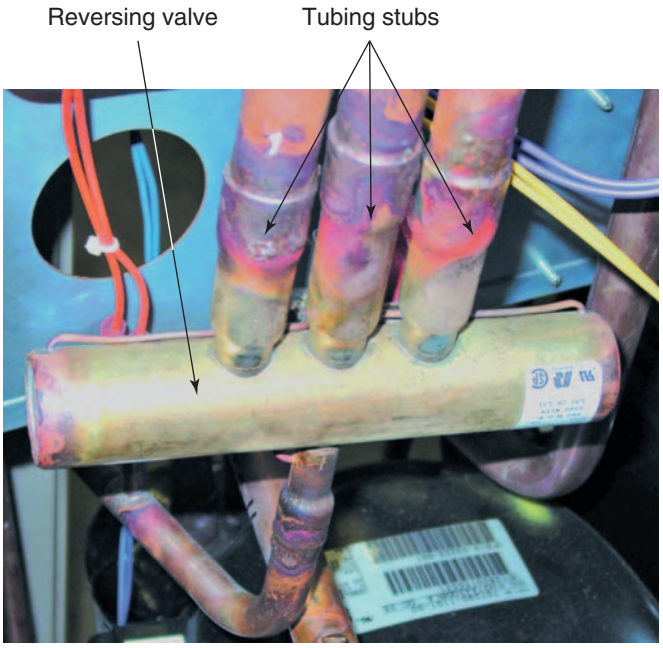
Figure 40-16. Refrigerant flows through a flow check piston where it is metered to a lower pressure and then distributed to either the indoor or outdoor coil.



York International Corp.

Figure 40-17. A heat pump's reversing valve controls the direction of refrigerant flow through the indoor and outdoor coils.

The connections to the two outer tubing stubs of a reversing valve are determined by the solenoid positions. Most heat pump systems are designed so that the heat pump is in heating mode when the solenoid is de-energized. This means that the de-energized solenoid position routes the outdoor coil to the suction line and the discharge line to the indoor coil. This provides a fail-safe that allows a heat pump system to continue to provide heating even if the reversing valve's solenoid burns out and remains in the de-energized position. This arrangement may be referred to as *failing into heating mode*.

However, this is not always the case, especially in warmer climates where heat pumps are used to provide cooling more frequently. In these systems, the solenoid's de-energized position corresponds to the cooling mode, which means the connections to the reversing valve's two outer tubing stubs are switched, **Figure 40-18**.

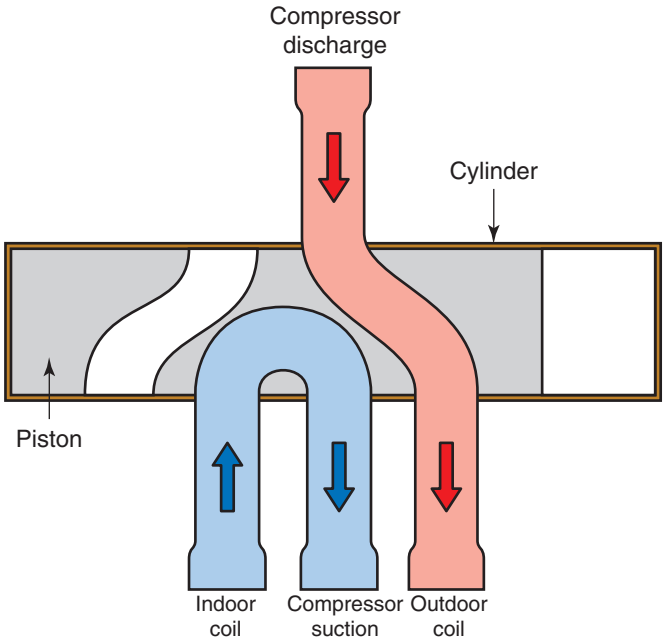
Types of Reversing Valves

There are two types of reversing valves used in heat pumps: direct acting and pilot operated. Smaller heat pumps require less force to move the piston and sliding section of tubing inside a reversing valve. These heat pumps use a ***direct-acting reversing valve***, which uses the direct mechanical action of the solenoid plunger to move the piston and sliding section of tubing inside the reversing valve. This type of reversing valve does not require a pilot solenoid valve.

Larger heat pumps require more force to move the piston and sliding section of tubing in the reversing valve. A ***pilot-operated reversing valve*** uses a solenoid valve to act as a pilot valve to harness the pressure difference between the compressor's suction and discharge lines. This type of reversing valve has capillary tubes from the suction and discharge lines running to the solenoid pilot valve, **Figure 40-19**.

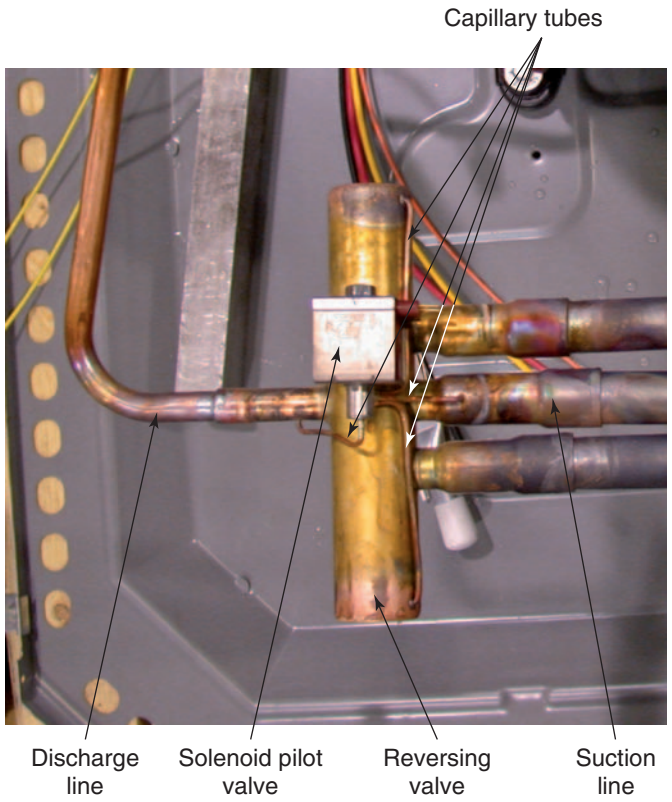
Copyright Goodheart-Willcox Co., Inc. 2017

The capillary tubes provide passageways for high-pressure discharge vapor from the compressor to push against the piston inside the reversing valve, moving it to one side or the other. A signal from a thermostat to the solenoid pilot valve causes the valve to change how the capillary tubes are connected to the suction and discharge lines. This enables the piston and sliding section of tubing to move to the cooling or heating mode position, **Figure 40-20**. Pilot-operated reversing valves are most commonly used in residential and commercial heat pump systems that operate with higher pressure refrigerants, such as R-410A.



Goodheart-Willcox Publisher

Figure 40-18. Even when a reversing valve's solenoid is inoperable or burnt out, the valve's de-energized position allows a heat pump system to provide fail-safe cooling or heating, depending on how the tubing is connected.



York International Corp.

Figure 40-19. A pilot-operated reversing valve has a solenoid pilot valve with capillary tubes connecting the pilot valve, suction line, and discharge line to opposite ends of the reversing valve.

40.4.5 Coils and Loops

Heat pumps have multiple heat exchangers. These heat exchangers circulate either refrigerant or a water solution through the heat pump system as it absorbs and releases heat. The amount of heat pump equipment that is located outdoors varies depending on the type of system. Air-source heat pumps have more equipment outdoors than ground-source heat pumps. An air-source heat pump has an outdoor unit that contains an outdoor coil, fan, compressor, metering device, and various controls. In a ground-source or water-source heat pump system, the compressor, metering device, and controls are usually located indoors in a cabinet unit that may look like some other appliance, **Figure 40-21**.

Figure 40-20. A solenoid pilot valve directs high-pressure vapor from the discharge line to one end of a reversing valve's piston and low-pressure vapor from the suction line to the other end of the piston. When the solenoid is energized, the pilot valve alters the path of vapor flow through the capillary tubes, causing the high-pressure vapor from the discharge line to move the reversing valve piston to the other side.

ClimateMaster

Figure 40-21. A water-to-water heat pump with service panel closed can resemble just another appliance, but it contains the components and controls designed to regulate indoor climate.

Direct-exchange heat pumps have outdoor coils filled with refrigerant that are buried underground. In contrast, water-source heat pumps have ground or water loops that are either buried underground or submerged in a body of water. The types of coils and loops in ground-source heat pumps can be divided into the following classifications:

- Air coil.
- Water coil.
- Ground coil.
- Water loop.
- Ground loop.

Pro Tip

Coils versus Loops

In the HVACR industry, parts and components often have multiple names. In the heat pump sections of this text, the term *coil* generally refers to tubing carrying refrigerant. The term *loop* generally refers to tubing or piping carrying a water-based solution.

Copyright Goodheart-Willcox Co., Inc. 2017

Coils and loops are named for the substances that contact the exterior of the tubing. Be mindful of the following terms and their uses as you study heat pumps:

- An *air coil* contacts air and circulates refrigerant.
- A *water coil* contacts water and circulates refrigerant.
- A *ground coil* contacts the ground and circulates refrigerant.
- A *ground loop* contacts the ground and circulates water.
- A *water loop* contacts water and circulates separate, isolated water.

Air Coils

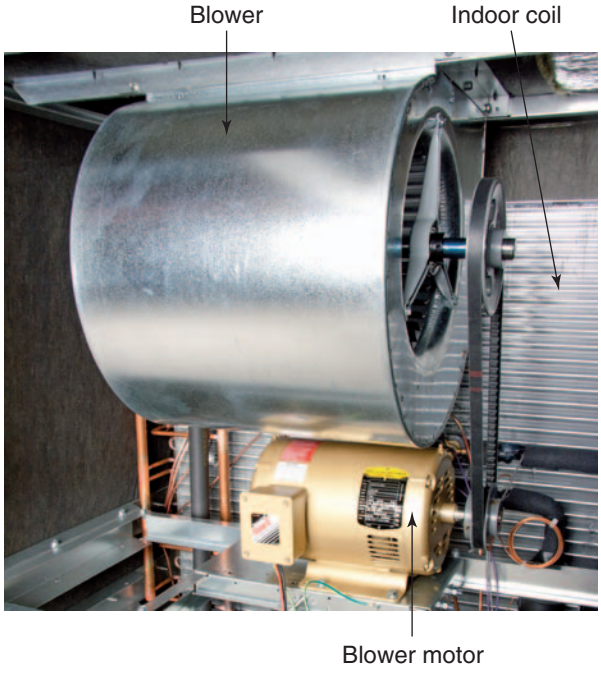
An ***air coil*** circulates refrigerant and absorbs heat from or releases heat to the air. In air-to-air heat pump systems, the indoor and outdoor coils are air coils. Both coils usually have fins bonded to the tubing to increase their surface area and ability to transfer heat. The indoor air coil is normally located in a furnace or air handler. A blower circulates the air being distributed to the conditioned space across the coil, **Figure 40-22**.

The outdoor air coil exchanges heat with the outdoor air and is usually housed in what looks like a condensing unit for a split air-conditioning system. A fan moves air across the outdoor coil to further increase heat transfer. Like a condensing unit, a heat pump's outdoor unit may be mounted on the outside wall of a building, on a roof, or any convenient place that does not restrict airflow, **Figure 40-23**.

Ground Coils

A ***ground coil*** is an underground length of tubing through which refrigerant is circulated in a ground-source heat pump system. It functions as the outdoor coil for a direct-exchange heat pump. This type of ground-source heat pump is called a direct-exchange heat pump because heat is directly exchanged between the earth and the coil of refrigerant, **Figure 40-24**.

Ground coils are made of copper. They are sized by the heat pump manufacturer to match the indoor coil capacity and must be purged and pressure tested before being charged with refrigerant. Compared to water-source heat pumps, which require a secondary loop filled with water to transfer heat to the refrigerant, direct-exchange heat pumps are more efficient because they transfer the earth's heat directly to the refrigerant through the ground coil. However, ground coils must be installed by a certified HVACR technician or licensed contractor. Any leak in a ground coil can be difficult to repair because the coil is buried underground.



ClimateMaster

EarthLinked Technologies, Inc.

Figure 40-24. Direct-exchange heat pump system with copper ground coils arranged in a diagonal configuration.

Water Coils

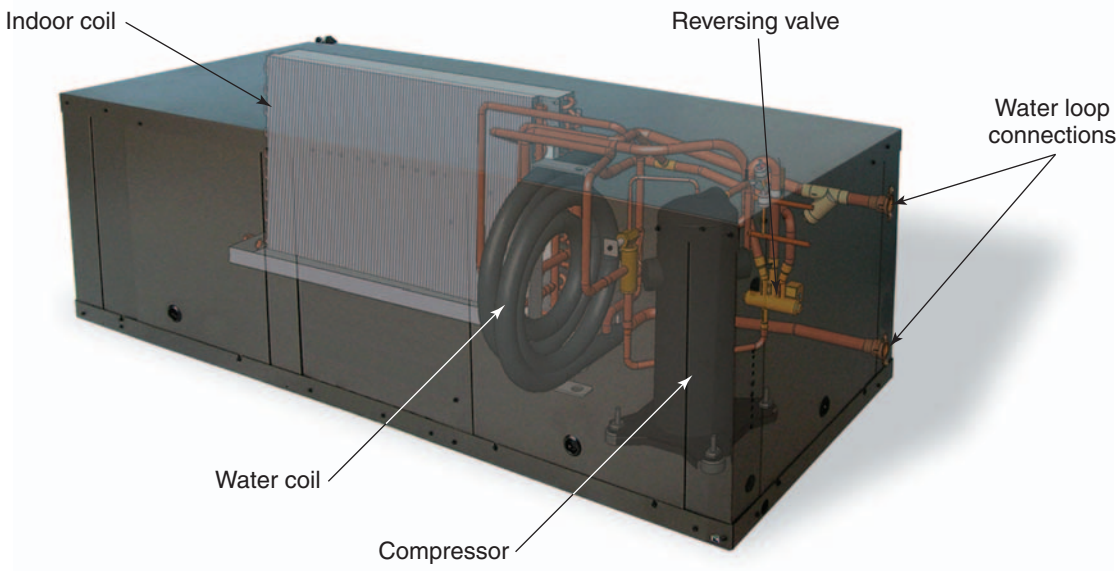
Water-source heat pumps circulate water or water-based solutions in ground loops buried underground or in water loops submerged underwater. Before heat to and from a conditioned space is transferred to a ground or water loop, it must be transferred through a water coil. A ***water coil*** is a heat exchanger where heat is transferred between the refrigerant from the indoor coil and water from the ground or water loop, **Figure 40-25**.

Water coils are often installed inside a building near the indoor coil and heat distribution equipment. In a water coil, refrigerant is pumped through one pathway and water (or a water-based solution) is pumped through an adjacent pathway. The refrigerant circulating through the water coil is the same refrigerant circulating through the indoor coil, and the water circulating through the water coil is the same water that is circulating through the water loop or ground loop. Each pathway is physically isolated, so that the refrigerant and water do not come into contact with each other or mix. Rather, they just exchange heat between each other.

Water Loops

Since bodies of water can maintain fairly steady, moderate temperatures in both warm and cool climates, they make good heat sources and heat sinks. A ***water loop*** is a length of tubing running to and from a water coil and is submerged in a body of water, where it absorbs or expels heat. The tubing is made of polyethylene, formed into loops, and submerged underwater, **Figure 40-26**.

Water loops are used in closed-loop heat pump systems. Water (or a water-based solution) is circulated



Daikin Applied

Corken Steel Products

Figure 40-26. Water loops made of polyethylene tubing ready to be submerged underwater.

through water loops by water pumps, transferring heat to the refrigerant in a water coil. The water does not mix with the refrigerant in the water coil unless a leak has developed. The water in the loop does not mix with the body of water in which the tubing is submerged. The water loop is closed to isolate the water in the loop from the body of water.

Water-based solutions can be made by adding salt, glycol, or alcohol to the water in proper proportions. Some commonly used salts, glycols, and alcohols include the following:

Salts:

- Calcium chloride.
- Sodium chloride.

Glycols:

- Propylene glycol.
- Ethylene glycol.

Alcohols:

- Methyl alcohol.
- Ethyl alcohol.
- Isopropyl alcohol.

Water loops are submerged at least six feet deep in ponds or lakes to avoid any fluctuations in water temperature that occur closer to the surface. The loops should be located about one foot above the bottom of the pond or lake to keep them from being immersed in silt buildup.

Ground Loops

At a depth of four to six feet, the temperature of the earth only fluctuates slightly. This makes the ground at that depth a good heat source and heat sink. A ***ground loop*** is a length of tubing running to and from a water coil and is buried underground, where its circulating water (or water-based solution) absorbs or expels heat. The water in a ground loop transfers heat between the heat pump's water coil and the ground. The tubing for a ground loop is usually made from plastic, such as polyethylene or polybutylene, **Figure 40-27**.

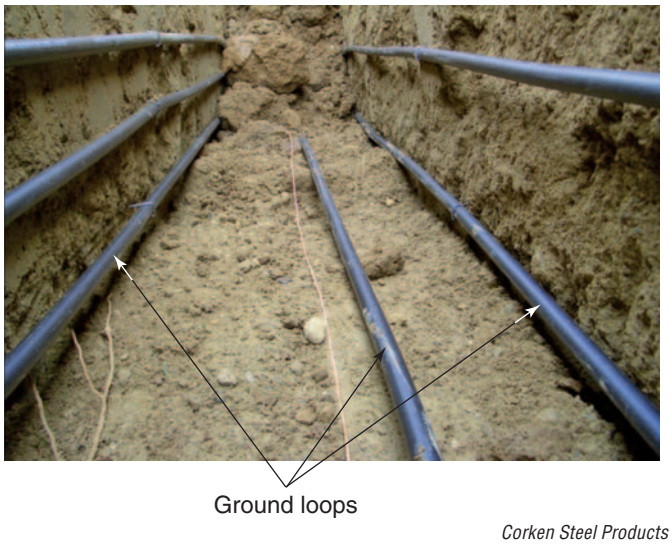
Thinking Green

EIA for Heat Pumps

Water loop heat pumps absorb or reject heat into a lake, stream, or pond. Local and state municipalities may require an ***Environmental Impact Assessment (EIA)*** prior to installation. An EIA can be used to assure that the heat pump system will not affect the quality of the lake, stream, or pond fish life and habitat. Currently there is no consistency in local and state regulations regarding this area, so it is important to determine if an EIA is required prior to installation.

Closed Ground Loops

Ground-source heat pumps that use ground loops may be closed-loop systems or open-loop systems. Closed ground loops have a set charge of water that circulates through the water coil and ground loop. These ground loops are generally buried in one of two different ways: vertically or horizontally. Vertical ground loops may be as deep as 400' and require less ground surface area than horizontal loops, **Figure 40-28**.



Corken Steel Products

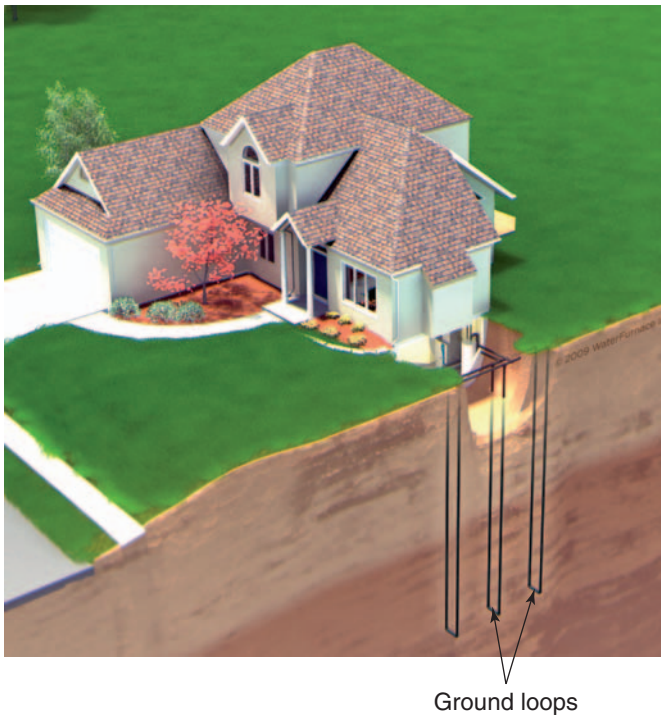
Horizontal Configuration



Vertical Configuration

WaterFurnace International, Inc.

Figure 40-28. Closed ground loops with a horizontal configuration and a vertical configuration.

Vertical and horizontal ground loops can be arranged in series or in parallel. The water in a series loop flows through a single path. Series loops have higher heat transfer, as they have less pressure drop through them. In most cases, fewer tubing connections are required and air pockets are easier to eliminate in series loops than in parallel loops. However, because all of the water is circulated through a single loop, a series loop requires larger sized tubing than a parallel loop, **Figure 40-29**.

A parallel loop provides several different paths for the circulating water to follow underground. Parallel loops can use smaller tubing than series loops for comparable capacity, and less water is needed than in series loops. However, parallel loops pose more difficulty in removing air pockets, may be problematic in balancing pressure among the different branches, and may require more tubing connections.

Open Ground Loops

Open ground loops are used to transfer the water pumped from a lake or well to the water coil and then return the water to either the same body of water or another one. Refer back to **Figure 40-8**. Examples of open ground loops include loops that pump and return water from a well, a river, a pond, or a lake.

Open-loop heat pump systems are considered to have ground loops, not water loops. This is because the heat exchanged with the body of water is ultimately exchanged with the ground that surrounds the body of water. Installation of an open ground loop requires an analysis as to the efficiency of the total system. In addition, ground-source heat pumps either add heat or remove heat from a lake or pond, requiring an environmental impact assessment prior to the installation. Local codes may not allow open ground loops to be installed in certain marine environments.

40.5 Heat Pump Controls

Heat pumps have temperature controls that allow the owner to maximize heat pump usage to achieve periods of high-efficiency heating. During summer cooling, a heat pump system operates just like any other mechanical refrigeration-type of cooling system. During winter heating, however, a heat pump system requires more than just temperature controls to keep the system operating. Defrost controls are needed to monitor ice buildup on the outdoor coil of an air-to-air system, and auxiliary heat is required to provide additional heating during defrost operation or lower than normal temperature conditions.

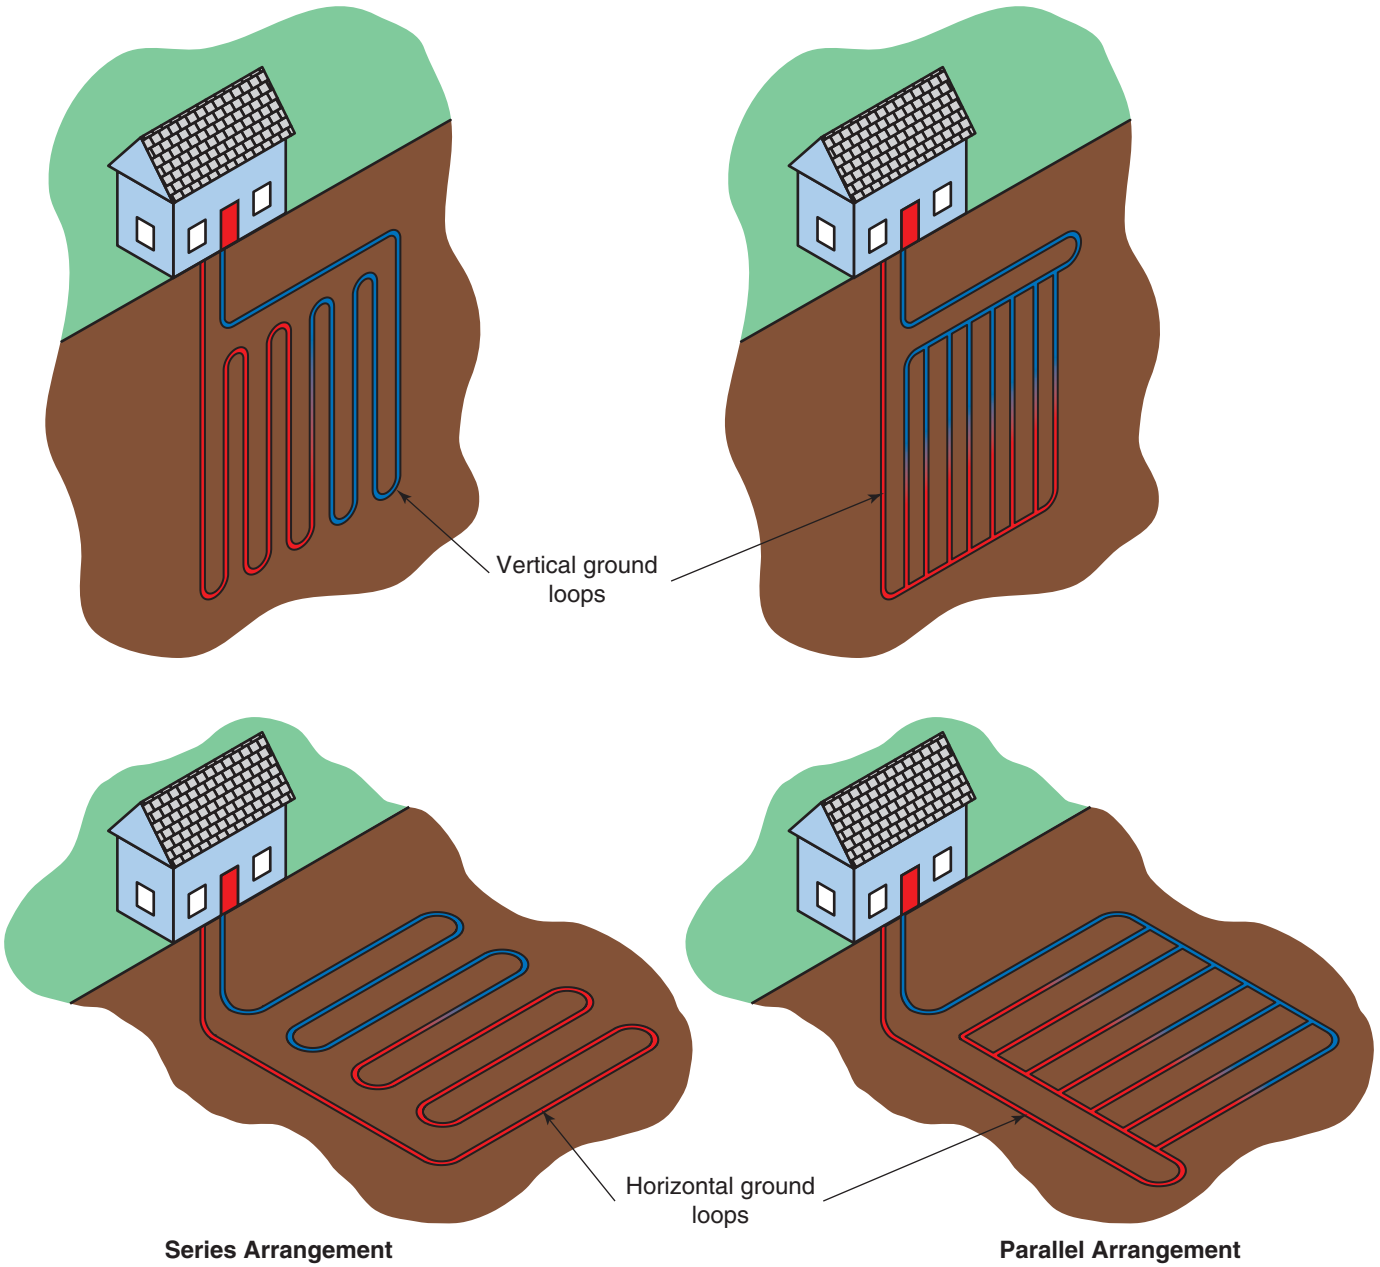
40.5.1 Temperature Controls

In most heat pump systems, the same compressor is used for both the heating and cooling modes. Its operation is controlled by a heating and cooling thermostat, **Figure 40-30**. These thermostats provide the following functions in a heat pump system:

- Turning the system on and off (temperature set points).
- Selecting cooling or heating mode.
- Selecting fan options.
- Initiating auxiliary heat.

A selector switch on the thermostat allows the owner to switch between heating and cooling modes. If the fan switch is in the *Auto* position, the indoor blower

Copyright Goodheart-Willcox Co., Inc. 2017



Goodheart-Willcox Publisher

Figure 40-29. In a series arrangement, all of the water flows through a single path. In a parallel arrangement, each path carries only a portion of the total amount of water.

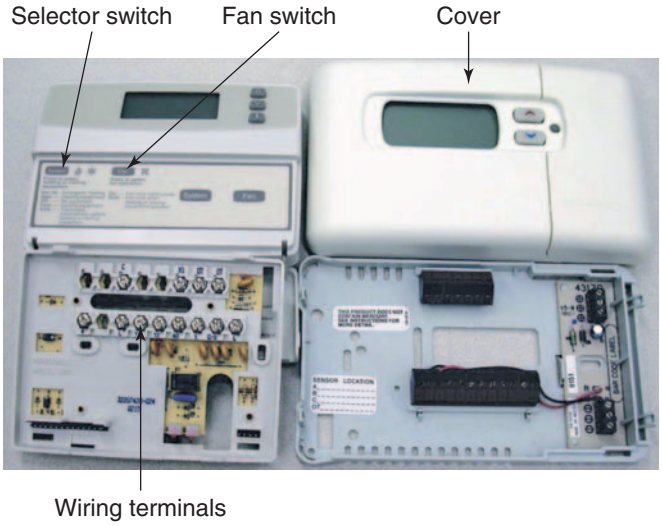
will turn on and off with the compressor during both the heating and cooling modes. If the fan switch is in the *On* position, the indoor blower will maintain continuous operation. If the heat pump system is not responding or if auxiliary heat is needed to maintain the desired conditions, the owner can substitute the auxiliary heat for the system by moving the switch on the thermostat to *Emergency Heat*. Some heat pump systems are also equipped with humidistats, which are useful when humidity is an issue.

Pro Tip

Thermostat Compatibility

Not all system thermostats are designed to be compatible with heat pumps. Heat pumps often require extra controls that are not used with standard central heating and cooling systems. When replacing a thermostat or choosing a thermostat for a new heat pump installation, be certain that the thermostat is compatible for your type of heat pump.

Copyright Goodheart-Willcox Co., Inc. 2017



York International Corp.

Figure 40-30. Disassembled thermostat for a heat pump system showing the thermostat's wiring terminals.

When dealing with thermostats, always refer to manufacturer specifications. Since different HVACR systems may offer different control options, thermostat terminals and wiring colors are not consistent among all manufacturers. However, it is helpful to be familiar with some common wiring terminal identification letters and the functions to which the letters correlate. The following is a list of commonly used thermostat terminal letters and their functions:

- Rh—calls for heat.
- Y1—cooling or cooling/heating stage 1.
- Y2—cooling or cooling/heating stage 2.
- W1—heating stage 1 or auxiliary heat.
- W2—heating stage 2 or auxiliary heat.
- H—humidity control.
- DH—dehumidifier control.
- G—fan control.
- E—emergency heat or auxiliary heat.
- O—cooling mode reversing valve.
- B—heating mode reversing valve.
- O/B—reversing valve.
- L—system monitor or service light/alarm.
- C—common (for 24 V circuits).
- GND—ground.
- OS—outdoor air sensor.
- OD—outdoor temperature sensor.
- ID—indoor temperature sensor.
- Aux—auxiliary output.
- DI1—digital input 1.
- DI2—digital input 2.
- RS—remote room-temperature sensor.
- Scom—sensor common.

Caution

Thermostat Wiring by Letter

When replacing a thermostat, be sure to label each wire with the letter of the terminal to which it is connected as you disconnect each wire. Rather than wiring a thermostat by wire color, wire according to each wire terminal's identification letters, **Figure 40-31**.

40.5.2 Defrost Controls

During winter, air-source heat pumps operating in heating mode sometimes develop frost or ice on the outdoor coil. Ice forms because moisture in the outdoor air condenses on the coil and freezes as heat is absorbed by the refrigerant. Ice formation is possible because the refrigerant inside the outdoor coil is significantly lower than 32°F (0°C).

Frost and ice act as heat insulators and block airflow around the coil, inhibiting heat transfer and reducing heat pump efficiency. Therefore, air-source heat pumps are equipped with defrost controls to prevent and remove ice accumulation (buildup). Heat pump defrost controls are typically initiated by time and temperature. This means that they combine the

DiversiTech Corporation

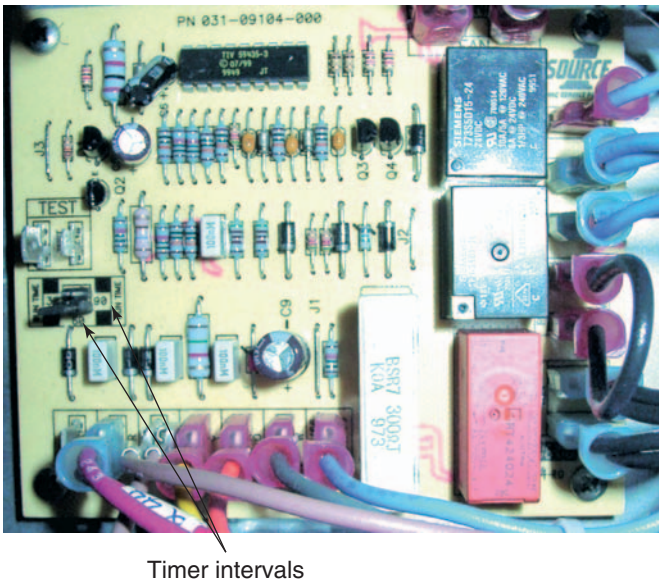
Figure 40-31. Use adhesive wire markers to label wires by their terminals when replacing a thermostat.

Copyright Goodheart-Willcox Co., Inc. 2017

actions of a timer, an outdoor temperature sensor, and a coil temperature (defrost) sensor to initiate the defrost cycle, **Figure 40-32**.

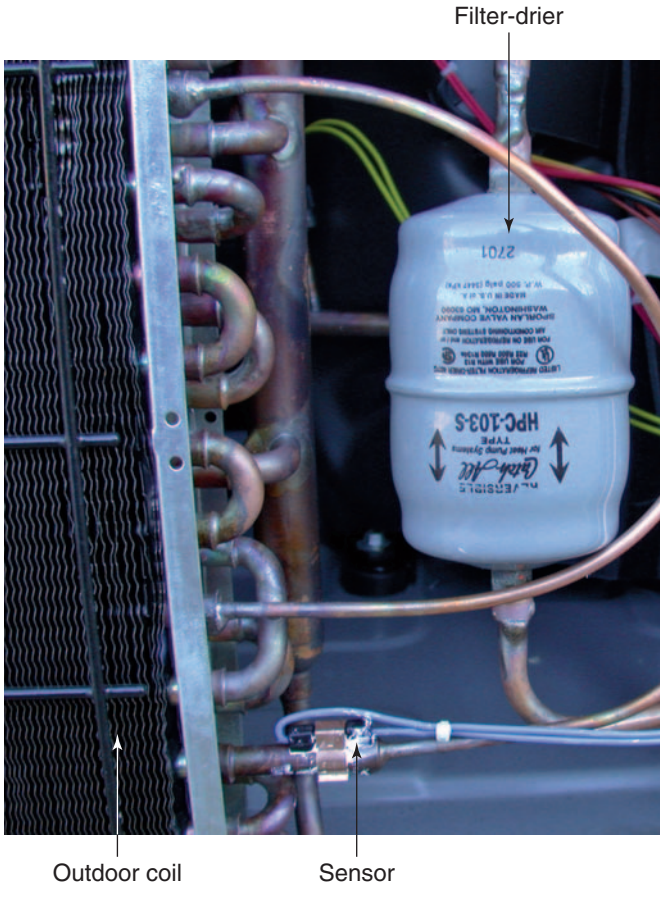
Many heat pump systems use a timer to signal when a defrost cycle is required. This prevents the defrost cycle from constantly interrupting the heating cycle while the heat pump is trying to warm the conditioned space. The timer sends a signal to the system controller at set intervals of time (usually every 30, 60, or 90 minutes) telling it to check the temperature sensors for the outdoor coil and outdoor air. The timer's interval can often be adjusted by arranging jumpers on the system's control circuit board, **Figure 40-33**.

Once the timer sends the signal, the system controller compares the temperature readings of the sensors for the outdoor coil and the outdoor air. If these two temperatures remain relatively stable, there is no frost or ice buildup, and the defrost cycle is skipped until the next defrost interval. However, as ice forms and insulates the outdoor coil, the temperature of the coil begins to drop. This temperature drop happens because the ice on the coil prevents the coil from absorbing heat. If the coil temperature drops low enough, usually below 26°F (–3°C), and the outdoor temperature remains the same, the system controller initiates the defrost cycle.



York International Corp.

Figure 40-33. A control circuit board allows a technician to adjust the timer interval for a heat pump's defrost controls.



York International Corp.

Figure 40-32. A sensor mounted near the outdoor coil is used to detect the outdoor coil's temperature at timed intervals.

Some control systems initiate the defrost cycle based on air pressure. A pressure switch is used to measure the air pressure across the outdoor coil. As ice forms on an outdoor coil, the air temperature drops, which creates a pressure drop. The pressure switch reacts to the pressure drop, initiating the defrost cycle. Oftentimes, a pressure switch is used in conjunction with a time- and temperature-initiated control system. In such a system, three conditions must be met before the defrost cycle can start:

- The timer must be at the defrost interval.
- The pressure switch must detect a pressure drop.
- The controller must determine that a temperature difference exists between the outdoor air and the outdoor coil.

Another method of initiating the defrost cycle relies on measuring the current draw of the outdoor coil's fan motor. As the outdoor coil becomes blocked with ice, the airway through the coil becomes smaller and smaller. This makes the fan draw more current to pull air through the smaller airway. The system controller measures the current draw of the fan motor and activates the defrost cycle if the fan begins to draw too much current.

Manufacturers have also designed heat pumps with defrost control systems that only run when performance begins to negatively affect efficiency. Having

Copyright Goodheart-Willcox Co., Inc. 2017

the defrost cycle on only when it is absolutely necessary is called ***demand defrost***. To achieve this ideal and maintain a high level of system efficiency, manufacturers design the defrost control system to measure additional system variables, such as the temperatures of the discharge line, liquid line, and indoor coil. Demand defrost also turns off the defrost cycle as soon as it has served its purpose. This is accomplished by using sensors to measure the temperatures of the outdoor air and outdoor coil or by having a timer that only allows the defrost cycle to operate for a given period of time, usually ten minutes.

Thinking Green

Minimize Coil Defrost Time

When an outdoor coil frosts or ices over, it can no longer transfer heat efficiently. This makes the system ineffective and wastes energy. However, time spent in defrost mode also reduces system efficiency because the system cannot function in heating mode while it is defrosting. Pressure switches and demand defrost help ensure maximum efficiency by preventing the system from defrosting when it is unnecessary and by keeping defrost cycle times to a minimum.

Reverse Cycle Defrost

Air-source heat pumps have two main defrost methods. In one method, called ***reverse cycle defrost***, refrigerant flow through the heat pump is reversed, which means the heat pump is essentially operating in cooling mode. The indoor coil functions as an evaporator, absorbing heat from the conditioned space, and the outdoor coil temporarily functions as a condenser, releasing heat that melts any ice buildup on the coil.

Caution

Heat Pump Defrost Steam

When an air-source heat pump is defrosting, it may appear that smoke is coming from the outdoor unit. Someone not familiar with this phenomenon may assume part of the system is on fire or burning up. Be sure to inform new owners that an air-source heat pump emitting steam in cold weather is only defrosting and operating as it should.

Reverse cycle defrost involves drawing heat from the conditioned space for just long enough to defrost the outdoor coil. The main difference between standard cooling mode and reverse cycle defrost is that the outdoor coil fan is turned off during reverse cycle defrost. This allows more heat to be concentrated in the outdoor coil, causing the frost to melt faster. Unfortunately, this heat to defrost the outdoor coil is coming from the conditioned space. To alleviate discomfort that might result while defrosting occurs, auxiliary heat is used to warm the cool air being introduced to the conditioned space by the indoor coil. Often, auxiliary heat is in the form of electric heating coils.

Electric Heat Defrost

The second defrost method is *electric heat defrost*, which uses an electric resistance heater near the outdoor coil to melt ice and frost. The heater will operate if the outdoor coil starts to ice over. A low-temperature control shuts off the heat pump's compressor when electric heat defrost is necessary. With the compressor off, the heater can defrost the outdoor coil without the coil continuing to absorb heat, which would make defrosting more difficult. A low-temperature control's cutoff setting is usually predetermined by the manufacturer at 0°F (–18°C). This setting may be adjusted by a technician to meet local temperature conditions.

Pro Tip

Condensate Drain Heater

During the defrost cycle, heat pumps with a condensate drain may require that the outdoor coil condensate drain to be heated, typically with electric heat tape. This ensures that drain water can flow away from the unit without freezing and blocking the drain. If excess ice buildup is found in and around an outdoor unit, check to see if the condensate line is blocked with ice. If it is, the condensate line is not receiving enough heat.

40.5.3 Auxiliary Heat

A heat pump is effective only when the ratio of heat pump output to heat loss from the conditioned space is at or above the ***balance point***. This is the point at which the heat pump's output equals the heat loss of the conditioned space. If the ratio of heat pump output to heat loss is less than the balance point, auxiliary heat is required to prevent the conditioned space from getting colder. ***Auxiliary heat*** is a supplementary heat source that can be turned on automatically at a given set point or manually when it is not possible for an air-source heat pump to extract enough heat from the outside air.

Auxiliary heat is most often supplied by electric resistance heating coils, **Figure 40-34**. These require little space and are located in the air handler plenum. Electric heating coils may also be installed in the supply air ducts to distribute heated air to the conditioned space. In addition, auxiliary heat may be produced by a gas or oil furnace. When a gas or oil auxiliary heat system turns on, the air-source heat pump compressor shuts off.

Copyright Goodheart-Willcox Co., Inc. 2017

Figure 40-34. Electric resistance heating coils are used to provide auxiliary heat in an air-source heat pump system.

Caution

Gas or Oil Furnace Auxiliary Heat

The heat produced by gas and oil furnaces for auxiliary heating cannot blow across a heat pump's indoor coil while the heat pump is operating. This added heat can cause the coil's head pressure to become extremely high and rupture the coil. During seasonal service, check system operation to ensure that the heat pump's compressor is not operating when gas or oil furnace auxiliary heat is operating.

Auxiliary heat is not as efficient to operate as a heat pump. Therefore, when auxiliary heat is running, the entire HVAC system's efficiency suffers. Auxiliary heat should be used only when necessary. The following are three major occasions when auxiliary heat is needed:

- When the outside temperature is so low that the heat pump cannot extract enough heat to keep the conditioned space warm.
- During reverse cycle defrost.
- For emergency operation, when a compressor is inoperable.

An air-source heat pump's heating output is directly related to the outdoor temperature. When the outdoor temperature drops, less heat is absorbed and pumped to the conditioned space. Heat pumps that operate in mild climates—where outdoor temperatures range from 20°F (–7°C) to 110°F (43°C)—typically do not require an auxiliary heat source. However, in colder climates, an air-source heat pump will not be able to produce enough heat to keep a conditioned space comfortable. Auxiliary heat is turned on to assist with the heating load. In such cases, auxiliary heat is automatically controlled by a room thermostat.

Auxiliary heat is also used to offset the cooling effect produced by reverse cycle defrost. When an air-source heat pump operates in reverse cycle defrost, it is essentially running in cooling mode. Heat absorbed by the indoor coil is pumped to the outdoor coil to melt frost or ice, removing heat from a conditioned space that is already calling for heat. By producing some heat, auxiliary heat keeps the defrost cycle from cooling the conditioned space.

If a heat pump's compressor becomes inoperable during the winter, the conditioned space will quickly become cold. Air-source heat pumps often have an *Emergency Heat* setting on the room thermostat. This thermostat setting allows the owner to manually turn off the heat pump and provide the conditioned space with auxiliary heat.

40.6 Heat Pumps and Solar Heating Systems

Variations of heat pumps have been designed to harness solar energy or use waste heat for domestic water heating. Several designs are used to link solar heating systems and heat pumps in residential applications. One system uses a solution of water and ethylene glycol to transfer the heat absorbed by the solar panels to the heat pump system. The solar panels are installed outside and a hydronic coil is placed in the air handler plenum, downstream from the indoor coil, **Figure 40-35**.

The solar panels are sized to meet the auxiliary heating needs of a heat pump. The solar panels absorb heat from the sun and transfer the heat to water in a heat storage tank. This heated water passes from the storage tank through the hydronic coil in the plenum to provide auxiliary heat when needed. The heat pump system will draw heat from the solar panels until the outdoor temperature drops to the point where additional auxiliary heat is required, usually from electric resistance heaters. A liquid-to-liquid heat exchanger can also be installed to provide domestic water heating.

Solar heating systems help heat pumps provide very efficient heating at minimum operating costs. In mild climates with a significant solar load, the solar panels can provide the needed auxiliary heat when the outdoor temperature drops below 20°F (–7°C). The cost of providing auxiliary heat with solar panels can be as little as 40% of the cost of electric resistance heating. However, the overall efficiency of a solar heating system depends on the location of the home and the amount of solar load available during winter months.

Figure 40-35. A solar heating system can provide auxiliary heat for a heat pump and help heat water for domestic use.

40.7 Heat Pump System Service

Heat pump systems differ from combustion heating systems and electric heating systems in their method of heat production. In many ways, heat pump systems are similar to other mechanical refrigeration systems in that they use many of the same operational and control devices. They also have the same purpose as other refrigeration systems, which is to displace heat for a designed purpose using expansion and compression of refrigerant.

Many of the installation and service instructions in Chapter 32, *Residential Central Air-Conditioning Systems* and Chapter 33, *Commercial Air-Conditioning Systems* can be applied to heat pumps. However, as a result of their ability to move heat in either direction, heat pumps are generally more complicated than other air-conditioning systems. Likewise, service performed on heat pumps may be more complicated. Areas of interest include the reversing valve, various sensors, controllers and their settings, and the indoor and outdoor coils.

40.7.1 Heat Pump Installation

Heat pumps must be carefully leveled. Electrical service must be the correct voltage and phase, and the wiring must be large enough to carry the electrical current without a critical voltage drop. See **Figure 40-36**.

Most standard split air-conditioning units do not run in cold seasons, but an air-source heat pump does. In areas where snow falls, airways above and around a heat pump's outdoor unit can become blocked. In cold climates, air-source heat pumps should be installed above the predictable total snow height for that area. This is approximately 8″ to 18″ (20 cm to 46 cm) aboveground in most localities. Always advise the owner to brush or shovel snow away from an air-source heat pump's outdoor unit. However, using ***risers*** is the best way to prevent blocking side airways, **Figure 40-37**.

Heat pump units installed in windows or mounted on walls use some of the same mounting techniques as those described in Chapter 31, *Ductless Air-Conditioning Systems*. A technician should closely follow manufacturer instructions. See **Figure 40-38**.

Figure 40-37. Heat pump risers keep an outdoor unit above the ground and help to prevent blocking side airways.

Inhabitant/Shutterstock.com

Figure 40-38. The outdoor unit of an air-source heat pump mounted on a wall using brackets.

Compared to combustion heating systems, the temperature of the heated air provided by heat pump systems is generally lower at room registers. Therefore, heat pump systems take longer to heat up a cold room than combustion heating systems. This may result in many first-time customer complaints about new heat pump installations.

40.7.2 Heat Pump Maintenance

When servicing residential heat pumps, there are specific procedures that should be performed to ensure maximum heat pump efficiency. The entire system should be inspected and serviced each season before it is used. Although the customer can perform simple maintenance procedures, such as replacing air filters, the following procedures should be performed by a service technician:

- Inspect and tighten all electrical connections. Check for corrosion inside all disconnect boxes and breaker boxes. If applicable and accessible, clean thermostat contact points.
- Check for tightness of thermistors and sensors. Clean and tighten as necessary.
- Inspect and thoroughly clean the indoor coil.
- Clean the indoor condensate drain pan and condensate trap.
- Use a high-pressure air hose to clean the drain line. When done, prime the trap and flush the drain line with one part household bleach to four parts water.
- Clean out duct passages and replace the indoor air filter. Check dampers in ducts and verify proper airflow.
- Clean the indoor blower and rebalance if necessary.
- Lubricate both the motor and blower bearings. Check belts for cracks and replace if necessary.
- Clean the outdoor unit. Apply a non-acid coil cleaner and rinse thoroughly with water. Clean the outdoor unit's base pan and check drainage ports for blockage. Check the gas and liquid lines for sweating or frosting.
- Verify proper voltage and current draw of indoor and outdoor electrical components: fan motors and compressor.
- Measure, record, and adjust (as necessary) the refrigerant charge of the system. Always follow manufacturer procedures. Typically, the refrigerant charge should be checked when the outdoor temperature is above 70°F (21°C) for cooling and below 40°F (4°C) for heating.

Copyright Goodheart-Willcox Co., Inc. 2017

- Measure and record superheat and subcooling values during normal operation.
- Check the operation of the reversing valve by running the system on each cycle. A reversing valve that does not operate must be replaced.
- Run the system and check for leaks and any unusual operational noise. Verify proper operation in the cooling mode, heating mode, and defrost mode.

In addition to performing these maintenance procedures, ask the customer about any problems or concerns. This will build a positive rapport with the customer. In addition, the information the customer provides will assist in diagnosing problems. If the customer reports any problems, the cause of the problem must be located and repaired. Always check the operation of the thermostat before any major changes are made. Review Chapter 36, *Thermostats*, for additional information.

40.7.3 Troubleshooting Heat Pumps

Troubleshooting a heat pump system is a process that involves using a troubleshooting chart. Care must be taken to ensure that a troubleshooting chart from a manufacturer is specific to the unit being serviced. Any additional system components must also be taken into consideration.

Prior to using a chart, a technician should listen to the customer's complaint. Common complaints include insufficient heating, insufficient cooling, excessive operation, and noisy operation. The chart should be carefully studied for all aspects and the appropriate possible causes located. The possible causes determine the test method or remedy to be used. For example, if the customer complains that a system is not working, follow the first column "System Will Not Start" down to the first intersecting row, which lists "Power failure" as the possible cause. The chart shows that the appropriate test method is to test the supply voltage, **Figure 40-39**.

Service Problem Analysis Guide for Heat Pump

Possible Cause	Complaint																				Test Method/ Remedy
	No Heating or Cooling												No Cooling			No Heating					
	System Will Not Start	Compressor Will Not Start—Fans Run	Compressor and Outdoor Fan Will Not Start	Indoor Fan Will Not Start	Outdoor Fan Will Not Start	Compressor Hums—Will Not Start	Compressor Cycles on Overload	Compressor Is Noisy	High Head Pressure	Low Head Pressure	High Suction Pressure	Low Suction Pressure	System Runs Continuously—Little Cooling	Too Cool and Then Too Warm	Not Cool Enough on Warm Days	Compressor Runs Continuously—Little Heat	System Runs—Blows Cold Air	Unit Defrosts—No Frost on Coil	Unit Will Not Terminate Defrost	Unit Will Not Defrost	
Power failure	✓																				Test voltage
Blown fuse	✓																				Inspect fuse type and size
Loose connection	✓					✓															Inspect connections
Shorted or broken wires	✓	✓	✓	✓	✓	✓															Test circuits with ohmmeter
Open overload		✓																			Test continuity of overload

Complaints regarding a foul odor during heat pump operation have become known as ***dirty sock syndrome***. This is due to the description of an odor of gym socks emanating from the room registers. The cause of this problem is the growth of mold and bacteria on the indoor coil. Heat pumps are susceptible to mold growth because their heating cycles are not hot enough to kill the microbes that thrive on the indoor coil during the cooling season. This mold creates a maintenance problem and results in dirty coils, decreased efficiency, dirty drain pans, and excessive energy use. The most successful way to eliminate bacteria and mold is through the use of germicidal ultraviolet lights, **Figure 40-40**.

The ultraviolet light attacks the bacteria and mold and either kills them immediately or prevents them from reproducing. Continued exposure degrades any organic material. Although ultraviolet lights remove almost all of the organic material found on the indoor coil, the plenum area and the drain pan should still undergo periodic chemical cleaning. See **Figure 40-41**.

DiversiTech Corporation

Figure 40-40. An ultraviolet light kit allows a technician to install a UV germicidal light in the best location possible in existing systems.

DiversiTech Corporation

Figure 40-41. Chemical tablets used to destroy odors and maintain a clean drain pan.

Caution

Plastic Drain Pans

Do not shine ultraviolet light on plastic drain pans. Ultraviolet light causes plastic and rubber to deteriorate. Place a shade or cover over the condensate drain pan to prevent ultraviolet rays from contacting any plastic drain pan.

There will be times when a heat pump's reversing valve goes bad and must be replaced. This can be a complicated procedure. There are four separate tubes going to this device that must be disconnected. If disconnecting at the stubs, remember that the tubes will have hardened brazing material that may need to be filed off. If this is necessary, it could be difficult to do this without getting filings down the tubing and into the refrigerant circuit. For this reason and the tightness of the overall fit, some technicians prefer to install all new tubing to the reversing valve. This can make initial fit-up work easier and help prevent filings and other contaminants from getting into the system.

Copyright Goodheart-Willcox Co., Inc. 2017

A reversing valve has certain components that are not designed to withstand the high heat produced by a brazing torch. A wet rag wrapped around the reversing valve's body or heat-blocking paste or gel can help prevent heat damage. Brazing tubing to a reversing valve can be tricky due to its arrangement. Using a tuning fork brazing tip can make the job quicker and easier, **Figure 40-42**.

Chapter Review

Summary

- A heat pump is a compression refrigeration system in which the flow of refrigerant can be reversed to transfer heat into or out of a conditioned space.
- When a heat pump is in heating mode, the outdoor coil functions as an evaporator, and the indoor coil functions as a condenser. In cooling mode, the direction of refrigerant flow is reversed, and the indoor coil functions as an evaporator, while the outdoor coil functions as a condenser.
- Air-source heat pumps use the outdoor air as a heat source or heat sink. Ground-source heat pumps use the ground or a body of water as a heat source or a heat sink.
- In direct-exchange heat pumps, the outdoor coil is composed of tubing coils buried underground, so refrigerant circulating through them directly exchanges heat with the earth. In water-source heat pumps, a loop filled with water acts as the heat-transfer medium between the earth or body of water and the heat pump's refrigerant circuit (water coil).
- Accumulators are installed in the suction line between the reversing valve and compressor inlet to prevent liquid slugging, especially during the heating mode. Instead of an accumulator, some systems use a charge compensator tank installed in the liquid line to hold excess liquid refrigerant.
- The most commonly used metering devices in heat pumps are thermostatic expansion valves (TXVs). A biflow TXV has an internal check valve that allows refrigerant to flow in both directions. Note that there are two different types of biflow TXVs: byflow *bypass* TXV and biflow *metering* TXV. Fixed-orifice metering devices, capillary tubes, and flow check pistons can also be used as metering devices in a heat pump.
- Reversing valves are used to reverse the direction of refrigerant flow through a heat pump system. Direct-acting reversing valves use the direct action of a solenoid plunger to change the valve position. A pilot-operated reversing valve uses a solenoid pilot valve and the pressure difference between the suction and discharge lines to control the reversing valve's position.
- The term *coil* refers to tubing that circulates refrigerant. The term *loop* refers to tubing or piping that circulates water or a water solution. Coils and loops are named for the substances that contact the exterior of the tubing (air, ground, or water). Loops can be further classified as horizontal or vertical, series or parallel, and open or closed.
- The two most common methods for defrosting a heat pump are electric heat defrost and reverse cycle defrost. Reverse cycle defrost briefly reverses refrigerant flow through the heat pump to melt ice buildup on the outdoor coil. Electric heat defrost uses electric resistance heaters to melt ice on the outdoor coil.
- Auxiliary heat is a supplementary heat source that is activated when a heat pump is unable to meet the heating demands of the conditioned space. Auxiliary heat is also used during reverse cycle defrost to keep the defrost cycle from cooling the conditioned space. In some cases, auxiliary heat can function for emergency heat.
- Solar heating systems can be used in combination with heat pumps to provide auxiliary heat and domestic water heating. Depending on climate conditions and installation, solar panel heating can be a cost-effective method of providing auxiliary heat over electric resistance heating.
- When servicing a heat pump system, a technician should inspect electrical connections, clean coils and drain pans, replace filters, check the refrigerant charge, check for leaks, and run the system to check operation in each of the different modes.
- Technicians should always refer to manufacturer-specific troubleshooting charts when they are available. A common problem in air-source heat pumps is dirty sock syndrome, which occurs when mold and bacteria grow on the indoor coil and produce a foul odor. To kill the bacteria and mold on the coil, use a germicidal ultraviolet light. Plenums and condensate drain pans should be regularly cleaned.

Review Questions

Answer the following questions using the information in this chapter.

1. When a heat pump switches from heating to cooling mode, _____.
   A. the blower fan reverses
   B. the outdoor fan turns off
   C. refrigerant flow through the compressor reverses
   D. refrigerant flow through the system reverses
2. When a heat pump is operating in heating mode, the outdoor coil _____.
   A. functions as a condenser
   B. functions as an evaporator
   C. functions as a metering device
   D. is disabled
3. In a heat pump, the direction of refrigerant flow through its compressor _____.
   A. changes direction based on the reversing valve
   B. is always in the same direction
   C. reverses in cooling mode
   D. reverses in heating mode
4. The two main types of air-source heat pumps are _____ heat pumps.
   A. air-to-air and air-to-water
   B. direction-exchange and air-to-water
   C. water-source and air-to-air
   D. water-source and direct-exchange
5. Which of the following statements about air-source heat pumps is true?
   A. As outdoor temperature decreases, the heating mode becomes less efficient.
   B. The reversing valve changes the direction of airflow through a building.
   C. When the heat pump is in cooling mode, the indoor coil serves as a condenser.
   D. When the heat pump is in heating mode, the indoor coil serves as an evaporator.
6. A(n) _____ heat pump uses a water coil to transfer heat between the refrigerant and the ground or water loop.
   A. air-source
   B. air-to-water
   C. direct-exchange
   D. water-source
7. In a direct-exchange heat pump, _____.
   A. refrigerant circulates through a copper coil buried in the ground
   B. water in a ground loop absorbs heat and transfers it to the system through a water coil
   C. a well or lake serves as both the supply and discharge source for the system
   D. None of the above.
8. The amount of liquid refrigerant in a charge compensator tank is affected by the temperature of the _____, which runs through the center of the tank but does not open inside it.
   A. accumulator line
   B. gas line
   C. liquid line
   D. reversing valve
9. A crankcase heater helps protect a heat pump compressor from _____.
   A. current overloads
   B. overheating
   C. migration of liquid refrigerant during the Off cycle
   D. All of the above.
10. In a heat pump system with two thermostatic expansion valves, a _____ is installed in tubing parallel to the TXVs to allow refrigerant to flow in both directions.
    A. biflow TXV
    B. capillary tube
    C. check valve
    D. flow check piston
11. A biflow thermostatic expansion valve _____.
    A. allows refrigerant flow in either direction
    B. cannot be used with a heat pump
    C. has a sensing bulb with an increased gas charge
    D. provides unrestricted refrigerant flow in both directions
12. The tubing stub on a reversing valve that is by itself on one side is always connected to the _____.
    A. discharge line
    B. indoor coil
    C. outdoor coil
    D. suction line

Copyright Goodheart-Willcox Co., Inc. 2017

13. A pilot-operated reversing valve changes valve position by _____.
    A. centrifugal force
    B. a direct-acting solenoid
    C. the forces of suction and discharge pressure
    D. a stepper motor

14. The term *coil* refers to tubing that carries refrigerant, and the term *loop* refers to tubing that _____.
    A. carries water or a water solution
    B. is always buried underground
    C. is arranged in a perfectly circular shape
    D. is the exact same thing as coil

15. A water loop should be submerged at least _____ feet deep in a pond or lake.
    A. 6
    B. 10
    C. 15
    D. 30

16. Ground loops can be subclassified as _____.
    A. series or parallel
    B. horizontal or vertical
    C. open or closed
    D. All of the above.

17. Which heat pump thermostat wiring terminal is used to control the reversing valve?
    A. G
    B. O/B
    C. W2
    D. Y1

18. A heat pump's defrost cycle is typically initiated by _____.
    A. a room thermostat
    B. a temperature sensor
    C. a timer
    D. both a timer and temperature sensors

19. The point at which a heat pump's output equals the heat loss of the conditioned space is the _____.
    A. absolute zero point
    B. balance point
    C. heat transfer equilibrium
    D. zero gain zone

20. In an air-source heat pump, electric resistance heaters may be used for _____.
    B. auxiliary heat
    A. defrost
    C. emergency heat
    D. All of the above.

21. In which of the following situations should auxiliary heat *not* be used? To provide heating _____.
    A. during reverse cycle defrost
    B. if the outdoor temperature drops below the heat pump's operating range
    C. in the event of a compressor failure
    D. when outdoor air temperature is over 65°F

22. During the cold season, an air-source heat pump's outdoor unit runs the risk of having its side airways blocked by accumulating snow. What can be included during installation to reduce this risk?
    A. A constant-operation fan in the outdoor unit.
    B. A crankcase heater.
    C. Risers.
    D. A wall-mounted electrical disconnect.

23. Which of the following service procedures should *not* be performed by a technician during a heat pump system's inspection?
    A. Check the operation of the reversing valve.
    B. Clean the indoor blower.
    C. Replace the indoor air filter.
    D. Vent any extra refrigerant if the refrigerant charge seems high.

24. A problem caused by the growth of mold and bacteria on a heat pump's indoor coil is called _____.
    A. bad breath (halitosis) affliction
    B. dirty sock syndrome
    C. drain pan rot
    D. germicidal apocalypse

25. Which of the following heat pump system components cannot be exposed to ultraviolet light?
    A. Blower wheel.
    B. Indoor coil's aluminum fins.
    C. Plastic drain pan.
    D. Return air duct.

CHAPTER 41 Gas-Fired Heating Systems

Chapter Outline

41.1 Gas Furnace Operation Overview
41.2 Combustion
- 41.2.1 Heat
- 41.2.2 Oxygen
- 41.2.3 Fuel
- 41.2.4 Combustion Efficiency

41.3 Gas Valves
41.4 Gas Burners
- 41.4.1 Atmospheric Gas Burners
- 41.4.2 Power Burners

41.5 Ignition Systems
- 41.5.1 Standing-Pilot Ignition System
- 41.5.2 Intermittent-Pilot Ignition System
- 41.5.3 Direct-Spark Ignition (DSI) System
- 41.5.4 Hot-Surface Ignition (HSI) System

41.6 Gas Furnace Controls
- 41.6.1 Ignition Control Modules
- 41.6.2 Safety Controls
- 41.6.3 Combustion Blower Controls

41.7 Gas Furnace Efficiency
- 41.7.1 Mid-Efficiency Gas Furnaces
- 41.7.2 High-Efficiency Gas Furnaces

41.8 Gas Furnace Venting Categories
41.9 Gas-Fired Radiant Heat
41.10 Gas-Fired Heating System Service
- 41.10.1 Gas Piping Installation
- 41.10.2 Heat Exchanger Service
- 41.10.3 Gas Furnace Maintenance
- 41.10.4 Troubleshooting Gas Furnaces
- 41.10.5 Venting System Installation

Learning Objectives

Information in this chapter will enable you to:

- Identify the components necessary for and products of combustion.
- Understand how the ratio of air to fuel affects combustion efficiency.
- Determine a furnace's combustion efficiency by measuring different flue gas variables.
- Summarize the operation and purpose of gas valves and gas burners.
- Explain the difference between atmospheric gas burners and power burners.
- Compare and contrast the methods used by different ignition systems to initiate and monitor combustion.
- List the functions managed by ignition control modules.
- Identify and explain the operation of various furnace safety controls.
- Describe the differences in design between medium-efficiency and high-efficiency gas furnaces.
- Install piping for a gas-fired heating system and perform a pressure test to check for leaks.
- Inspect a heat exchanger in a gas-fired heating system for leaks and perform other routine maintenance and service procedures.
- Install both horizontal and vertical piping for venting combustion heating systems.
- Classify the different types of materials used for chimneys and flue pipes.

Review of Key Concepts

Reviewing these concepts from earlier chapters will help you understand new concepts presented in this chapter:

- A heat exchanger in a furnace is a chamber where the heat of combustion is transferred to the conditioned air. Heat exchangers also carry combustion gases to the exhaust flue where they are released outdoors. (Chapter 38)
- A solenoid valve is an electromagnet with a movable core, called a plunger, that opens and closes a fluid passage. (Chapter 22)
- A venturi is an internal restriction in a passageway that causes fluid to speed up as it passes through the restriction, creating a low pressure. (Chapter 39)
- Combustion blowers bring fresh air into the combustion chamber and expel combustion gases out through the heat exchanger and flue. There are two types of combustion blowers: induced-draft blowers and forced-draft blowers. (Chapter 38)
- A rollout switch is a safety control that shuts down a gas-fired heating system if the burner flames "roll out" or travel beyond the combustion chamber. (Chapter 39)

Introduction

This chapter covers the process of combustion, the fuel gases used in heating, and the operation of the components in gas-fired heating. The operation of a gas-fired, forced-air furnace starts when a thermostat or other controller calls for heat. When the temperature in the conditioned space drops to the cut-in temperature, the thermostat initiates a call for heat. At the furnace, the heating process begins with the fuel gas.

Copyright Goodheart-Willcox Co., Inc. 2017

41.1 Gas Furnace Operation Overview

In a gas-fired, forced-air furnace, fuel gas is piped to the furnace and kept under constant low pressure by a pressure regulator. This low-pressure gas is controlled by a gas valve. Often, a pressure regulator is built into the gas valve. When heat is called for, a solenoid valve in the gas valve opens to allow fuel gas to pass into a manifold that distributes the gas into individual gas burners. The furnace's safety controls verify certain conditions before igniting the flame. Ignition methods vary and are discussed in detail later in this chapter, **Figure 41-1**.

After ignition, the gas burners continue to release fuel gas, which feeds the flames in the heat exchanger. The part of the heat exchanger containing the flames is called the combustion chamber. Heat from the flames warms the heat exchanger. An indoor blower circulates cool air from the conditioned space across the outside of the heat exchanger. The cool air picks up heat from the heat exchanger and is then distributed through a supply duct system to warm the conditioned space. Fuel gas consumed by the flames in the heat exchanger turns into exhaust fumes that are vented to the outdoors through the flue. In some furnaces, an inverted opening in the flue, called an air break, helps keep a constant pressure in the combustion chamber and prevents back

Copyright Goodheart-Willcox Co., Inc. 2017

pressure from ambient air from reaching the furnace flame. When the thermostat is satisfied, it ends its call for heat and the furnace cycles off.

41.2 Combustion

Combustion is a chemical process of rapid oxidation in which fuel and oxygen produce heat and light. Combustion fuels most commonly used for heating purposes are natural gas, liquefied petroleum (LP) gas, and fuel oil. The physical properties of a fuel are considered when determining requirements for combustion.

The three basic elements necessary for combustion are fuel, heat, and oxygen, **Figure 41-2**. Combustion occurs when the chemicals in the fuel combine rapidly with oxygen. Heat is required to initiate the reaction. As the fuel and oxygen combine, heat and light energy are released. The following chemical formula shows the products of stoichiometric combustion:

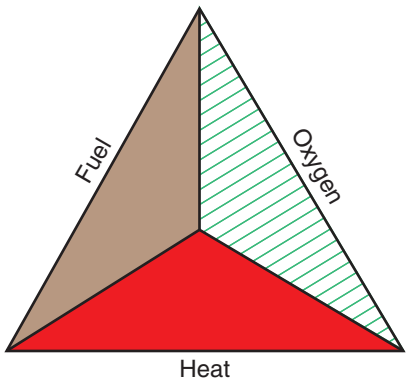
Formula for stoichiometric combustion:

$$CH_4 + 2\,O_2 = CO_2 + 2\,H_2O + \text{energy}$$

where

CH_4 = methane
O_2 = oxygen
CO_2 = carbon dioxide
H_2O = water

Stoichiometric combustion is the term for perfect combustion. In stoichiometric combustion, the burning of fuel occurs with the exact amount of oxygen needed to change the carbon and hydrogen molecules into water and carbon dioxide. Although gas furnaces cannot achieve stoichiometric combustion, they can achieve ***complete combustion***, which occurs when fuel is burned in the presence of excess oxygen to produce water and carbon dioxide. Nevertheless, a technician must understand the formula for stoichiometric combustion in order to analyze the combustion process. The formula shows that in stoichiometric combustion, the ratio of oxygen to fuel (methane) is 2:1 and that the only products of combustion are carbon dioxide, water, and energy.



Goodheart-Willcox Publisher

Figure 41-2. The combustion triangle shows all three components necessary for combustion to occur.

41.2.1 Heat

A concentration of heat is needed to start the chemical process of combustion. The heat required to initiate combustion, called the ***ignition temperature***, is typically provided by a pilot light or a heated surface. The ignition temperature of natural gas is between 1100°F and 1200°F (593°C and 649°C). In comparison, the ignition temperature of LP gas is between 920°F and 1020°F (493°C and 549°C). Once the combustion process has begun, chemical energy stored in the fuel is released and converted to heat and light energy. As long as the fuel and oxygen are present in the correct ratio, no additional external input of heat is required to sustain combustion.

41.2.2 Oxygen

Combustion can occur only when the ratio of air to fuel is within an acceptable range. Although the ideal oxygen to methane ratio is 2:1, the ratio of air to fuel must be much higher (about 10:1 for methane) because the air is made up of about 78% nitrogen and only 21% oxygen. In a mixture of fuel and air, the fuel's ***flammability limits*** are defined as the range of fuel concentrations within which the fuel will burn when an ignition source is present. Each fuel source has unique flammability limits required for combustion. See **Figure 41-3**.

Fuel Gas Flammability Limits

Fuel Gas	Upper Flammability Limit (%)	Lower Flammability Limit (%)
Methane	14.0	5.3
Ethane	12.5	3.2
Natural gas	14.0	4.0
Propane	9.5	2.4
Butane	8.5	1.9

Goodheart-Willcox Publisher

Figure 41-3. The range of fuel concentrations within which proper combustion occurs for various fuel gases. A mixture that is too lean will not burn, and a mixture that is too rich either will not burn or will result in incomplete combustion (unburned fuel in the exhaust).

Copyright Goodheart-Willcox Co., Inc. 2017

For example, for combustion to take place with natural gas, the fuel-air mixture must have a concentration of natural gas between 4% and 14% (to go with 96% or 86% air). The ideal concentration is between 8% and 10% natural gas. A concentration of natural gas less than 4% is too ***lean***, meaning there is not enough fuel for combustion. A concentration of natural gas greater than 14% creates a mixture that is too ***rich***, meaning there is not enough oxygen available for all of the fuel present.

The amount of air required for combustion is different for each fuel. ***Primary air*** is air mixed with fuel prior to ignition. Enough primary air must be available to support ignition. As oxygen is consumed during the combustion process, it must be constantly replaced. ***Secondary air*** is air added to a flame after ignition to support combustion, **Figure 41-4**. Secondary air surrounds the outermost area of a flame and maintains the combustion process. Primary air and secondary air are commonly referred to together as ***combustion air***. This is the air that is necessary for complete combustion.

41.2.3 Fuel

All fuels contain hydrogen and carbon atoms in varying amounts. Substances that contain only hydrogen and carbon are referred to as *hydrocarbons*. Because hydrogen burns more quickly and at a lower temperature than carbon, hydrogen burns first, using the oxygen from the air that it needs for complete combustion. Hydrogen flames are a bluish color.

Since the hydrogen in the fuel burns before the carbon, the carbon atoms must travel to the outside edge of the flame to get oxygen from secondary air for complete combustion to occur. Carbon particles burn more slowly and at a higher temperature than hydrogen. A carbon flame produces a bright yellow light.

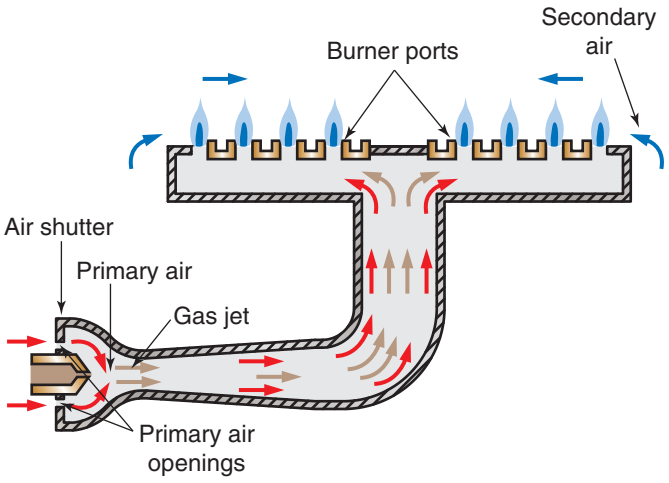
Flame color indicates when a proper amount of primary air is present in a gas furnace. The flame should have a blue inner core surrounded by light blue. This indicates that there is no unburned carbon. ***Incomplete combustion*** occurs when a flame does not receive enough oxygen to finish the combustion process. If there is insufficient primary air, the flame tip will be yellow, **Figure 41-5**.

A yellow tip is due to carbon particles that are not burned. If the outer edges of the flame burn orange, it is due to the burning of dust particles drawn in with the primary air, and it is not a sign of a lack of primary air.

Safety Note

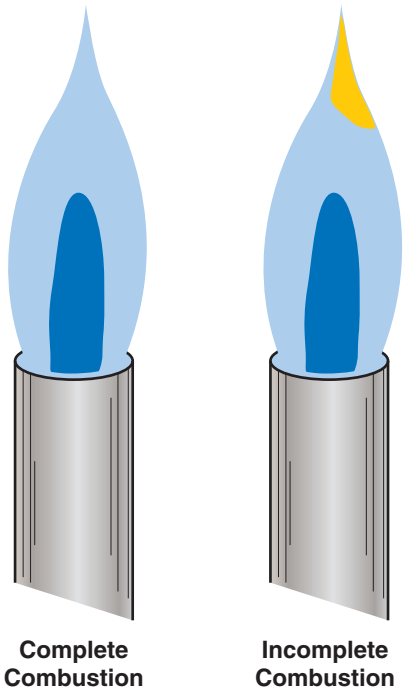
Carbon Monoxide

A by-product of incomplete combustion is carbon monoxide. Carbon monoxide is a colorless, odorless, highly toxic gas that can be fatal to a building's occupants. Therefore, all service calls must include inspection of the flame during operation to check for incomplete combustion. A carbon monoxide meter is a quick method of checking CO levels, **Figure 41-6**.



Goodheart-Willcox Publisher

Figure 41-4. Primary air enters the gas stream prior to ignition through an air shutter. Secondary air surrounds the flames' outermost areas and supports complete combustion of the fuel gas.



Goodheart-Willcox Publisher

Figure 41-5. A lack of primary air causes incomplete combustion. Without enough oxygen, some carbon particles are not being burned, which results in a yellow tip on the flame.

Fluke Corporation

Figure 41-6. A technician using a carbon monoxide meter on a gas furnace.

There are two primary types of fuel gases used in gas furnaces:

- Natural gas.
- Liquefied petroleum (LP) gas.

Natural Gas

Natural gas is obtained from gas deposits in the ground. Natural gas is lighter than air and consists of about 95% methane (CH_4) and 5% ethane (C_2H_6) or other hydrocarbons. Natural gas has a heating value between 1000 Btu/ft^3 and 1100 Btu/ft^3. To burn 1 ft^3 of natural gas, 10 ft^3 of air is required. However, some excess air is needed to prevent the possibility of incomplete combustion. Therefore, about 15 ft^3 of air is used for each cubic foot of natural gas, which provides 50% excess air.

Excess air is any secondary air that exceeds the amount of air necessary for complete combustion. By designing furnaces to take in a certain amount of excess air, manufacturers provide a safety buffer in case of damage or a malfunction that impedes airflow and reduces the amount of air provided for combustion. While furnaces with lower efficiency ratings take in between 20% and 50% excess air to ensure complete combustion, furnaces with higher efficiency ratings use as little as 10% excess air.

Excess air is also important for condensing furnaces as it reduces the dew point of the flue gas. Dew point is the temperature at which a gas condenses into a liquid. By reducing the dew point, excess air causes the flue gas to condense at a lower temperature, ensuring that a furnace will capture the heat of condensation from the flue gas.

As a mix of 1 ft^3 of natural gas and 15 ft^3 of air burns, it yields about 1 ft^3 of carbon dioxide and 2 ft^3 of water vapor. It also yields 12 ft^3 of nitrogen and 1 ft^3 of oxygen, which are leftover from the excess air used in the combustion process. If there is too much primary air, the flame will be noisy and jump around above the burner. If the exhaust contains carbon monoxide (CO), there is either too little or too much combustion air.

LP (Liquefied Petroleum) Gas

LP gas is liquefied petroleum, which consists of liquefied propane (C_3H_8) and butane (C_4H_{10}). Most commonly, this mixture is primarily propane with some butane. Because LP gas is heavier than air, it can be easily liquefied under pressure, stored, and transported in cylinders or tanks. When the pressure is reduced as the LP gas leaves the tank, it vaporizes and changes into its gaseous form before it is burned.

Propane boils at –44°F (–42°C) at atmospheric pressure and has a heating value of 2500 Btu/ft^3. Butane boils at 32°F (0°C) and has a heating value of 3200 Btu/ft^3. Although LP gas can produce more heat per pound than natural gas, it requires more oxygen as well for complete combustion. To burn 1 ft^3 of LP gas, 24 ft^3 of air is required. About 35 ft^3 of air is needed to provide 50% excess air.

41.2.4 Combustion Efficiency

Combustion efficiency is a measure of a furnace's combustion quality, which is essentially its ability to achieve complete combustion. Incomplete combustion can cause a loss of flame temperature, carbon monoxide production, and reduced heat transfer in the heat exchanger. To test a furnace's combustion efficiency, a technician measures the following variables:

- Carbon dioxide content.
- Oxygen content.
- Carbon monoxide content.
- Gas pressure.
- Stack temperature.

Carbon Dioxide (CO_2) Content

Carbon dioxide content is measured as a percentage of the total flue gas being vented to the outdoors. Technicians can use a combustion analyzer to measure carbon dioxide content. To measure the carbon dioxide content in the flue gas, a technician places the analyzer's sensor in the flue or vent pipe. In addition to measuring carbon dioxide content, combustion analyzers

Copyright Goodheart-Willcox Co., Inc. 2017

are often capable of measuring other variables, such as oxygen content, carbon monoxide content, and stack temperature, **Figure 41-7**.

Ultimate carbon dioxide content is the specific amount of carbon dioxide by volume that is present in flue gas when the exact amount of air is supplied to achieve complete combustion. For natural gas, the ultimate carbon dioxide content is approximately 11.9%. LP gas produces around 13.9% carbon dioxide by volume. However, these values do not take into account the excess air that a furnace takes in to ensure complete combustion. This excess air dilutes the amount of carbon dioxide by volume in the flue gas. As a result of excess air dilution, the carbon dioxide content for natural gas furnaces should be closer to 7.6%. For LP gas furnaces, the carbon dioxide content should be approximately 8.9%.

Oxygen (O_2) Content

Since excess air provides excess oxygen to help ensure complete combustion, the oxygen content in flue gas can also be used as a measure of combustion efficiency. For both natural gas and LP gas furnaces, the percentage of oxygen in the flue gas should be between 6% and 9%. Ideally, the percentage of oxygen is 7.5%. This is true for both noncondensing and condensing furnaces.

Bacharach, Inc.

Figure 41-7. A combustion analyzer capable of measuring a number of variables when its sensor is placed in a furnace's flue.

Carbon Monoxide (CO) Content

The presence of carbon monoxide in flue gas is a direct measure of the quality of combustion. Excessive carbon monoxide production indicates that there is incomplete combustion. According to the American National Standards Institute (ANSI), the maximum concentration of carbon monoxide permitted in furnace flue gas is 400 parts per million (ppm). However, many manufacturers specify that a concentration greater than 50 ppm indicates a problem.

Although the correct percentage of carbon dioxide (or oxygen) in flue gas is vital for determining combustion efficiency, the correct percentage only indicates complete combustion if there is no carbon monoxide being produced. For example, in a natural gas furnace, the flue gas can have a carbon dioxide content of 6.7%, an oxygen content of 9%, and a carbon monoxide content of 200 ppm. These values are all relatively close to the desired values. However, since the carbon dioxide content is low and the oxygen content is high, the presence of carbon monoxide is most likely an indication that there is too much excess air. Too much excess air decreases the flame temperature and allows some carbon monoxide molecules to pass through the combustion zone without burning. On the other hand, if the carbon dioxide content is high and the oxygen content is low, the presence of carbon monoxide may indicate that there is a lack of air to mix with the fuel, **Figure 41-8**.

Gas Pressure

Gas pressure is another factor that can affect a furnace's combustion efficiency and cause the production of carbon monoxide. An increase in gas pressure can cause incomplete combustion due to a lack of air to mix with the increased amount of gas. Thus, increased gas pressure leads to similar conditions as a lack of air: high carbon dioxide content and low oxygen content in

Acceptable Amounts of Combustion Products in Flue Gas

Combustion Product	Natural Gas	LP Gas
CO_2	7.6%	8.9%
O_2	6–9% (ideally 7.5%)	6–9% (ideally 7.5%)
CO	Less than 50 ppm	Less than 50 ppm

Goodheart-Willcox Publisher

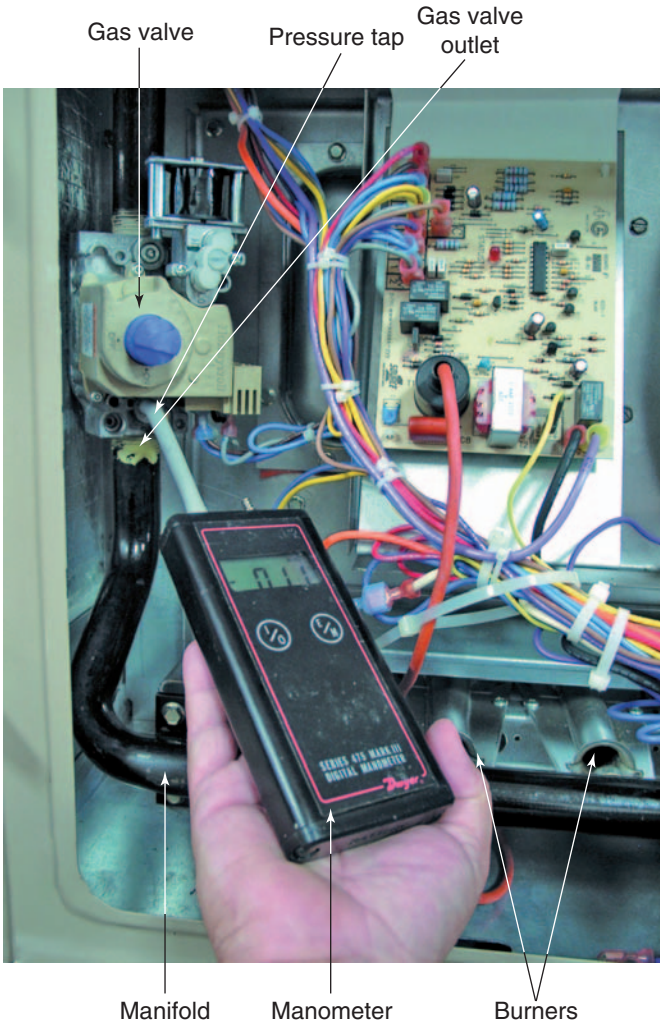
Figure 41-8. Range of desirable measurements for a combustion analyzer.

Copyright Goodheart-Willcox Co., Inc. 2017

the flue gas. A decrease in gas pressure decreases the flame temperature and leads to similar conditions as too much excess air: low carbon dioxide content and high oxygen content in the flue gas.

Since both the amount of excess air and the gas pressure produce similar variations in carbon dioxide content and oxygen content, a technician must check the gas pressure to make sure that it is not the cause of the problem. Gas pressure is checked at the gas valve manifold using a manometer, **Figure 41-9**.

Gas pressure to a gas-fired furnace is usually very low, so it is measured in inches of water column (in. WC). Inches of water column are used to measure small pressures above or below atmospheric pressure. About 28 in. WC equals only 1 psi. The gas pressure for natural gas should be 3.5 in. WC, and the gas pressure for LP gas should be 10.5 in. WC.



York International Corp.

Figure 41-9. A manometer is connected to a pressure tap on the gas valve to measure the pressure of gas entering the manifold.

Stack Temperature

Stack temperature, also called *net stack temperature*, is the temperature of the flue gas in the flue minus the temperature of the combustion air. When combustion air enters from the furnace room at room temperature, stack temperature is essentially flue gas temperature minus room temperature. When combustion air is drawn in from outside, the temperature is colder.

Flue Gas Temperature
– Combustion Air Temperature
Stack Temperature

Stack temperature is directly related to the amount of excess air and inversely related to a furnace's efficiency. As excess air increases, a furnace's stack temperature also increases, and the furnace's efficiency decreases. This is because the increased excess air carries more heat through the flue to the outdoors. The result is an increased stack temperature, which indicates that less heat is being transferred in the heat exchanger to the air circulated through the ductwork. Less excess air and lower stack temperature result in more efficient furnace combustion, **Figure 41-10**.

In general, there is about a 1% decrease in efficiency for every 40°F increase in stack temperature. The stack temperature in noncondensing furnaces should be between 325°F and 500°F (163°C and 260°C). For condensing furnaces, the stack temperature should be less than 140°F (60°C).

41.3 Gas Valves

In older furnaces, a gas valve was a simple solenoid valve that controlled the supply of gas to the manifold and burners. A separate pressure regulator set the gas pressure for the furnace. One solenoid valve controlled gas supply to the pilot, and another solenoid valve controlled gas supply to the burners. Over time, these components

Combustion Efficiency (%)						
Excess (%)		Net Stack Temperature (°F)				
Air	Oxygen	200	300	400	500	600
9.5	2.0	85.4	83.1	80.8	78.4	76.0
15.0	3.0	85.2	82.8	80.4	77.9	75.4
28.1	5.0	84.7	82.1	79.5	76.7	74.0
44.9	7.0	84.1	81.2	78.2	75.2	72.1
81.6	10.0	82.8	79.3	75.6	71.9	68.2

Goodheart-Willcox Publisher

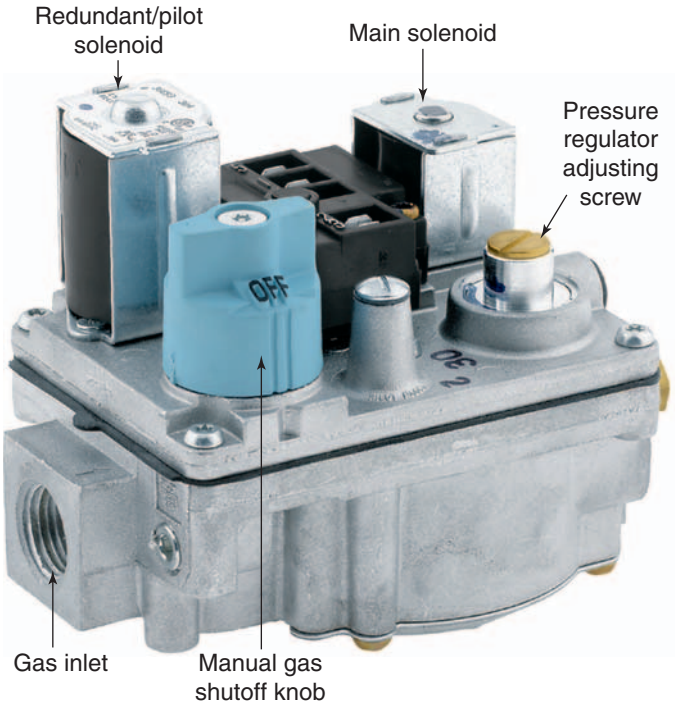
have been combined into a single gas valve to adapt to changing functions within gas furnaces. A single gas valve—containing features such as a manual shutoff valve, multiple solenoid valves, a pressure regulator, and adjustment and safety shutoff for the pilot—is called a ***combination gas valve,*** **Figure 41-11**.



Emerson Climate Technologies

Figure 41-11. A combination gas valve combines the functions of multiple solenoid valves with a pressure regulator.

While a combination gas valve has a manual shutoff valve to control gas flow, gas flow is typically controlled by a thermostat's signal to the gas valve. In older furnaces with pilot ignition systems, one solenoid valve in the gas valve opens for the pilot when the thermostat calls for heat. Once safety controls have verified that the pilot is lit, a second solenoid valve in the gas valve opens for the burners to ignite. After gas flows through the gas valve, it is distributed to individual burners by a manifold. See **Figure 41-12**.

Pro Tip

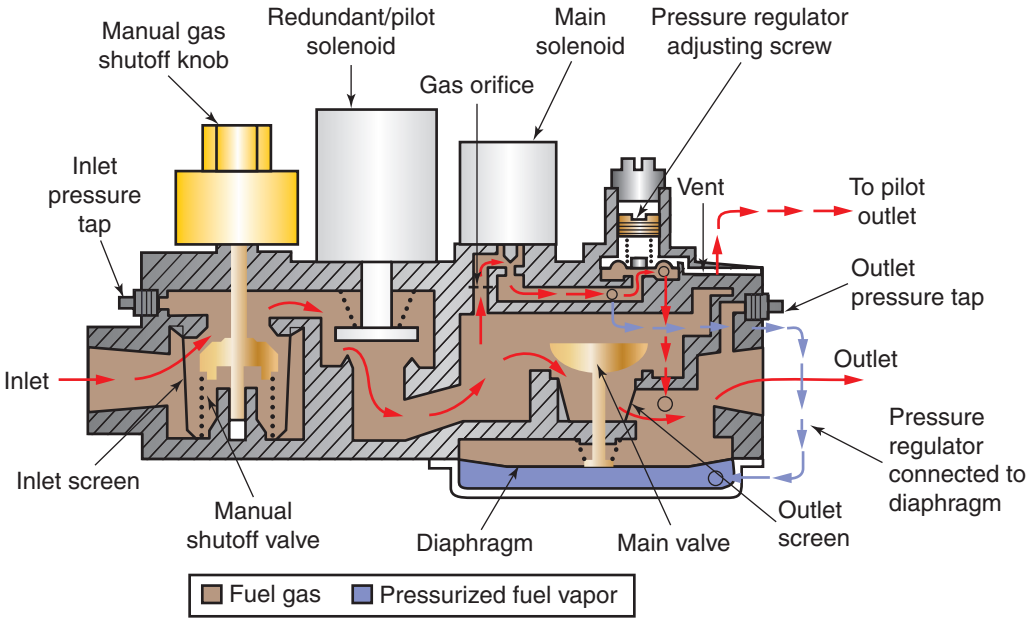
LP Gas Pressure Regulators

Natural gas furnaces usually have a pressure regulator built into the gas valve. However, LP gas furnaces often have a pressure regulator that is separate from the gas valve.

41.4 Gas Burners

A ***gas burner*** is a device that mixes primary air and fuel gas from a manifold to burn a flame aimed into a furnace's heat exchanger. Gas combustion occurs at a furnace's gas burners.

Gas burners have a simple design. Gas is carried to the burner assembly through a pipe with multiple openings, called a ***gas manifold***. Gas manifolds have small sockets into which spuds are installed. ***Spuds*** are burner attachments with specially sized orifices that direct an exact amount of gas into the gas burner. They are typically threaded into the gas manifold, **Figure 41-13**.



White-Rodgers Division, Emerson Climate Technologies

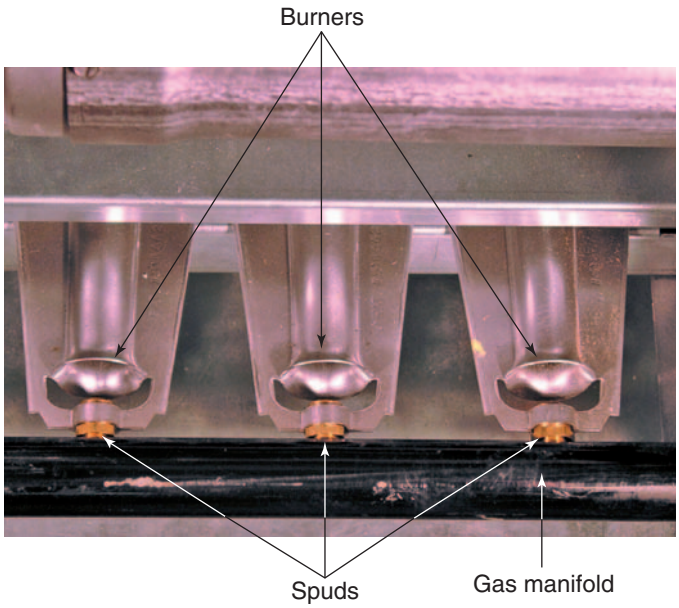
Copyright Goodheart-Willcox Co., Inc. 2017



York International Corp.

Figure 41-13. Spuds are typically threaded into the gas manifold and are replaceable.

Gas mixed with a certain amount of primary air is fed through the orifice in the spud. This mixture passes to the burner where combustion takes place and the burning gas mixes with the secondary air.

Caution

Spud Orifice Size

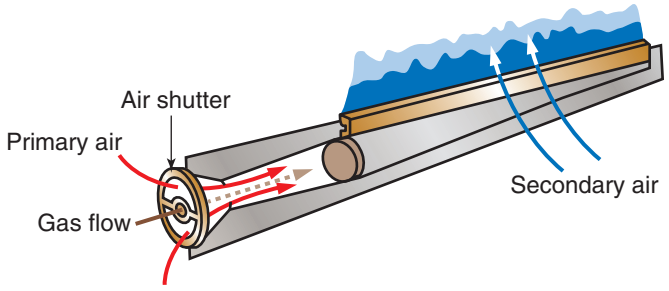
The rate of gas flow through the orifice in a spud depends on the gas pressure and the specific gravity of the gas. At equal pressure, less LP gas will flow through an orifice than natural gas because LP gas is heavier. As a result, when converting a natural gas furnace to an LP gas furnace, remove and replace the spuds with a different orifice size for the different flow necessary for LP gas.

Gas burners are used in forced-air furnaces, unit heaters, and boilers for hydronic systems. They ensure the proper mixture of primary air and gas, so it can be readily ignited and burned. There are two types of gas burners:

- Atmospheric burners.
- Power burners.

41.4.1 Atmospheric Gas Burners

An ***atmospheric gas burner*** uses the siphoning action of gas flow through the orifice to induce airflow through the burner without the need for a blower. Atmospheric gas burners are usually constructed of steel and may be of varying lengths and sizes. Gas burners in older furnaces have primary air shutters that can be adjusted to regulate the amount of primary air that is added to the mixture, **Figure 41-14**. Newer furnaces no longer have adjustable air shutters.



Goodheart-Willcox Publisher

Figure 41-14. An air shutter controls the amount of primary air that is mixed with the fuel gas prior to ignition.

The bodies of atmospheric gas burners have an hourglass shape. They are narrower in the center and wider at the two ends. The narrower section of the burner produces a ***venturi effect***, which is the reduction in pressure that occurs when a fluid flows through a constricted section of pipe. As gas enters an atmospheric gas burner, it must speed up as it passes through the narrow area. This creates a low pressure, which draws in air from the primary air shutter. The primary air mixes with the fuel gas as they pass through the narrow, constricted center of the gas burner. The venturi effect produced by the narrow passage also causes the fuel gas and air to swirl into a mixture.

There are three different styles of atmospheric gas burners: ribbon, slotted, and single port. These three styles are classified by how the fuel gas and air are fed into the flame. ***Ribbon burners*** feed the fuel gas and primary air mixture along the length of a burner producing a solid flame on top. ***Slotted burners*** feed a mixture of fuel gas and primary air through a series of narrow slots, **Figure 41-15**.

Single-port burners can be manufactured in a variety of patterns to meet specific design needs. The most efficient single-port burner is the ***inshot burner***. An inshot burner directs the mixture of air and fuel gas through a large orifice to produce a large flame that is directed into the heat exchanger, **Figure 41-16**. Due to efficiency and the design of heat exchangers, most new furnaces use inshot burners.

Pro Tip

Gas Furnace Capacity and Altitude

As altitude increases, the capacity of a furnace decreases because there is less air and, as a result, less oxygen. To compensate for less oxygen, a smaller orifice must be used in a gas burner so that less fuel is fed through the orifice. A burner orifice correction must be made when at altitudes over 2000′ (610 m).

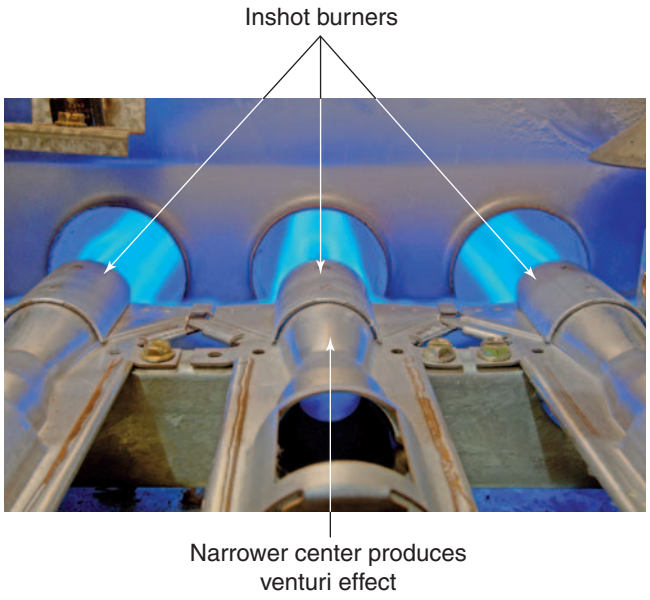
Figure 41-15. A slotted burner.



Carolina K. Smith MD/Shutterstock.com

Figure 41-16. Inshot burner flames aimed into a heat exchanger.

41.4.2 Power Burners

A ***power burner*** is a type of gas burner that uses a blower to force both primary and secondary air into the burner tube. The burner tube has angular deflector plates to spin or twirl the flame for more efficient burning, **Figure 41-17**.

A spark igniter or glow coil is used for igniting the flame. Power burners are not common in residential gas furnaces. Most are found in larger commercial or industrial applications. The use of fuel oil requires a power burner. Power burners are able to achieve higher burning efficiency due to their ability to better control the ratio of fuel to air.

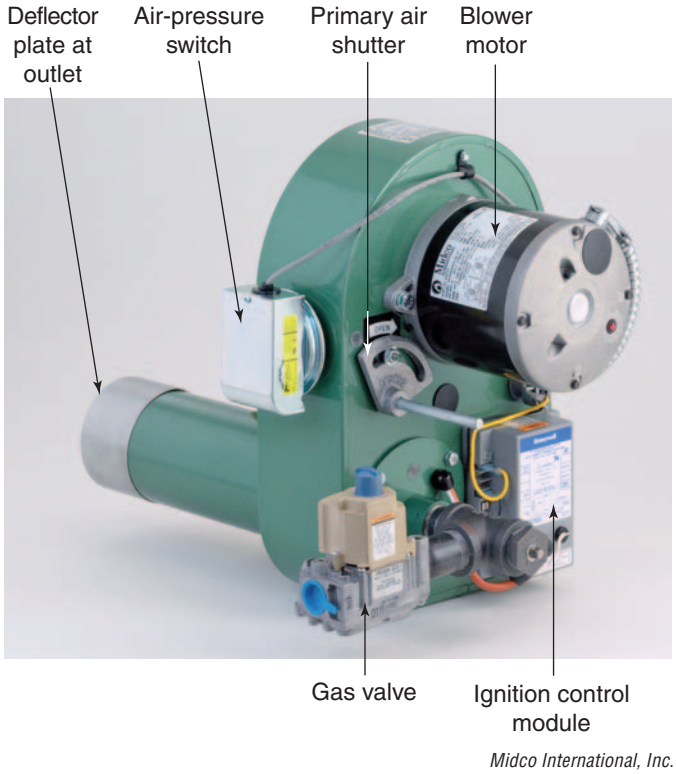
41.5 Ignition Systems

The purpose of an ***ignition system*** is to light a burner safely and monitor for continued safe operation. An ignition system is controlled by a furnace's ignition control module. There are four types of ignition systems used in gas furnaces:

- Standing-pilot ignition.
- Intermittent-pilot ignition.
- Direct-spark ignition.
- Hot-surface ignition.

41.5.1 Standing-Pilot Ignition System

A ***pilot light***, or *pilot flame*, is a small flame located near a furnace's gas burners that provides the initial heat to ignite the furnace. A ***standing-pilot ignition system*** consists of a continuously burning pilot that ignites the burners when there is a call for heat. Wired to the ignition control module, a thermocouple, thermopile, or bimetallic element senses if the pilot is correctly lit prior to allowing the main gas valve to open during a call for heat, **Figure 41-18**.



Midco International, Inc.

Goodheart-Willcox Publisher

Figure 41-18. The setup of a standing-pilot ignition system for a gas furnace. Notice how the pilot light is positioned to constantly provide heat for the thermocouple to sense and for the burner to ignite.

A thermocouple generates a small electric current, which rises or falls based on the amount of heat applied to it. When the pilot is lit, the thermocouple sends a signal that tells the ignition control module to send fuel gas through the gas burner. If the pilot is not lit, the thermocouple sends a signal to the control module to prevent the flow of fuel gas through the gas burner. A system that uses a thermocouple, thermopile, or bimetallic element to sense if a pilot light is on is referred to as a ***thermal detection system***. More information on thermocouples and thermopiles is found in Chapter 14, *Basic Electronics*.

Thinking Green

Standing Pilots

Standing-pilot ignition systems are found only in older furnaces. Since a standing pilot constantly burns gas, even during the Off cycle, standing-pilot ignition systems have become obsolete due to their inefficiency. The majority of gas furnaces now use more efficient options, such as intermittent pilots, direct-spark ignition, or hot-surface ignition.

Safety Note

LP Gas

If a pilot fails to light on a furnace that burns natural gas, the gas will rise through the flue and vent outdoors since natural gas is lighter than air. However, LP gas is heavier than air. If an LP gas pilot fails to light, the gas can collect in a low area, such as a crawlspace or basement. This creates pockets of highly explosive gas and can cause suffocation in a crawlspace due to lack of air. If an odor is detected, the gas is present.

41.5.2 Intermittent-Pilot Ignition System

An ***intermittent-pilot ignition system*** burns and monitors its pilot light only while the thermostat is calling for heat. When the furnace is off, the pilot is not lit, and the ignition control module does not attempt to sense the pilot. When the thermostat calls for heat, the gas valve for the pilot opens, and a spark igniter or hot-surface igniter attempts to ignite the pilot flame. The ignition control module also begins trying to sense the flame using a flame detection device.

Once the pilot has been started and detected, the ignition control module opens the gas valve to the gas burners. The gas burners are ignited by the pilot light, producing heat to warm the conditioned space. When the thermostat no longer calls for heat, the gas valve closes (lockout), stopping gas flow to the pilot and gas burners. Natural gas systems may be 100% lockout, but LP gas systems must be 100% lockout.

Intermittent-pilot ignition systems require verification that the pilot has been lit before gas can flow to the burners. The ignition control module uses flame rectification or thermal detection to verify the presence of the pilot flame. ***Flame rectification*** is the process of using a pilot flame or gas burner flame to change a small electric current from alternating current to direct current.

The flame burns between two electrodes of different sizes. These electrodes can be a grounding strap, flame hood, flame rod (flame sensor), or part of a gas burner. The flame allows electrons to flow in only one direction across the gap between the electrodes. The ignition control module then applies a small alternating current to the electrodes. The flame rectifies this current by forcing it to flow in only one direction across the gap. The control module measures the direct current to verify the presence or absence of a pilot flame. Flame rectification systems report the presence of a flame immediately. Other ignition systems may use local sensing, which consists of a combination igniter/sensor.

Pro Tip

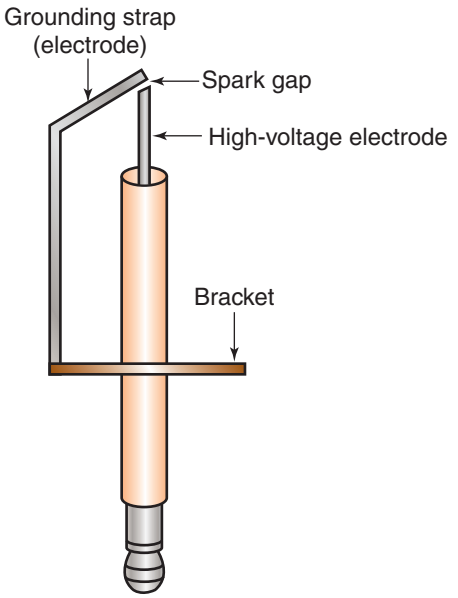
Flame Rod

Flame rod is the most widely used name for a device that is known by several names in the HVACR industry. Other names that you may encounter in the field include *ionization electrode* and *flame electrode*.

41.5.3 Direct-Spark Ignition (DSI) System

A ***direct-spark ignition (DSI) system*** uses an electric spark to ignite gas burners. No pilot is used in this system. A ***spark igniter*** creates an electric spark across a gap between two electrodes when the ignition

Copyright Goodheart-Willcox Co., Inc. 2017



Goodheart-Willcox Publisher

Figure 41-19. The components of a direct-spark ignition assembly. Some DSI systems use the same components to both ignite the flame and detect the flame.

control module applies a high voltage to the electrodes. The spark occurs when current leaps across the gap. This spark is hot enough to ignite the fuel gas in the gas burners, **Figure 41-19**.

When a thermostat calls for heat, several things happen. The gas valve opens to allow fuel gas to flow through the manifold to the furnace's gas burners. Also, the furnace's ignition control module applies a voltage to the electrodes to produce a spark. When the spark arcs across the electrodes, it ignites the gas flowing through the gas burners. The flame produced is then detected by sensors, and the gas furnace heats air that is circulated to the conditioned space.

If a flame is not produced or if the sensors do not detect a flame, the system locks out for a given period of time. All DSI systems (natural gas or LP) provide a lockout function, which stops the system from applying an ignition spark. Like intermittent-pilot ignition systems, DSI systems incorporate flame rectification as a means of flame detection.

Direct-spark ignition systems may have components that are designed to serve two purposes. For instance, DSI systems require both a high-voltage electrode and grounding strap to start the spark and a flame rod and grounding strap to conduct current for flame rectification. Some systems combine the high-voltage electrode and flame rod into a single device. When a system's electrode and flame rod are packaged together, it is known as ***local sensing***. When a system has an electrode for starting the spark and a separate flame rod for detecting the flame, it is known as ***remote sensing***.

Direct-spark ignition systems have the advantage of inexpensive parts, rugged design, long operating life, and low maintenance. A disadvantage is that the sparks create ***electromagnetic interference (EMI)***, or electrical noise. EMI can disrupt electronics, such as the ignition control module on the furnace itself. To minimize EMI disruptions, keep electrical cables as short as possible and avoid allowing the high-voltage wire to cross in front of the ignition control module.

41.5.4 Hot-Surface Ignition (HSI) System

A ***hot-surface ignition (HSI) system*** uses a silicon carbide igniter to light the gas burners directly. No pilot is used. A ***hot-surface igniter*** is a high-resistance heating element that produces a great deal of heat when current passes through. This heat is high enough to ignite fuel gas flowing through a furnace's gas burners. Hot-surface igniters are often called ***glow coils***, referring to how they illuminate when conducting electric current, **Figure 41-20**.

HSI systems operate similarly to DSI systems. When a thermostat calls for heat, the ignition control module starts the combustion blower to purge the heat exchanger. After a brief period of time, a voltage is applied to the glow coil. The combustion blower continues to operate while the glow coil heats up. An HSI

Sealed Unit Parts Co., Inc.

Figure 41-20. A hot-surface igniter made of silicon carbide. As current passes through the igniter, it heats up to glowing hot.

Copyright Goodheart-Willcox Co., Inc. 2017

system's control module waits before turning on fuel gas to the gas burners. Some HSI systems use a timed relay to wait for a set period of time. Other HSI systems measure the resistance of the glow coil to determine whether it is hot enough to ignite fuel gas.

The ignition control module opens the gas valve to supply fuel gas to the burners when the glow coil is hot enough to ignite the gas. Within a few seconds of the gas valve opening, the glow coil should de-energize. If a flame sensor does not detect a flame within a few seconds, the gas valve closes. Some systems attempt to relight the burners for a limited number of times. HSI systems provide a lockout function regardless of whether they are natural gas or LP gas.

Once a flame is detected through flame rectification, the control module starts the indoor blower after a brief delay. This delay allows the heat exchanger to warm up and heat the air circulated to the conditioned space. After the thermostat is satisfied with the temperature, it signals the ignition control module to close the gas valve and then turn off the combustion blower after a brief period of time.

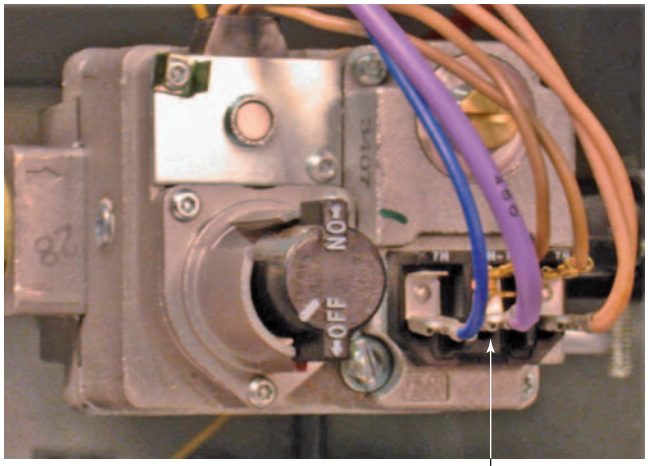
Since an HSI system's glow coil requires only 24 V or 120 V, rather than a DSI system's higher voltage, no EMI is produced. HSI systems are also ideal for equipment with high gas flow. However, hot-surface igniters cost more than spark igniters and take longer to ignite a gas burner flame. Also, glow coils are very fragile, sensitive to shock and vibration, and easily broken. While DSI systems can use their high-voltage electrode for both ignition and flame sensing, HSI systems require a flame rod for flame sensing.

41.6 Gas Furnace Controls

Gas furnaces have controls to ensure safe start-up and safe operation of the gas burners. A furnace's operation is primarily controlled by an HVAC system thermostat and an ignition control module, both of which are wired to the gas valve. See **Figure 41-21**.

On a call for heat, the thermostat sends a signal to the ignition control module to open the gas valve to allow gas flow to the burners. However, before the ignition control module opens the gas valve, it initiates a start-up sequence to prevent the system from functioning unless all proper operating conditions are met.

An ignition control module monitors a series of safety or limit controls that act as electric interlocks. ***Electric interlocks*** are safety devices that prevent operation of certain devices unless certain conditions are met. In the case of a gas furnace, electric interlocks prevent the ignition control module from opening the gas valve or turning on the indoor blower until conditions are safe. Once the desired conditions are met,



Gas Valve

A high-limit switch is one example of an electric interlock that must be closed before the ignition control module continues with ignition.

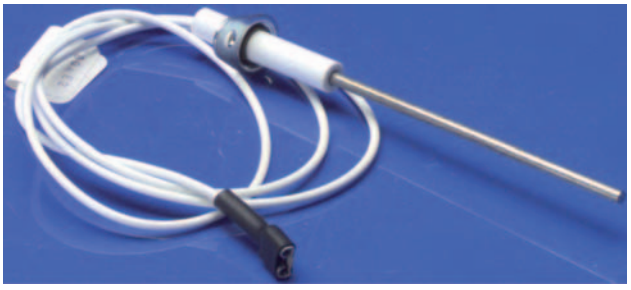
Copyright Goodheart-Willcox Co., Inc. 2017

current can flow through the circuit to open the gas valve or to close a relay that turns on the indoor blower to distribute conditioned air.

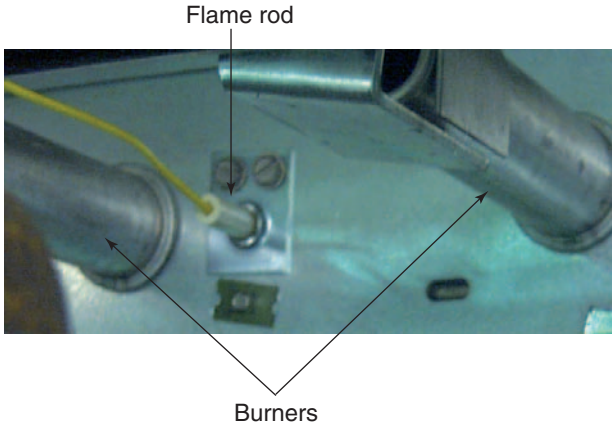
41.6.1 Ignition Control Modules

An ignition control module functions as the "brain" of a gas furnace and continuously monitors the furnace during start-up and operation. The start-up sequence begins when the ignition control module receives a call for heat from the thermostat. The ignition control module activates the combustion blower for approximately 15 seconds to clear the furnace plenum of residual combustion gases. It then sends a signal to open the gas valve and ignite the burners.

During operation, the ignition control module senses heat from the burner flame through the use of a flame rod. When the flame rod is heated by the burner, it sends a microamp signal back to the control module, which indicates that the burner is on. If the ignition control module does not receive the signal that a flame is present, it shuts off the gas valve to prevent the buildup of gas in the furnace, **Figure 41-22**.



Flame Rod



Flame Rod Installed

Figure 41-22. A flame rod senses heat from an active burner flame and sends a microamp signal back to the ignition control module confirming that the burner flame is on.

Types of Ignition Control Modules

There are two types of ignition control modules currently available: nonintegrated and integrated. A ***nonintegrated ignition control module*** can open and close a gas valve, control a spark or hot-surface igniter, and monitor the interlocks. This type of ignition control module is found primarily in older, less-efficient furnaces. An ***integrated ignition control module*** is a control module that uses advanced electronics to provide greater control and functionality than a nonintegrated control module, **Figure 41-23**.

An integrated ignition control module's additional functionality includes the ability to perform self-diagnostics. If a problem occurs, the control module uses an LED to indicate a trouble code. Some integrated ignition control modules are able to vary (modulate) the burner flame size. This type of ignition control module is used in conjunction with an electronic thermostat, a variable speed blower, and a modulating gas valve.

Burner flame size is regulated based on the temperature difference between the thermostat set point and the room temperature. The greater the temperature difference is, the larger the flame. As room temperature approaches the thermostat set point temperature, the flame size is reduced. The ignition control module initially starts the flame between 20% and 50% of its full capacity and then adjusts the flame size to suit the temperature difference.

Pro Tip

Modulating Furnace Thermostats

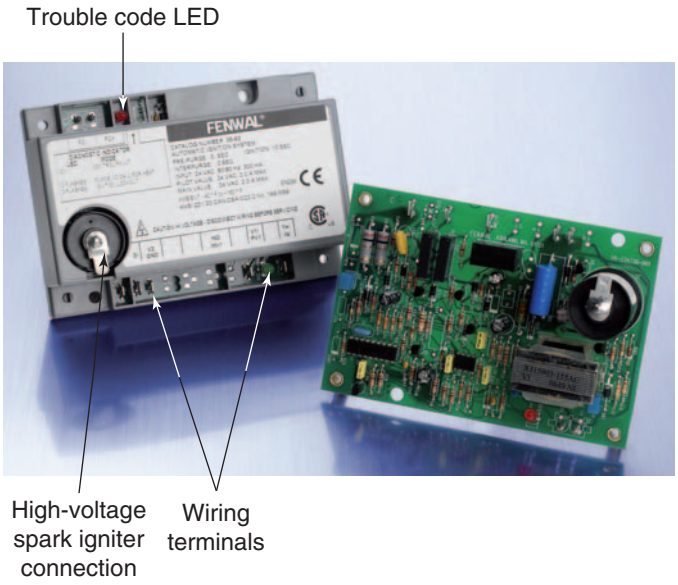
On some models of modulating furnaces, the ignition control module controls flame modulation based on an algorithm applied to the previous run time. In other modulating furnaces, special communicating thermostats send modulating signals to the ignition control module. If a standard programmable thermostat is used with one of these furnaces, the furnace will not function as a modulating furnace.

Ignition Control Module Functions

Before a gas furnace's heating cycle can begin, different ignition methods require that different operational and safety sequences be run. Depending on the furnace design, the functions of an ignition control module include some or all of the following operational and safety features:

- Pre-purging.
- Inter-purging.
- Post-purging.
- Gas valve operation.
- Pilot valve operation.

Copyright Goodheart-Willcox Co., Inc. 2017



Fenwal Controls

Figure 41-23. An integrated ignition control module used with an intermittent-pilot ignition system.

- Soft lockout.
- Hard lockout.
- Shutoff.
- Trial for ignition (TFI) time.
- Number of ignition attempts.

Purging a gas furnace is accomplished by turning on a combustion blower to vent any remaining combustion gases from the heat exchanger. Before ignition is even tried on a heating cycle, an integrated ignition control module performs a ***pre-purge*** by cycling on the combustion blower to vent any combustion gases remaining in the heat exchanger. This operation empties the heat exchanger of combustion gases and fills it with fresh air to prevent any incomplete combustion or misfires.

Integrated ignition control modules allow igniters a limited amount of time to ignite a gas burner flame. This period of time is called ***trial for ignition (TFI)***. TFI is usually measured in seconds. On some control modules, TFI may be chosen from a group of preprogrammed selections. Refer to manufacturer service information to properly set TFI.

Sometimes an ignition system fails to ignite during its TFI. If the time set for TFI is exceeded, the ignition control module places the furnace in a state of shutoff, also called a *lockout*. An ignition control module with a ***soft lockout*** briefly quits trying to ignite for a specified time before attempting ignition again. After a soft lockout's waiting period, the system automatically tries ignition again. The waiting time of a soft lockout can vary greatly, depending on the module used for a given system and application.

During this brief waiting period between ignition attempts, ignition control modules often inter-purge the furnace. An ***inter-purge*** is when a combustion blower cycles on during a soft lockout to vent any combustion gases remaining in the heat exchanger after a failed ignition attempt.

Some ignition control modules do not allow a soft lockout. If a gas furnace with such a control module misfires, it goes into a hard lockout. A ***hard lockout*** is a system shutdown for an unspecified amount of time after a furnace fails to light during its TFI. A hard lockout requires a service call to reset or interrupt power to the ignition control module.

Even after a furnace runs successfully and goes into the Off cycle, the heat exchanger may still contain some combustion gases. Some ignition control modules initiate a ***post-purge***, in which the combustion blower remains on for a given period of time after gas burner operation has ceased in order to vent any combustion gases in the heat exchanger.

Gas furnaces with pilots typically have shutoff controls. A gas furnace with an ignition control module that has ***100% shutoff*** closes the gas valve and the pilot valve when the flame rod does not detect a flame. With the advent of features such as soft lockout, control modules with 100% shutoff are no longer as prevalent as they once were.

A gas furnace with an ignition control module that has ***non-100% shutoff*** closes the gas valve but not the pilot valve when the flame rod does not detect a flame. Furnaces with non-100% shutoff have shutoff times that are long enough for a dangerous amount of gas to dissipate before attempting to reignite the pilot.

A gas furnace may have an ignition control module with ***100% shutoff with continuous retry***. For these systems, the gas valve and pilot valve close when the flame rod does not detect a flame. However, after a waiting period, the control module attempts to reignite the pilot. The system cycles between attempting to reignite the pilot and waiting during shutoff periods until the pilot is lit.

Ignition Control Module Wiring

Wiring terminal abbreviations for ignition control modules vary with manufacturers. Always refer to an installation manual. However, some commonly used abbreviations include the following:

- GV, MV, or V1—main gas valve.
- PV—pilot valve.
- MV/PV—combined main gas valve and pilot valve.

Copyright Goodheart-Willcox Co., Inc. 2017

- GND, BRN GND, or GND Burner—burner ground connection.
- 24 V GND (or 25 V)—unswitched leg of the secondary transformer.
- 24 V (or 25 V)—switched leg of the secondary transformer.
- TH or TH-W—thermostat heat signal.
- SENSE or REMOTE SENSE—flame sensor.
- SPARK or IGN COIL—spark igniter or combined spark igniter and flame sensor.
- FS—flame sensor.
- IGN—hot-surface igniter.
- P1—vent damper control.
- PSW—pressure switch.
- IND—combustion blower.

41.6.2 Safety Controls

The high temperatures in a gas furnace can cause damage to the furnace itself. The sheet metal chamber where heat collects before being distributed is called the ***bonnet***. It contains the heat exchanger. If a blower fan does not operate when it should, the heat exchanger can overheat. To prevent such occurrences, a ***high-limit switch***, also called a *safety stat*, is placed in the bonnet near the heat exchanger to protect the heat exchanger from overheating. One example of a high-limit switch is a bimetallic snap disc, **Figure 41-24**. If the heat around the heat exchanger rises too high, such as when a blower fan does not run during burner operation, the high-limit switch snaps open to de-energize the gas valve and stop the flow of fuel gas to the gas burners. Most of the time, a high-limit switch automatically resets once conditions are safe again.

For various reasons, flames in a gas furnace are not always contained as well as they should be. If a spud or gas burner is misaligned or there is a draft problem, part of the flame may spill backward out of the burner, which is called ***flame rollout***. Flame rollout can be caused by a cracked heat exchanger, rust on burners, poor draft, or incorrect flue pipe height. A safety device that monitors for flame rollout is a ***rollout switch***. This device is located near the burners. If a flame rollout occurs, a rollout switch cuts off the supply of fuel gas by opening the circuit controlling the gas valve to close it, **Figure 41-25**.

Pro Tip

Resetting a Rollout Switch

Rollout switches must be reset manually. However, these switches should not be reset simply to return a furnace to operation again. A tripped rollout switch indicates that something is wrong and needs to be corrected. Always investigate to find the root cause of a tripped rollout switch.

41.6.3 Combustion Blower Controls

The burning of fuel gas results in the production of carbon dioxide and water vapor if the combustion

is complete and clean. To ensure that the products of combustion flow through the flue into the chimney and not into the conditioned space, combustion blowers are used. A furnace's combustion blower performs two important functions: it pre-purges the heat exchanger and exhausts flue gases.

The ignition control module must verify that the combustion blower is on and has established a steady draft before it signals the gas valve to provide gas to the burners. The device used to detect combustion blower operation may be a sail switch, an end switch, or a pressure switch. A ***sail switch*** is a type of flow switch that uses a large paddle to catch a draft to open or close its contacts. It can be manufactured as a single-pole, single-throw (SPST) switch or as other configurations as well. Sail switches are also called *vane switches* or *airflow switches*.

End switches come in a variety of forms, but in forced-air furnaces, they often connect to the end of a damper motor shaft. When the damper is turned open a certain amount or angle, the end switch closes. This allows the end switch to send a signal to the ignition control module to open the gas valve for combustion to begin. End switches may also be used to signal the control module to turn on the combustion blower. Some end switches are a type of mercury switch, similar to those found in older thermostats.

Different types of ***pressure switches*** may also be used for confirming combustion blower operation. Since an induced-draft combustion blower pulls the products of combustion through the heat exchanger to exhaust them, it creates a negative pressure in the heat exchanger. A pressure switch uses a diaphragm that is sensitive to differences in pressure to compare pressure on each side of the combustion blower, **Figure 41-26**. Negative pressure pulls and positive pressure pushes the diaphragm to actuate the switch.

41.7 Gas Furnace Efficiency

The measurement of gas furnace efficiency is the ***annual fuel utilization efficiency (AFUE) rating***. AFUE is used for all furnaces, including gas, oil, and electric. This rating compares a furnace's yearly or seasonal energy output to the energy input for the same time period. The higher the AFUE rating, the more efficient and cost-effective a furnace is. A furnace's AFUE rating is printed on a label attached to the furnace, **Figure 41-27**.

ANSI/ASHRAE Standard 103 designates the efficiency testing methods for determining a furnace's AFUE rating. Federal law requires a minimum efficiency of 78% AFUE for all new furnaces. The higher the efficiency of a gas furnace, the more likely it is that condensation will develop in the furnace's heat exchanger or flue vent. Gas furnaces rated over 83% AFUE develop condensation, while those at or below 83% AFUE do not develop condensation.

Increased efficiency is accomplished through the use of new technologies, such as high-transfer heat exchangers, design improvements in flue pipe routing, and secondary heat exchangers. Higher efficiency is achieved by keeping more heat in a system, which is done by drawing more heat from combustion and the

Figure 41-27. An EnergyGuide label shows important information about a furnace, including its make, model, size, and AFUE rating compared to other similar furnaces. In Canada, AFUE ratings are found on EnerGuide labels.

products of combustion. This reduces flue gas temperature and allows escaping flue gas to condense more easily. Since condensation can cause system problems, additional design features and parts are required to protect furnaces that allow condensation formation. The condensate must be allowed to flow freely to an approved drain.

Gas furnace efficiency can be divided into three general categories: low-efficiency, mid-efficiency, and high-efficiency. Older gas furnaces have low efficiency ratings, ranging from 68% to 72% AFUE. Flue gases are vented by natural convection. Since these gases are so hot, they naturally rise through flue piping. Of course, much of the heat created by older, low-efficiency furnaces is lost in these naturally rising flue gases. Low-efficiency furnaces also have standing pilot lights that burn fuel continuously and heat exchangers that are large and heavy.

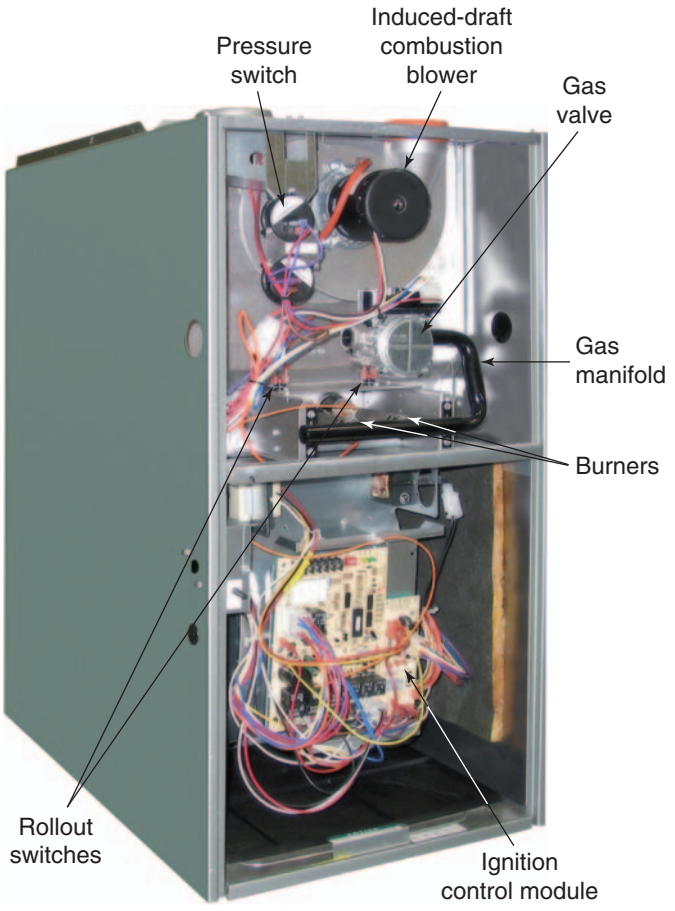
Thinking Green

Tax Credits

Familiarize yourself with all available tax credits for energy-efficient HVACR equipment. Making the customer aware of an available tax credit may make the difference between the customer purchasing more expensive high-efficiency equipment or lower-efficiency equipment that has a lower initial cost.

41.7.1 Mid-Efficiency Gas Furnaces

A ***mid-efficiency gas furnace*** is a furnace with an AFUE range of approximately 79% to 83%. This type of furnace uses a heat exchanger capable of high heat transfer, a spark igniter instead of a standing pilot, and an induced-draft combustion blower, **Figure 41-28**. These features help increase the AFUE rating. Most mid-efficiency furnaces have a flue gas outlet of only three inches. This is due to the heat exchanger design and the decrease in the products of combustion.



Goodman Manufacturing Company

Figure 41-28. A mid-efficiency gas furnace with an 80% AFUE. Most mid-efficiency furnaces have burners located at the bottom of the heat exchanger.

Copyright Goodheart-Willcox Co., Inc. 2017

Mid-efficiency furnaces may use a Class B chimney or an approved flex chimney liner as the main chimney. A technician should check with a local municipality's heating inspector when installing a furnace's exhaust vent piping. Some manufacturers have designed their mid-efficiency furnaces to be low profile with the option of being installed either vertically or horizontally. The installation of all furnaces should conform to the recommendations of the manufacturer and to local codes and restrictions.

Mid-efficiency furnaces vary from high-efficiency furnaces in two ways: they have no secondary heat exchanger and they require a chimney for flue gases. While high-efficiency furnaces use plastic pipe to vent their lower-temperature flue gases, mid-efficiency furnaces send hot flue gases directly through the chimney, which means more heat energy is lost in these hot flue gases.

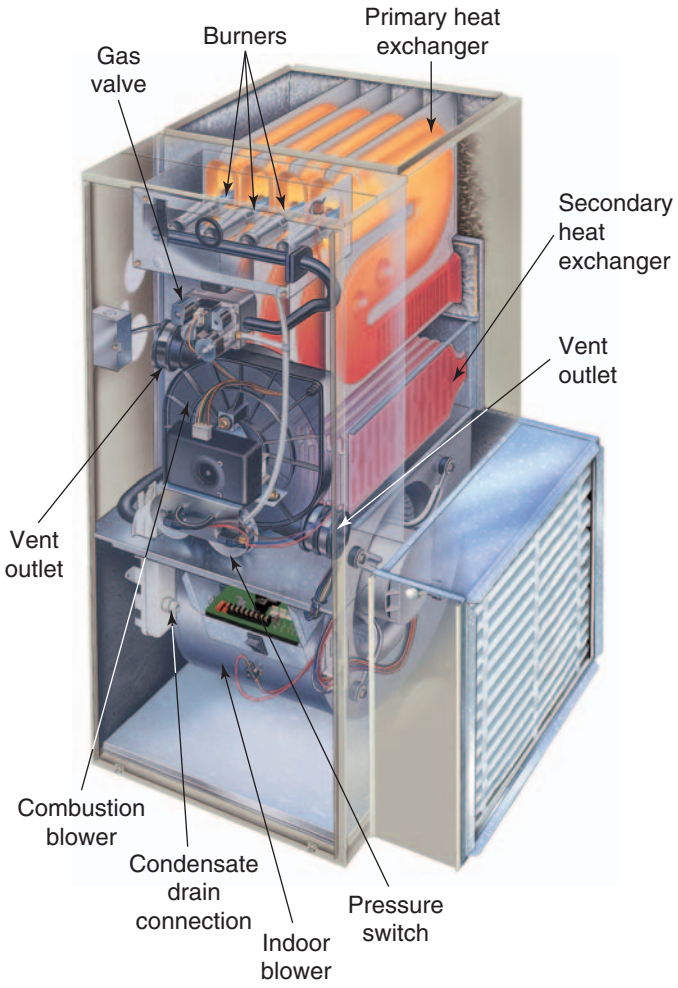
41.7.2 High-Efficiency Gas Furnaces

A ***high-efficiency gas furnace*** is a furnace that has a secondary heat exchanger capable of extracting enough heat from flue gases to cause them to condense into liquid. Since high-efficiency gas furnaces allow some flue gases to condense, they are also often called *condensing furnaces*. These furnaces have an AFUE rating between 90% and 97%. Rising fuel gas prices make high-efficiency models attractive to homeowners.

A high-efficiency gas furnace uses gas burners to heat its primary heat exchanger. A combustion blower draws hot combustion gases through the primary and secondary heat exchangers. In the secondary heat exchanger, the latent heat is captured from the combustion gases as they condense. This latent heat is lost through the chimney in a mid-efficiency gas furnace. In a high-efficiency gas furnace, it is transferred from the secondary heat exchanger to the air circulated to the conditioned space, **Figure 41-29**.

For the best transfer of heat from combustion gases to circulating air, a counterflow design is used. While circulating air flows in one direction around the heat exchanger, combustion gases flow in the other direction. This places the coldest circulating air in contact with the coolest part of the heat exchanger (secondary), and it places the warmest circulating air in contact with the hottest part of the heat exchanger (primary). This design allows maximum heat transfer from the combustion gases to the circulating air. The upflow furnace in **Figure 41-29** demonstrates this design of high-efficiency furnaces.

High-efficiency furnaces do not need a traditional chimney to vent flue gases. Since the latent heat of condensation is captured by the secondary heat exchanger, flue gas temperatures are considerably lower than the flue gas temperatures in less efficient gas furnaces. These lower-temperature flue gases are vented outdoors through a PVC pipe attached to the flue exhaust.



Carrier Corporation, Subsidiary of United Technologies Corp.

Figure 41-29. Components of a high-efficiency gas furnace. Note the combustion blower has vent outlets on both the right and left sides, so vent piping can be installed to either side.

High-efficiency furnaces often have a sealed combustion chamber, which is a box that contains the gas burners and connects to the inlet of the primary heat exchanger. Depending on installation practices and local codes, this allows the owner to choose either ambient air or outdoor air for combustion in the furnace.

Ambient air is simply the air around the furnace. For this option, a technician secures a grille on the air inlet leading to the combustion chamber that allows ambient air to enter the furnace. Using ambient air for furnace combustion is ideal when a furnace is located outside a living space or outside a conditioned space. It is also preferable in locations where it would be difficult to install piping to reach the outdoors.

Copyright Goodheart-Willcox Co., Inc. 2017

Using ambient air for furnace combustion poses a few disadvantages if the furnace is located in the living space or conditioned space of a building. Since air from the conditioned space is consumed and vented during combustion, the building will have a slight negative pressure that will cause some infiltration of outside air. This means cold air from outside will seep into the conditioned space as ambient air is consumed for combustion. Also, the quality of the air in the building may decline.

Homes with more airtight construction want to avoid a negative pressure and anything promoting infiltration. To do this, use outdoor air for furnace combustion. A PVC pipe run from outside to the sealed combustion chamber inlet allows outdoor air to flow into a furnace's combustion chamber through its air inlet. Using outdoor air for combustion avoids consuming any conditioned air. It also avoids creating a negative pressure that promotes infiltration. By having one PVC pipe dedicated to venting flue gases and another PVC pipe dedicated to bringing in fresh air for combustion, a high-efficiency gas furnace does not affect the pressure of the conditioned space. A furnace with a two-pipe system for releasing flue gases and drawing in fresh combustion air is a ***direct-venting system***.

Another benefit of having a pipe dedicated to bringing in fresh outdoor air is that the pipe provides more than enough air for proper combustion. There is no shortage of combustion air or excess air. Increasing the excess air available lowers the dew point of flue gases, and a lower dew point increases the amount of flue gas that condenses. This helps the furnace capture as much heat as possible to transfer to the conditioned space.

41.8 Gas Furnace Venting Categories

How a gas furnace operates influences how it is classified and how it must be vented. The primary determining variables are the temperature and vent pressure of the furnace's flue gas. Based on these variables, a gas furnace is assigned a category number in the *National Fuel Gas Code*, which is a standard published by the International Code Council. See **Figure 41-30**.

A ***Category I furnace*** is a negative-pressure venting, noncondensing furnace. The flue gas temperature is at least 140°F (60°C) (higher than its dew point), so very little condensate forms. Category I furnaces include older, low-efficiency furnaces that are vented by natural convection and newer, mid-efficiency furnaces with induced-draft combustion blowers. Category I furnaces are the most commonly used furnaces in residential heating.

Gas Furnace Categories			
Category Number	Vent Pressure	Condensing or Noncondensing	Vent Pipe Material
I	Negative	Noncondensing	Class B
II	Negative	Condensing	Special per manufacturer
III	Positive	Noncondensing	Stainless steel
IV	Positive	Condensing	PVC

Goodheart-Willcox Publisher

Figure 41-30. Gas furnaces are categorized based on the vent pressure and the temperature of the flue gas.

A ***Category IV furnace*** is a positive-pressure venting, condensing furnace. The flue gas temperature is less than 140°F (60°C) (lower than its dew point). As a result, some of the flue gas condenses and drains away in liquid form. Category IV furnaces are high-efficiency condensing furnaces with secondary heat exchangers and PVC vent piping.

A ***Category II furnace*** is a negative-pressure, condensing furnace. A ***Category III furnace*** is a positive-pressure, noncondensing furnace. Both Category II and Category III furnaces require special vent materials. Category III furnaces are typically vented with stainless steel piping. Due to limited applications and high installation costs, Category II and Category III furnaces are rarely used in residential heating.

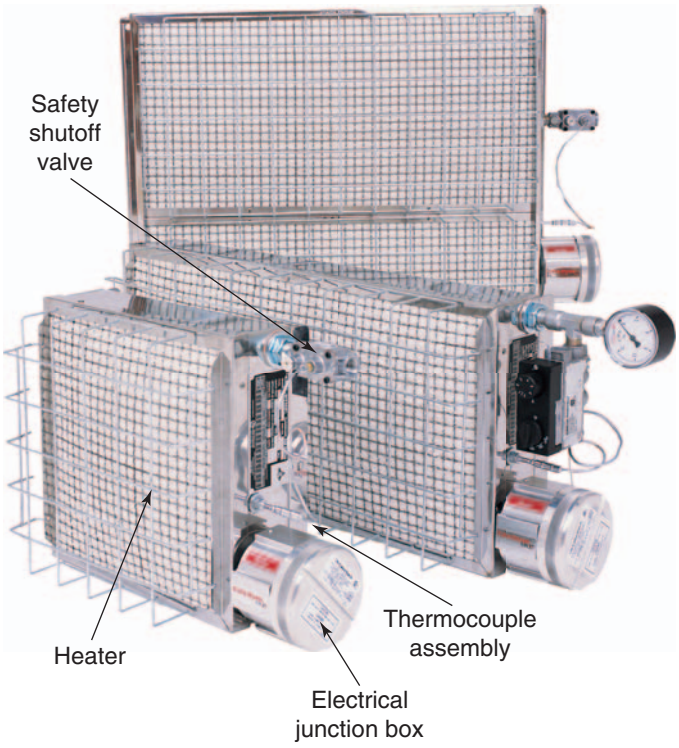
41.9 Gas-Fired Radiant Heat

Gas combustion is not used solely in central forced-air or hydronic heating systems to warm the air or water that is distributed throughout a conditioned space. Gas combustion may also be used for spot heating using radiant heating. Radiant heating heats ceramic elements to incandescence. A reflector is used to focus this heat. In gas-fired radiant heaters, about 50% of the heat energy is converted into radiant heat. These units typically operate at about 700°F to 1600°F (371°C to 871°C), **Figure 41-31**.

41.10 Gas-Fired Heating System Service

Gas-fired heating systems provide heat through the combustion of natural gas or liquefied petroleum (LP) gas. When installing a new gas-fired heating system, a technician should record certain information about the system, such as the type of fuel gas, the model number of the furnace, the filter size and

Copyright Goodheart-Willcox Co., Inc. 2017



CCI Thermal Technologies Inc.

Figure 41-31. Gas-fired radiant heaters are designed to operate on either natural gas or LP gas.

type, the gas pressure at the gas valve manifold, and the stack temperature. Upon completion of the installation, a copy of this information should be given to the homeowner, and one copy should be retained and kept on record at the HVAC service company. This information will be valuable during future service calls because it can provide baseline data during troubleshooting. Areas of interest include gas piping, gas burners, operational controls, the combustion chamber and heat exchanger, and the flue and venting.

Code Alert

Gas Furnace Installation

All localities have building code requirements covering the installation of gas-fired heating systems. Some local building codes refer to the International Residential Code (IRC) for residential construction and to the International Building Code (IBC) and International Fuel Gas Code (IFGC) for commercial construction. The IRC includes a chapter on fuel gas. The requirements in this IRC chapter are the IFGC requirements applicable to residential construction. Local building codes may adopt the IRC, IBC, and IFGC directly or with exceptions. Always follow local building codes when installing fuel gas systems.

Service Call Scenario

41A: Residential Furnace—No Warm Air

Customer Complaint: No Warm Air

Description of Problem: The owner of a 2000 ft² home, Ms. Jones, contacts the service call center complaining that no warm air is coming out of her home's furnace. Prior to arrival at the residence, the HVAC technician, Juan, reviews the complaint and begins constructing an action plan. He arrives promptly at the residence, introduces himself, and listens carefully to Ms. Jones's complaint, making notes as needed.

Possible Causes: Defective ignition control module, defective transformer, open limit switch.

Testing: Juan places the thermostat on a call for heat. Entering the basement where the heating equipment is located, he observes the furnace operation and notes the gas fuel is not igniting. The furnace uses a 120-volt ignitor. Juan uses his multimeter and checks for the correct voltage at the ignitor. There is no voltage present at the ignitor. Next, he checks the ignition control module for output voltage to the ignitor. The result shows there is no voltage at the output terminal of the module. The ignition control module will need to be replaced. To make certain the ignitor is functional, Juan checks the ignitor by performing a resistance test with an ohmmeter. The reading shows that the ignitor is operational.

Solution: Juan shares with Ms. Jones that the ignition control module will need to be replaced and receives approval to do so. He replaces the module, and he then observes the system to ensure it is operating satisfactorily. He checks the air filter to ensure there are no airflow problems. The filter needs to be replaced, and Juan receives approval from Ms. Jones to do so. He provides her with a bill and informs her that he will follow up with a call to ensure the system is operating satisfactorily.

Safety: Turn off the electrical power to the furnace while installing an ignition control module. The main voltage to the module is 120 V, which can cause serious injury.

Copyright Goodheart-Willcox Co., Inc. 2017

41.10.1 Gas Piping Installation

There are several options to use for fuel gas piping. Black iron pipe is most commonly used for natural gas applications, but corrugated stainless steel (CSS) is also used. Black iron pipe is treated so that it will not flake and contaminate the gas.

Code Alert

Gas Pipe Material

Building codes specify allowable materials and specifications for gas piping. The IRC and IFGC allows approved types of steel (including black iron pipe), corrugated stainless steel, wrought iron, copper, copper alloy, aluminum, and plastic. These codes prohibit the use of cast iron pipe.

Fuel gas piping must be sized correctly to meet the demands of the applications in the building. Factors that affect pipe size include the pressure drop of the piping, the specific gravity of the gas, and the amount of gas consumed by the furnace per hour. See **Figure 41-32**.

The following are some typical fuel gas piping installation guidelines. Always follow applicable code requirements:

- When buried, fuel gas piping must be at least 12″ below grade.
- Fuel gas piping must be supported at the distances shown in **Figure 41-33**.
- When installed outdoors and above ground or on a roof, fuel gas piping must be elevated at least 3 1/2″ above the ground or roof surface.

When assembling threaded pipe and fittings, use a pipe compound on the threads to ensure a leakproof connection. To prevent the pipe compound from getting into the pipe and potentially clogging orifices, do not apply the compound to the first two threads at the end of the pipe, **Figure 41-34**.

A ***drip leg*** is installed at the furnace along with a manual shutoff valve. The drip leg functions as a trap and collects possible moisture or sediment that may flow with the gas. See **Figure 41-35**. A drip leg is also required at the outlet of the gas meter to prevent condensate from running into the meter.

Code Alert

Drip Leg Requirements

The IRC and IFGC refer to drip legs as *drips*. Drip legs must be readily accessible for cleaning or emptying, and cannot be located where they may be subject to freezing. If the furnace does not include a sediment trap at the fuel gas inlet, a drip leg is installed for this purpose as near the furnace inlet as practical and "downstream" of the shutoff valve.

Gas Pipe Capacity (ft^3/hr)

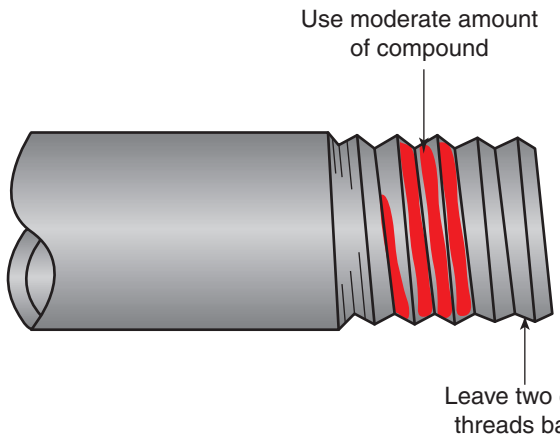
Figure 41-33. Gas piping requires support at different intervals based on its size and material.



Honeywell, Inc.

Figure 41-34. The proper way to apply pipe compound to pipe threads.

After the gas piping has been assembled and connected to the appliance, the technician must perform a standing pressure test to check for leaks. A manometer with a proper range of measurement shall be used to test pressure. If pressure does drop, use soap bubbles or another approved gas detector to locate leaks and then repair them before performing another pressure test.

Goodheart-Willcox Publisher

Figure 41-35. A drip leg installed in the gas supply pipe to a gas furnace will trap dirt and moisture.

Code Alert

Gas Pipe Testing

After piping is installed but before it is placed into service, the IRC and IFGC require a visual inspection and a pressure test. The pressure test can be performed using air, nitrogen, carbon dioxide, or an inert gas. Oxygen cannot be used. Generally, a pressure of one-and-one-half times the maximum working pressure of the system must be held for at least ten minutes.

Safety Note

Gas Leak Testing

When checking for a gas leak, always use soap bubbles or a leak detector designed to detect fuel gas. Never use a halide torch or an open flame.

Copyright Goodheart-Willcox Co., Inc. 2017

Code Alert

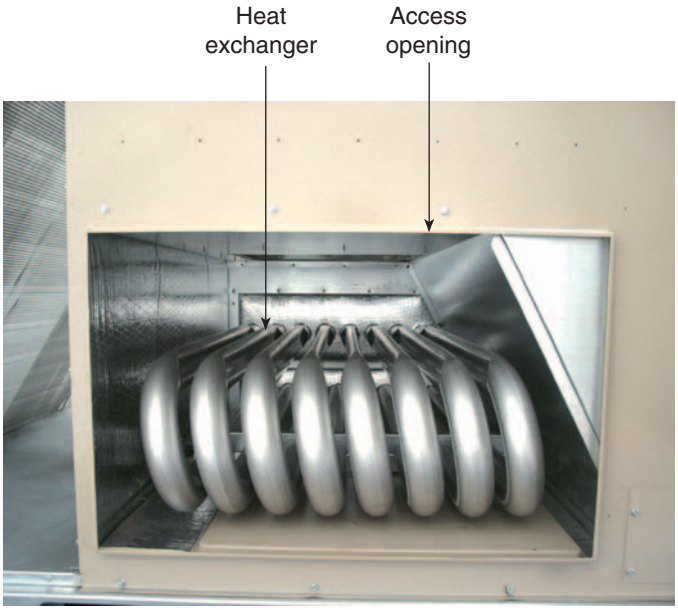
Gas Pipe Identification

The IRC and IFGC require exposed gas piping to be marked with a yellow label with the word *Gas* in black lettering. The maximum space between labels is 5′ intervals. This marking is not required for steel pipe and is not required for piping in the same room as the appliance.

41.10.2 Heat Exchanger Service

A heat exchanger should be tested prior to each heating season for possible cracks or open seams. These can be caused by heat or mechanical stress. Rust should be noted as well as any thinning of the heat exchanger wall (by 50% or more of the original thickness). Rust can be caused by condensate or a damp location. Check also for gasket or seal leaks. See **Figure 41-36**.

While checking a heat exchanger for leaks, a technician should consider the system and its operational characteristics. For instance, combustion gas should only be produced while the furnace is on. Also, the combustion blower should be operating while the furnace is on to provide the proper draft in the flue. When a system is off during inspection, be aware that some cracks may only be open or visible while the heat exchanger is hot from combustion heat.



York International Corp.

Figure 41-36. With the access panel removed, a technician can visually inspect a furnace's heat exchanger.

Heat Exchanger Leak Test Procedure

A telescoping mirror and flashlight allow inspection of a small amount of a heat exchanger. However, do not rely on visual inspection alone as a true test of the heat exchanger's condition. The Gas Appliance Manufacturers Association (GAMA) recommends the following three-point check for gas furnaces.

1. Observe the flame before and after the indoor blower comes on to see if there is any change to the flame characteristics. If the flame characteristics change when the blower comes on, it can be an indication of severe deterioration of the heat exchanger or gasket material, a split seam, an open crack, or a physical separation of connected parts.
2. Perform a visual inspection of the heat exchanger. Look for rust, warping, holes, cracks, or other signs of deterioration. Visual inspection can be very limited in residential units because of evaporator coils or the shape of the heat exchanger.
3. Perform a chemical test on the heat exchanger. This test is done by introducing a chemical into the exchanger and using a device that detects the chemical in the supply air at room registers or grilles.

Safety Note

Carbon Monoxide (CO) Detection

Combustion gases containing carbon monoxide (CO) that escape from the heat exchanger into the supply air can be fatal to occupants. Technicians working on combustion appliances should be properly trained in carbon monoxide detection and have the equipment necessary to perform combustion analysis. Be aware that readings indicating the presence of combustion gas in the supply air can be produced by conditions other than a leaking heat exchanger, such as pressurization problems in the mechanical room.

41.10.3 Gas Furnace Maintenance

Annual maintenance of a gas furnace improves a furnace's performance and ensures the comfort and safety of customers. The following items should be checked by a technician during the annual inspection of a gas furnace. During the inspection, power to the furnace must be shut off for the technician's safety.

- Fresh air grilles and louvers must be open and unobstructed to provide combustion air.

Copyright Goodheart-Willcox Co., Inc. 2017

- Burners should be inspected for rust, dirt, and signs of water.
- Flue pipe must be inspected for rust, dirt, signs of water, and damaged or disconnected joints.
- Furnace compartment should be inspected for rust, dirt, signs of water, and burned or damaged wires or components.
- Blower access door should be in place and provide a seal between the return air and the room in which the furnace is installed.
- Return air ducts must be properly attached and provide an air seal to the furnace.
- With the system running, the operating performance of the furnace and vent system should be checked.
- Flue gases must be analyzed and compared to the furnace's specifications.

Upon completion of the annual furnace inspection, the customer should be reminded to notify the technician and shut off the furnace if any of the following is noted:

- New or unfamiliar sounds while the furnace is operating.
- Unusual odors.
- Unusual amount of moisture in the conditioned space.
- Visibly burned components or unusual dirt or rust accumulation on the flue pipe or furnace.
- Flu-like symptoms that subside when the home's inhabitants are away from the house (indicating exposure to carbon monoxide).

41.10.4 Troubleshooting Gas Furnaces

The following tools and instruments should be brought on a service call in order for a technician to be well prepared:

- Digital manometer to measure duct static pressures and gas pressure.
- Multimeter to measure flame sensor rectification signals.
- Thermometer to measure air temperatures.
- Snake for plumbing and drain cleaning.
- Small inspection mirror.
- Combustion analyzer.

Begin an inspection of a gas furnace with a check of the general condition of the furnace and surrounding area. Some application and installation factors that frequently cause problems include the lack of satisfactory combustion air, improperly sized vents, malfunctioning air filters, and electrical shorts due to a water leak in the evaporator coils or humidifier.

Prior to beginning a lengthy troubleshooting process, check the obvious. Note any blown fuses or tripped breakers, loose wires or connections, burned components, or open safety switches. Check the manufacturer's instructions, observe the sequence of

Service Call Scenario

41B: Commercial Packaged Unit—No Heat

Customer Complaint: No Heat

Possible Causes: Dirty flame sensor, defective flame sensor, insufficient gas flow, defective gas valve.

Description of Problem: Mr. Thompson, owner of a small business, has reported that the furnace is not providing heat when it is needed. Prior to arriving at the jobsite, the technician, Scott, reviews the work order. Upon arriving at the place of business, he identifies himself to Mr. Thompson and listens carefully to his comments.

Testing: Scott sets the wall thermostat to call for heat. He observes that the burners come on, but then shut down very quickly. He checks the flame rod and notices a film coating on the metal rod. This is due to oxidation. The presence of the film confirms that the rod is not able to sense the burner flame correctly. He knows from previous experience that the flame rod needs cleaning. He informs Mr. Thompson of the issue and offers a solution and the cost for such. Mr. Thompson agrees to have Scott perform the services.

Solution: Scott shuts off the electrical source to the furnace. He then removes the flame rod and cleans it, using sand cloth or steel wool. He further checks for cracks on the ceramic portion and checks for loose connections. The flame rod is reinstalled. He is careful not to crack the ceramic base of the flame rod during reinstallation of the sensor. He starts the unit and the burners now remain on through the combustion cycle. Scott observes the entire heat cycle and is satisfied that all systems are working properly. He then provides Mr. Thompson with the bill and informs him that a follow-up call will occur.

Safety: Be careful when handling flame rods that may have recently been exposed to flame. The flame rod may be very hot to the touch and may cause burns.

operation, and confirm correct wiring. If the furnace's ignition control module has an LED that indicates trouble codes, use the trouble codes to save time and guesswork. See **Figure 41-37**.

When servicing any type or make of heating equipment, always refer to the manufacturer's manuals for that equipment. The following are basic checks that should be implemented during a service call:

- Visually check all electrical components for loose wiring or defective (cracked) wires.
- Make sure electrical power is available at the furnace by checking the circuit breaker position.
- Check the disconnect switch at the furnace to ensure it is in the correct position.
- Make sure the blower door is secure. The door depresses an interlock switch that permits the furnace to operate.
- If a standing-pilot ignition system is used, check for a burning pilot light.
- Check the condition of the air filter.
- If a belt-driven blower is used, check the condition and adjustment of the belt.
- Check for any accumulation of dirt on the blower motor and blower cage.
- Start furnace operation by turning the thermostat to a high setting.
- Observe burner start-up and operation.
- Observe blower motor start-up.
- Allow the furnace to run for ten minutes. Then, check for airflow at room registers.
- Turn the thermostat to a lower setting to shut off burner operation. Check that the burner flames are off and the pilot light remains on (if a standing-pilot ignition system is used).
- Listen carefully to determine if the blower shuts off shortly after burner flames are extinguished.
- Check the flue gases for carbon monoxide level.

Ignition System Troubleshooting

Gas-fired heating systems have one of four types of ignition systems: standing pilot, intermittent pilot, direct spark, or hot surface. Knowing how each ignition system works is critical to troubleshooting. Both direct-spark and hot-surface ignition systems depend on an ignition control module that sends and receives signals to and from other components in the ignition system. A troubleshooting flowchart for a hot-surface ignition system is shown in **Figure 41-38**.

The charts provided by manufacturers cover many of the possible problems a system may experience. Troubleshooting flowcharts will vary depending on the type of ignition system used in a furnace. Note that due to the number of problems or causes of bad operation, one troubleshooting chart may refer to another chart for a different sequence of steps to follow. A troubleshooting flowchart for a direct-spark ignition system is shown in **Figure 41-39**.

Flame Troubleshooting

Gas furnaces are equipped with numerous control devices. Many times burners do not operate properly due to the conditions to which control devices react. For example, a furnace plenum may be equipped with a pressure switch. A pressure switch detects air pressure to ensure that the combustion blower is operating prior to burner ignition. If the combustion blower is not running, the pressure switch turns off the burner. Turning off a burner when the blower is not operating prevents a dangerous buildup of heat in the furnace. If the burner does operate when the combustion blower is not operating, the pressure switch may be ruined.

Proper start-up and operation of a furnace requires the correct gas pressure and mixture of fuel gas and air. Primary air promotes complete combustion. The amount of primary air entering some burner is controlled by adjusting a shutter. If a burner does not have a shutter adjustment, check the manufacturer's literature. When the proper amount of primary air is supplied, the burner flame has a soft-blue color without evidence of yellow tipping or lifting. The flame should not flash back, pop, float, or roll out. See **Figure 41-40**.

Figure 41-39. Visual check flowchart for a direct-spark ignition system.

Gas Furnace Flame Conditions		
Problem	**Possible Cause**	**Remedy**
Yellow flame	Lack of primary air.	Reset primary air and check for blockage.
Lifting flame	Gas velocity faster than the speed the gas can burn.	Reduce input gas or primary air.
Popping flame	Flashback during shutoff, burning continued.	Increase gas pressure, reduce primary air, reduce orifice size, check gas valve and burners.
Floating flame	Very dangerous! Incomplete combustion causing release of carbon monoxide.	Check gas flow, flue, burners, secondary air sources, and primary air.
Flame rollout	Very dangerous! Blocked flue, poor draft, insufficient air supply, burner overfiring.	Check gas flow, flue, burners, secondary air sources, and primary air.

41.10.5 Venting System Installation

A combustion heating system, such as an oil-fired or gas-fired heating system, must be vented to remove flue gases from the system. A technician must consider the following factors when installing venting systems: furnace capacity, heat load, type of flue pipe, length of flue pipe, rate of flue gas flow, and number of elbows. The manufacturer's recommendations should be checked when determining venting requirements. Consult the local municipality to confirm code requirements.

The rate of flue gas flow affects the amount of combustion air entering a furnace or boiler. This flow is affected by the pressure difference between the combustion air entering the appliance and the flue gas leaving the flue. In many systems, both the pressure in the building and the atmospheric pressure also affect the flow of flue gases. The temperature of the flue gases has an effect as well. If the flue gases are too cold, the flow will be slow. If flue gases are too hot, the flow will be fast. A chimney or flue pipe should extend at least 2′ (0.6 m) above the highest part of a roof. This helps prevent flue gases from flowing back into the chimney or flue pipe under certain wind conditions.

Some venting systems consist of a flue pipe that joins a chimney vented to the outside. Depending on the type of combustion heating system installed, the flue pipe can reach a temperature between 500°F and 600°F (260°C and 320°C). There are three types of flue pipes (or chimneys) that are commonly used: Class A (masonry type), Class B (double-wall metal type), and PVC. Some venting systems use a metal flex liner that is inserted into the entire length of Class A masonry chimneys.

Before installing a flex liner in a Class A chimney, make sure the chimney is clear and unobstructed. Care must be taken to clear the chimney completely, removing any obstructing mortar, tar, or creosote. Check the chimney for any cracked, loose, or missing bricks and make any repairs necessary to ensure safe internal and external conditions. The existing chimney must provide at least 1/2″ (1 cm) space between the metal flex liner and the masonry inner wall. The liner must be the proper size to ensure good exhaust. Manufacturer installation instructions will provide specifics regarding the proper liner sizing. After installing the metal flex liner and starting up the furnace, check for proper venting.

In high-efficiency furnaces and boilers, a conventional Class A or Class B chimney is not needed. Flue gases leave the appliance at 115°F to 118°F (46°C to 48°C), which means flue gases can be vented to the outside through a plastic pipe (PVC or CPVC). Fresh combustion air is often brought into the combustion chamber from the outside through another PVC pipe. These two air passageways can also be installed in a single length of concentric piping. By running a smaller diameter pipe through the length of a larger diameter pipe, a technician needs to cut only one hole through a wall or roof to install both airways for flue gas venting and combustion air intake, **Figure 41-41**.

Service Call Scenario

41C: Residential Gas-Fired Condensing Furnace—No Heat

Customer Complaint: No Heat

Possible Causes: Defective igniter, defective flame sensor, open safety switches.

Description of Problem: Ms. Frazier is the owner of a 2700 ft^2 residence located in the Midwest. She has reported that her furnace is no longer heating. Prior to arriving at the jobsite, Hal, the technician, reviews the work order. Upon arriving at the home, Hal identifies himself to Ms. Frazier and listens carefully to her comments.

Testing: Hal places the wall thermostat to call for heating. He observes the furnace operation. Hal notes that the furnace is not starting the combustion cycle. He notes that the combustion blower is not operating as would be expected and that the low-pressure switch is closed. Hal sees that the hot-surface igniter is not glowing red. With the electrical power off, he performs a resistance check on the igniter. The reading indicates that the igniter is opened due to a small crack. He determines that the igniter must be replaced. Hal informs Ms. Frazier of the issue and offers the solution and cost for such. Ms. Frazier agrees to have Hal perform the needed service.

Solution: Hal replaces the igniter and restores the electrical power to the furnace. The hot-surface igniter now glows cherry red and ignites the gases. The heating cycle is further checked and all operations are performing in a satisfactory manner. Hal provides Ms. Frazier with the bill and informs her that a follow-up call will occur.

Safety: Always use caution when checking the operation of hot-surface igniters. When energized, they produce very hot temperatures that can cause serious burns. Never touch an energized igniter.

DiversiTech Corporation

Figure 41-41. A concentric pipe used for fresh air intake and flue gas venting for a high-efficiency condensing furnace. Combustion gases flow through a central pipe, and intake air flows through a larger pipe around the central pipe. Two separate airways are contained in one body.

When installing a PVC flue pipe for high-efficiency furnaces or boilers, a technician may install the pipe either vertically or horizontally. Either way, a flue pipe should use the shortest route possible with the fewest number of elbows. The combustion air intake and flue pipe outlet must exit the exterior wall at the proper distance and direction from each other. The proper distance is specified by the furnace manufacturer.

Code Alert

Vent System Sizing and Locations

Appendix B in the IRC and IFGC provides guidelines for the sizing and installation of venting systems, including systems serving multiple appliances. Appendix C provides location guidelines for through-wall vent exhausts.

All PVC connections must be leakproof. A wall termination kit can be installed at the ends of the PVC pipes to prevent objects from entering the pipes while still allowing for the proper intake of combustion air and for the venting of the appliance. Due to the lowered flue gas temperature, a drain line is needed to dispose of condensate. Care should be taken to prevent condensate from freezing.

It is usually best for a furnace or boiler to be individually vented. However, if a flue or chimney must be shared by two or more gas-burning appliances, thoroughly review manufacturer literature and requirements and recommendations from the International Fuel Gas Code.

Some installations with Class A and Class B chimneys or flues use a ***draft regulator***. This is a device that regulates the intake of indoor air into the flue to moderate or stabilize the flow of flue gas. A draft regulator is installed in the flue pipe outlet opening or as a section of the flue pipe.

Draft regulators are sometimes called vent dampers. Draft regulators may be controlled thermostatically, electrically, or barometrically. A thermostatic draft regulator opens when a bimetal element senses and reacts to the heat of flue gas. An electric draft regulator uses a motor or actuator to open when the thermostat calls for heat and to close when the call for heat ends. A vacuum draft regulator operates like a barometric damper by opening under pressure difference, such as when pulled open by the negative pressure of flue gas suction. An adjustable counterweight keeps a vacuum draft regulator closed when no suction is present, **Figure 41-42**.

Field Controls, LLC

Figure 41-42. A vacuum draft regulator has a counterweight that can be adjusted to change the amount of air intake, which affects the rate of airflow in the flue pipe.

Chapter Review

Summary

- Combustion is a chemical process of rapid oxidation that requires fuel, heat, and oxygen. The products of complete combustion are carbon dioxide, water, and energy.
- Combustion occurs only when the ratio of air to fuel is within an acceptable range. A fuel's flammability limits are the range of fuel concentrations within which the fuel will burn when ignited.
- Primary air is air mixed with fuel prior to ignition. Secondary air is air added to a flame after ignition to maintain combustion. Excess air is any secondary air that exceeds the amount of air necessary for complete combustion.
- To determine a furnace's combustion efficiency, a technician measures the carbon dioxide (CO_2) content, carbon monoxide (CO) content, fuel gas pressure, oxygen (O_2) content, and stack temperature. The carbon dioxide, oxygen, and carbon monoxide content indicate whether complete combustion is occurring. Checking the gas pressure helps a technician identify the cause of incomplete combustion. The stack temperature can be used to calculate a furnace's efficiency.
- A combination gas valve incorporates a manual shutoff valve, multiple solenoid valves, a pressure regulator, and safety shutoff in a single valve body.
- Atmospheric gas burners use the venturi effect to induce airflow through the burner without the need for a blower. Atmospheric gas burners can be subcategorized as ribbon, slotted, or single-port burners. Power burners use a blower to force both primary and secondary air into the burner tube.
- Standing-pilot ignition systems have a continuously burning pilot light that is monitored by a thermocouple. Intermittent-pilot ignition systems have a pilot light that is ignited only when needed. Flame rectification or a thermocouple is used to verify the presence of a flame.
- Direct-spark ignition (DSI) systems use an electric spark to ignite the gas burners. The electrodes used to create the spark can also be used for flame detection. Hot-surface ignition (HSI) systems use glow coils to produce the heat needed to ignite the burners.
- An ignition control module initiates a furnace's On cycle when it receives a call for heat signal from a system thermostat. Ignition control modules are responsible for opening and closing the gas valve, operating the ignition system, and monitoring safety and limit controls to ensure the proper operating conditions. Control modules come with a number of functions, some of which include trial for ignition, soft lockout, hard lockout, pre-purging, inter-purging, and post-purging.
- Gas furnace safety controls include high-limit switches, which prevent overheating, and rollout switches, which shut down the furnace in cases of flame rollout. Rollout switches must be reset manually. End switches or pressure switches are used to verify that a combustion blower is operating before the burners can be ignited.
- Mid-efficiency furnaces have an efficiency rating between 79% and 83% AFUE and do not generate condensate from flue gases. High-efficiency furnaces have a secondary heat exchanger and achieve an efficiency rating between 90% and 97% AFUE. High-efficiency furnaces do not require a traditional chimney, but must be designed to withstand corrosive condensate.
- Gas furnaces are categorized by their flue gas temperature and vent pressure. The two most common furnace types are Category I and Category IV. Category I furnaces are negative-pressure venting, noncondensing furnaces. Category IV furnaces are positive-pressure venting, condensing furnaces. Category II and Category III furnaces are rarely used.
- Black iron pipe is commonly used for gas piping in a gas-fired heating system.
- A drip leg and a manual shutoff valve must be installed in gas piping to a gas furnace. After gas piping has been assembled, a technician must perform a standing pressure test and find and fix any leaks if the standing pressure has dropped.
- Heat exchangers should be visually inspected and tested chemically for cracks or leaks prior to each heating season. A chemical test indicates whether combustion gases are escaping from the heat exchanger into the supply air.
- The three types of flue pipes or chimneys commonly used are Class A (masonry type), Class B (double-wall metal type), and PVC. An approved metal flex liner can also be installed in a Class A chimney. A PVC flue pipe for high-efficiency appliances can be installed either vertically or horizontally.

Review Questions

Answer the following questions using the information in this chapter.

1. All fuels contain hydrogen and _____ atoms.
   A. carbon
   B. helium
   C. oxygen
   D. silicon
2. A fuel-air mixture in which there is not enough fuel for combustion is _____.
   A. energy efficient
   B. lean
   C. rich
   D. stoichiometric
3. If a flame tip is yellow, it is a sign of a(n) _____.
   A. closed gas valve
   B. excess of primary air
   C. ignition lockout
   D. lack of primary air
4. The maximum concentration of carbon monoxide (CO) permitted in furnace flue gas is _____.
   A. 100 ppm
   B. 200 ppm
   C. 300 ppm
   D. 400 ppm
5. As stack temperature increases, combustion efficiency _____.
   A. decreases
   B. increases
   C. remains unaffected
   D. All of the above.
6. An increase in gas pressure causes similar conditions as a(n) _____.
   A. decrease in flame temperature
   B. excess of air
   C. lack of air
   D. All of the above.
7. Gas manifolds have threaded holes in which _____ are installed.
   A. burners
   B. pressure switches
   C. rollout switches
   D. spuds
8. The most efficient type of atmospheric gas burner is the _____ burner.
   A. inshot
   B. power
   C. ribbon
   D. slotted
9. A thermal detection system for a standing pilot furnace uses a(n) _____ or bimetallic element to sense a pilot light.
   A. diaphragm switch
   B. fluid-filled bladder
   C. glow coil
   D. thermocouple
10. Flame rectification is the process of detecting a flame by _____.
    A. measuring heat intensity with an infrared sensor
    B. measuring light intensity with an optical sensor
    C. refocusing a flame's direction with a deflector plate
    D. using the flame to change alternating current to direct current
11. One disadvantage of a(n) _____ ignition system is that it can create electromagnetic interference, which can disrupt the operation of the ignition control module.
    A. direct-spark
    B. hot-surface
    C. intermittent-pilot
    D. standing-pilot
12. Ignition control modules allow igniters a limited amount of time, called _____, to ignite the burner.
    A. hard lockout
    B. post-purge
    C. soft lockout
    D. trial for ignition
13. An ignition control module with _____ requires a service call to reset or interrupt power to the module.
    A. hard lockout
    B. non-100% shutoff
    C. post-purge
    D. soft lockout
14. A _____ is used to detect a flame that spills backward out of a burner.
    A. flame rod
    B. high-limit switch
    C. rollout switch
    D. thermocouple
15. A(n) _____ is connected to the end of a damper motor shaft and is used to verify that a combustion blower is on.
    A. end switch
    B. high-limit switch
    C. pressure switch
    D. rollout switch

Copyright Goodheart-Willcox Co., Inc. 2017

16. A high-efficiency furnace _____.
    A. has an AFUE rating of 90% and above
    B. has a secondary heat exchanger
    C. uses PVC pipe to vent flue gases
    D. All of the above.

17. The two primary factors determining a furnace's venting category are _____.
    A. ignition system and gas pipe material
    B. thermostat type and furnace blower cfm rating
    C. type of fuel gas used and burner type
    D. vent pressure and flue temperature

18. Gas-fired heating systems are most often supplied with natural gas using _____.
    A. ABS pipe
    B. black iron pipe
    C. cadmium tubing
    D. PVC pipe

19. Installed in the gas supply piping at the furnace, a(n) _____ functions to trap and collect possible contaminants that may flow with the gas.
    A. drip leg
    B. in-line filter
    C. open vent in the piping
    D. P trap

20. When checking for a gas leak, technicians should use _____.
    A. a halide torch
    B. open flames
    C. soap bubbles
    D. ultraviolet light

21. Which of the following would be most useful to ensure that gas piping is installed correctly?
    A. ANSI/ASHRAE Standard 103.
    B. International Fuel Gas Code.
    C. International Plumbing Code.
    D. National Electrical Code.

22. When the proper amount of primary air is supplied to a gas furnace, the flame should have a(n) _____ color.
    A. black
    B. blue
    C. orange
    D. red

23. A chimney or flue pipe should extend at least _____ above the highest part of a roof.
    A. 3″ (0.0762 m)
    B. 2′ (0.6 m)
    C. 5′ (1.5 m)
    D. 10′ (3 m)

24. High-efficiency furnaces typically vent flue gases and bring in fresh outdoor air through _____.
    A. black iron pipe
    B. copper tubing
    C. PVC pipe
    D. stainless steel pipe

25. A draft regulator may be installed in some _____ to moderate or stabilize the flow of flue gas.
    A. combustion air inlets
    B. combustion chambers
    C. flue pipes
    D. heat exchangers

42.8 Oil-Fired Heating System Service
- 42.8.1 Storage Tank and Fuel Line Installation
- 42.8.2 Oil Burner Installation
- 42.8.3 Oil Furnace Maintenance
- 42.8.4 Troubleshooting Oil Furnaces

Learning Objectives

Information in this chapter will enable you to:

- Summarize the basic operation of an oil furnace.
- Identify the characteristics of fuel oil.
- Perform several tests to check the combustion efficiency of an oil-fired heating system.
- Compare the advantages and disadvantages of using a one-pipe or two-pipe fuel delivery system.
- Describe the functions of different fuel line components.
- Identify oil burner components and explain their purposes.
- Explain how stack relays and cad cell relays are used to detect the presence of a flame.
- Describe the difference between interrupted and intermittent ignition.
- Define the various functions of a primary control unit.
- Follow code requirements for installing fuel lines and storage tanks for an oil-fired heating system.
- Bleed an oil-fired heating system's fuel lines and perform other routine maintenance and service procedures.

Review of Key Concepts

Reviewing these concepts from earlier chapters will help you understand new concepts presented in this chapter:

- The measurement of furnace efficiency is the annual fuel utilization efficiency (AFUE) rating. The higher the AFUE rating, the more efficient and cost-effective a furnace is. (Chapter 41)
- A fluid with high viscosity resists flowing while a fluid with low viscosity flows more easily. The lowest temperature at which a fluid will flow is referred to as its pour point. (Chapter 9)
- Technicians use a combustion analyzer to measure flue gas variables, such as carbon dioxide content (CO_2), carbon monoxide content (CO), and oxygen content (O_2), by measuring in a furnace's flue. (Chapter 41)
- Stack temperature, or net stack temperature, is the temperature of the flue gas in the flue minus the temperature of the combustion air. As excess air increases, a furnace's stack temperature also increases, and the furnace's efficiency decreases. (Chapter 41)
- Some Class A and Class B chimneys or flues use a draft regulator, which is a device that regulates the intake of indoor air into the flue to moderate or stabilize the flow of flue gas. A draft regulator is installed in the flue pipe outlet opening or as a section of the flue pipe. (Chapter 41)
- A transformer uses an alternating current in one coil of wire to generate a magnetic field that induces an alternating current in another coil of wire that is electrically isolated from the first coil. A transformer with more turns in its secondary coil than in its primary coil is a step-up transformer. (Chapter 12)

Introduction

Oil-fired heating systems use the combustion of vaporized fuel oil to create heat for distributing throughout a conditioned space. Oil-fired systems come in a variety of designs, such as forced-air oil furnaces, oil-fired boilers, and oil-fired unit heaters. Heat from fuel oil combustion is transferred through a heat exchanger into a medium, such as air or water, which then distributes the heat throughout a conditioned space. The products of combustion are piped from a combustion chamber into a flue leading outdoors.

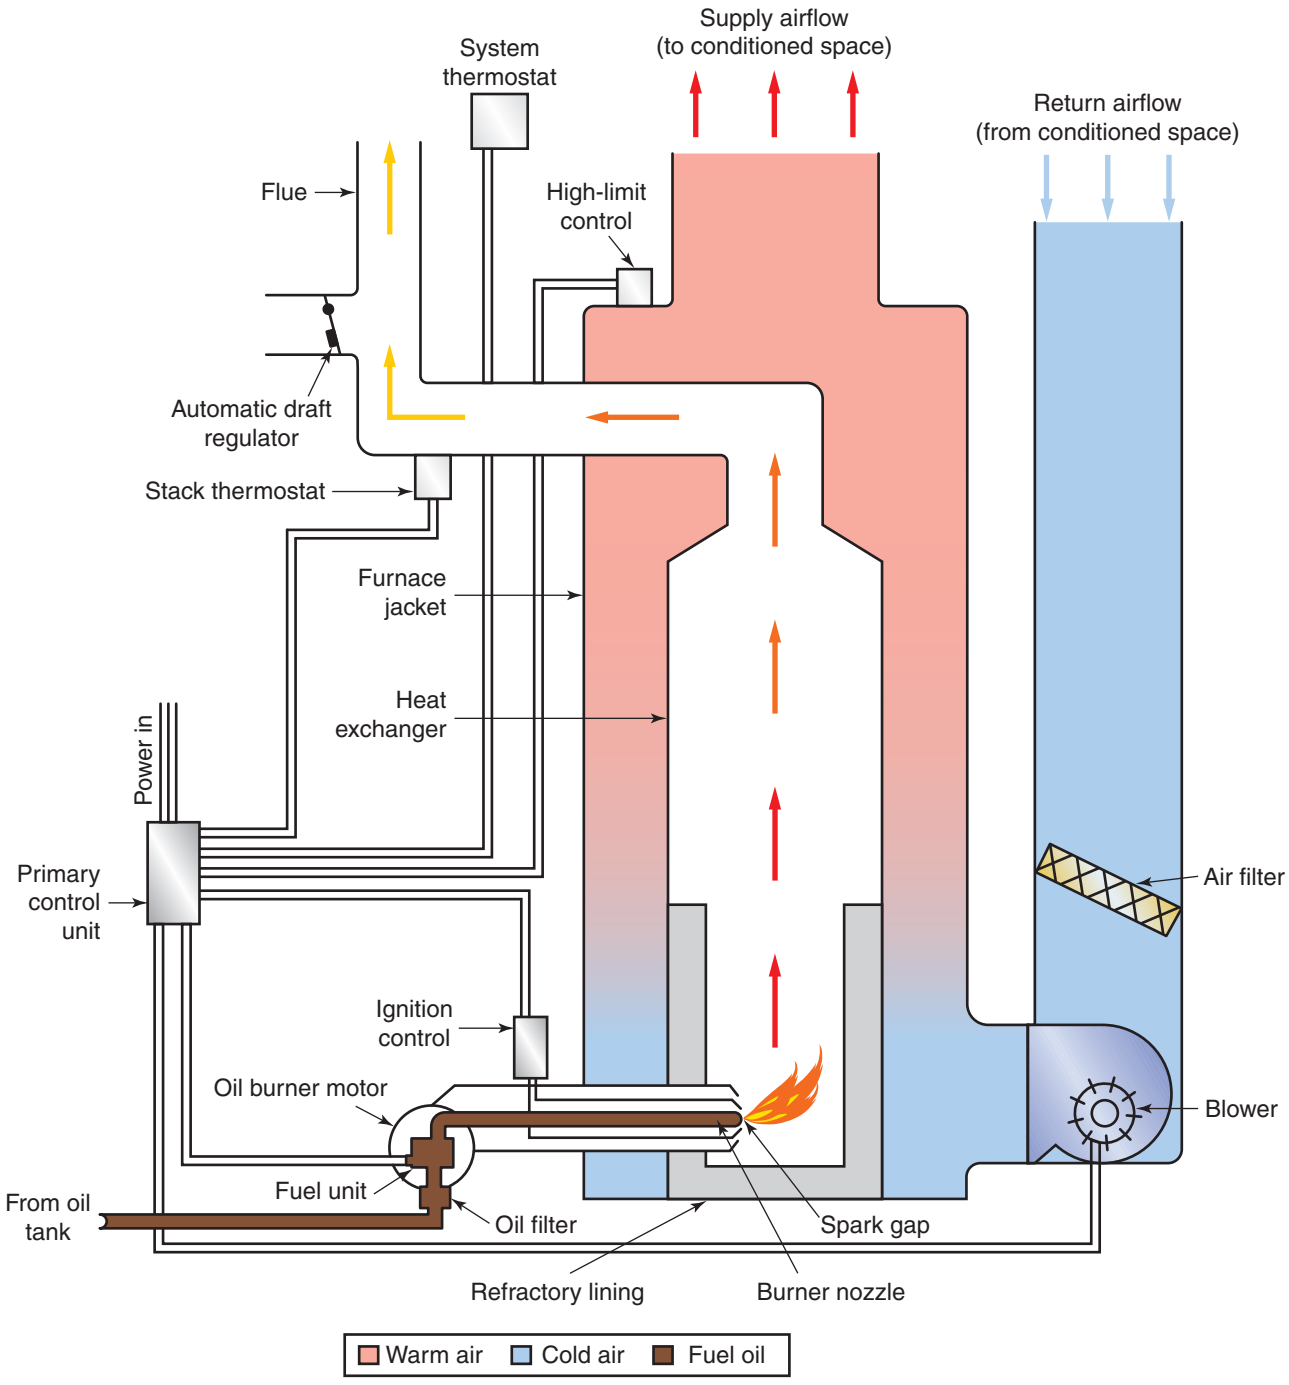
Oil furnaces are available in a broad range of Btu capacities and in upflow, downflow, and horizontal designs. The minimum allowable annual fuel utilization efficiency (AFUE) rating for an oil furnace is 78%. Manufacturers of standard oil furnaces have mostly kept AFUEs below 85% to minimize problems resulting from flue gases that cool and condense into a corrosive liquid. However, some manufacturers have produced oil-fired condensing furnaces with over 90% AFUE that can capture additional heat from flue gas and safely pipe away corrosive condensation.

Copyright Goodheart-Willcox Co., Inc. 2017

42.1 Basic Oil Furnace Operation

The main focus of this chapter on oil-fired heating systems is the forced-air oil furnace. Comprehending the basic operation of a forced-air oil furnace will help you understand the function of the system's individual components as they are covered in detail later in this chapter, **Figure 42-1**.

A system thermostat calling for heat initiates oil furnace ignition. The primary control unit receives the thermostat signal and responds by turning on the oil burner motor. This motor turns a fan to provide combustion air and also turns a pump inside the fuel unit that delivers fuel oil to the oil burner. The primary control unit also opens a solenoid valve in the fuel line. The primary control unit later closes this solenoid



Goodheart-Willcox Publisher

Copyright Goodheart-Willcox Co., Inc. 2017

valve to stop oil flow to the oil burner when the thermostat ends its call for heat.

As the oil burner motor operates the fan and fuel unit pump, air and fuel oil mix and are blown into a combustion chamber. The primary control unit signals ignition control to send high-voltage electricity to the electrodes positioned at the outlet of the oil burner. The high voltage arcs across the electrodes and ignites the mixture of air and fuel oil.

As more air and oil burn, heat building up in the combustion chamber warms the heat exchanger. The primary control unit turns on an indoor blower that circulates air from the conditioned space around the heat exchanger. Heat within the heat exchanger is transferred to this air, which warms a building as it circulates throughout. Meanwhile, the products of combustion are contained within the heat exchanger away from air circulated to the conditioned space. Eventually, the products of combustion are vented to the atmosphere. When the thermostat is satisfied with the temperature in the conditioned space, it stops its call for heat. The primary control unit closes the fuel supply line solenoid and turns off the oil burner motor, which stops pumping fuel oil and combustion air. The indoor blower may be allowed to run for a short while longer to extract accumulated heat in the heat exchanger. This ends an oil furnace's On cycle.

42.2 Fuel Oil

To produce heat, oil-fired heating systems burn a substance called ***fuel oil***, which is a refined form of petroleum. Fuel oil grades are established by the US Department of Commerce and conform to specifications set forth by the American Society for Testing and Materials (ASTM). There are six common fuel oils. The most commonly used fuel oil in residential and light commercial heating applications is No. 2 fuel oil. No. 2 fuel oil is also called *heating oil*. Fuel oil is stored in a tank that is located outside a building, inside a building, or underground, **Figure 42-2**.

Fuel oil has a number of characteristics that should be understood by HVACR technicians:

- Heating value.
- Flash point.
- Ignition point.
- Distillation quality.
- Viscosity.
- Pour point.
- Carbon residue.
- Ash content.
- Water and sediment content.

Donald Gargano/Shutterstock.com

Figure 42-2. Fuel oil tank installed outside the building being heated. In cold climates, an additive must be mixed with fuel oil stored in outdoor tanks to prevent the oil from gelling or forming wax.

Heating value is how much heat (in Btu per gallon) a fuel oil can produce. The heating value of No. 2 fuel oil is generally approximated to be 140,000 Btu per gallon. However, the actual value ranges from 137,000 Btu per gallon to 141,800 Btu per gallon. This value varies because there is variation in the carbon and hydrogen content of different batches of fuel oil. Just like the fuel gases used in gas furnaces, fuel oils are hydrocarbons. Generally, fuel oils contain about 85% carbon and 12% hydrogen. Various other elements make up the remaining 3% of the fuel oil. The greater the carbon content is, the higher the heating value.

A fuel oil's flash point is the minimum temperature at which a flame will ignite fuel oil vapor above a pool of liquid fuel oil. Just above a fuel oil's flash point is its ***ignition point***, which is the minimum temperature at which a flame will ignite and continue to burn fuel oil vapor as it rises from a pool of liquid fuel oil. Since fuel oil must burn as a vapor, instead of a liquid, its ability to vaporize is important to engineers and manufacturers. This ability is called a fuel oil's ***distillation quality***.

Viscosity is a measure of a liquid's resistance to flow. A fuel oil's viscosity plays a part in determining what size burner nozzle orifice should be used by an oil burner. An orifice that is too small results in a cool or weak flame caused by having insufficient fuel to burn. An orifice that is too large results in unburned fuel oil, which creates excessive smoke and a buildup of soot in the combustion chamber.

Pro Tip

Saybolt Universal Second

The Saybolt universal second (SUS or SSU) is a measurement of viscosity based on the amount of time required for a specific volume of oil to flow through a specific size orifice at a specific temperature. This unit of measure is generally considered obsolete, but is still widely used in the petroleum industry.

The viscosity of No. 2 fuel oil varies from between 50 SUS and 100 SUS at 0°F (–18°C) to between 35 SUS and 45 SUS at 70°F (21°C). This means that gun burners may have pumping and combustion problems when the fuel oil is cold.

As the temperature decreases, substances like fuel oil begin to solidify and do not flow as easily. A fuel oil's pour point determines the minimum temperature at which it can be stored, retrieved, and used. A fuel oil's pour point also determines where the fuel oil tank is located for a given application. In some climates, this may be outside or underground. In other climates, it must be inside a building.

Ideally, there should be no carbon residue left after combustion. However, in some cases where not enough oxygen is available for combustion, carbon residue may result in the form of soot. The amount of residue produced by combustion should be kept to a minimum.

Fuel oils may also contain certain amounts of materials that do not burn in the combustion process. These materials are contaminants that cause wear and tear on oil furnace components. The amount of noncombustible contaminants in fuel oil is referred to as the fuel oil's ***ash content***.

Although manufacturers strive to produce pure fuel oil, some small amounts of water and contaminants may get into fuel oil at some point. The water and sediment content should be as minimal as possible. Sediment can clog filters, and water corrodes fuel oil tanks and can decrease the quality of a flame.

42.3 Combustion Efficiency

During fuel oil combustion, carbon (C) and hydrogen (H) combine with oxygen (O_2) in the air. This produces carbon dioxide (CO_2) and water (H_2O) in vapor form. A certain amount of fuel oil requires a certain amount of oxygen to burn properly. This process also requires a certain amount of air to displace the products of combustion and move them safely out of the flue. About 106 lb of air is required to burn one gallon of No. 2 fuel oil.

Pro Tip

Air Density

The density of dry air increases as temperature increases. As a result, the actual volume of air required for combustion varies depending on temperature which varies based on whether the air is drawn from inside the building or outside the building.

When complete combustion occurs, the proper flame appearance is luminous, mainly yellow. A flame that is dull orange or red may be caused by incomplete combustion. However, to properly diagnose incomplete combustion and to determine combustion efficiency, an HVACR technician must monitor several variables using a combustion testing kit, **Figure 42-3**.

A combustion testing kit allows a technician to calculate oil furnace efficiency by conducting the following individual tests:

- CO_2 test.
- Stack temperature test.
- Draft test.
- Smoke test.

42.3.1 CO_2 Test

The amount of carbon dioxide (CO_2) in flue gas is an indicator of combustion efficiency. A ***CO_2 test*** measures the amount of CO_2 in the flue gas to determine if complete combustion is taking place. Measuring CO_2 can be done using traditional testing instruments or a digital combustion analyzer. When using a combustion analyzer, a technician inserts the analyzer's probe into a small hole in the flue pipe. The probe should be positioned near the hottest part of the flue to obtain accurate readings.

Safety Note

Combustion Analyzer Probe

The combustion analyzer probe can be a burn hazard. Do not touch the probe after removing it from the flue pipe. Allow the probe about five minutes to cool before handling it.

In the traditional method, a flue gas sample is exposed to a chemical that absorbs only carbon dioxide. If 10 cm^3 of flue gas reduces to 9 cm^3 of gas after exposure to the chemical, the flue gas contains 1 cm^3 of carbon dioxide, which is 10%, **Figure 42-4**.

If the gas cools during the traditional testing procedure, however, its volume is reduced. This means the technician will obtain an incorrect reading indicating that the amount of CO_2 is too high. As a result, the flue

Bacharach, Inc.

Figure 42-4. Traditional CO_2 testing instruments include a measuring cylinder with attached aspirator bulb and a sampling tube.

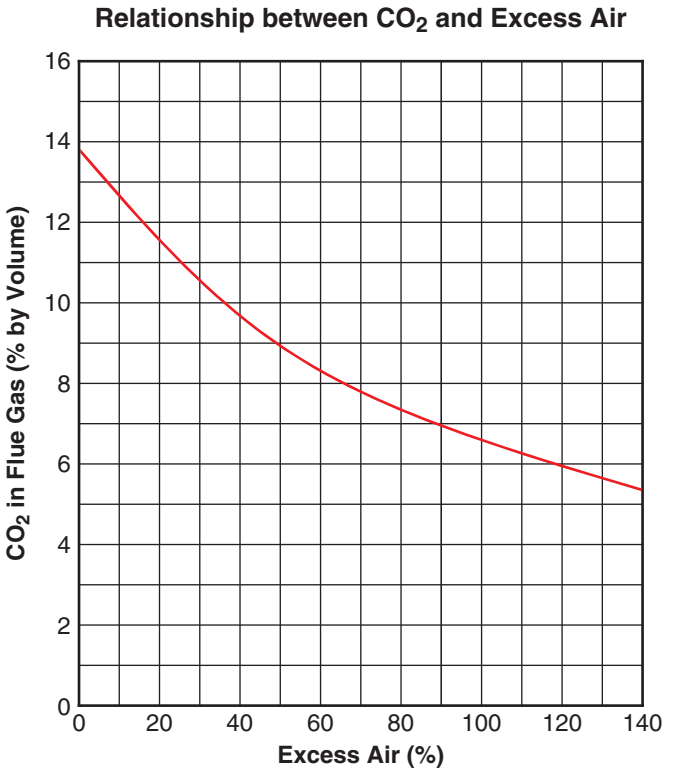
gas temperature must be known before and after testing, and a correction must be made for accurate results. Tables are provided by equipment manufacturers.

When stoichiometric combustion (perfect combustion), takes place, about 15% of the flue gas volume is CO_2. However, oil furnaces cannot achieve perfect combustion because they use excess air to ensure complete combustion, which dilutes the amount of CO_2 in the flue gas. See **Figure 42-5**.

Oil furnace exhaust will vary in CO_2 content. Some operate correctly with as low as 8% CO_2 while others operate correctly with as high as 12% CO_2. The manufacturer's service manual will state the correct amount for the system being tested.

A low CO_2 reading (below 8%) indicates that incomplete combustion is occurring. Causes of low CO_2 measurements include a burner nozzle that is too small, air leaking into the heat exchanger, and underfiring. A CO_2 content that is too high usually results in excess smoke in the flue gas. Causes of high CO_2 measurements include an insufficient draft and overfiring. ***Overfiring*** is a condition in which a heating system creates too much heat. This causes high flue gas temperature and may even result in the flue pipe turning red.

Copyright Goodheart-Willcox Co., Inc. 2017



Goodheart-Willcox Publisher

Figure 42-5. As excess air increases in an oil furnace, it reduces the percentage of carbon dioxide in the flue gas by volume.

In oil-fired heating systems, overfiring often happens because a technician has replaced the original oil burner nozzle with a nozzle that has a higher capacity. A higher-capacity nozzle causes the oil burner to pump too much fuel into the combustion chamber. The result is more heat than the heat exchanger can absorb and distribute, and the excess heat escapes up the flue. Overfiring can also produce smoke from fuel oil that is not completely consumed in the combustion process. Replacing the burner nozzle with the appropriate size will remedy this situation.

Another less common cause of overfiring is increased oil pressure. Oil pressure is typically set at 100 psi (700 kPa). However, a confused or frustrated technician may have increased the pressure in a poor effort to fix one problem. If a thermostat is not satisfied quickly enough, an overfiring furnace may short cycle.

42.3.2 Stack Temperature Test

Stack temperature is an indicator of combustion efficiency. Stack temperatures vary from 300°F to 900°F (150°C to 500°C). Manufacturers provide average stack temperatures for individual furnaces. These average temperatures should be compared to operational readings, **Figure 42-6**.

Stack Temperature Test Procedure

Stack temperature is the temperature of the flue gas in the flue pipe minus the temperature of the combustion air. As a result, this procedure requires technicians to take two temperature measurements and perform a subtraction operation. Since combustion air enters most furnaces at room temperature, this combustion air temperature is essentially room temperature.

1. Insert a stem thermometer or combustion analyzer probe into a hole in the flue pipe.
2. Increase the system thermostat temperature and let the furnace run for at least five minutes.
3. After letting the furnace run for five minutes, write down the value measured by the stem thermometer. By this time, the temperature reading should be steady. If it is still rising, wait until it levels off before recording the temperature value: _____.
4. If combustion air is being drawn in from the furnace room, measure the ambient temperature of the room in which the furnace is located. If air is being drawn in from elsewhere, measure and record that value: _____.
5. Subtract the combustion air temperature from the flue temperature measurement and write down the answer: _____.
6. Review the manufacturer's recommended stack temperature for the equipment being tested. Are the manufacturer's number and the calculated number close in value? Perform any recommended service procedures provided by the manufacturer.

A high stack temperature reading indicates that an oil furnace is not operating at peak efficiency. The

Oil Furnace Combustion Efficiency

Net Stack Temperature (°F)	Net Stack Temperature (°C)	Combustion Efficiency (%)
1,000	538	65–69
800	427	70–73
600	316	76–79
400	204	82–84

Goodheart-Willcox Publisher

Figure 42-6. The average combustion efficiency of an oil furnace can be determined based on the net stack temperature.

Copyright Goodheart-Willcox Co., Inc. 2017

causes of high stack temperature vary. Not enough heat may be transferring to the distribution medium, such as when the heat exchanger is insulated by soot deposits. Also, there may be too much draft through the combustion chamber, which reduces the time flue gas has to transfer heat. The furnace may be producing too much heat, such as when the oil pressure is set too high. In all these cases, excess heat is being lost up the flue, reducing the furnace's combustion efficiency.

42.3.3 Draft Test

Efficient, safe combustion in a furnace requires a proper draft. In a combustion heating system, ***draft*** is the movement of flue gas. Draft affects combustion as it allows for the supply of oxygen for burning. Draft also affects how quickly combustion gases pass through the heat exchanger, which plays a part in how much heat is transferred to the conditioned space and how much heat escapes through the flue. Draft depends on two things:

- The density of the flue gas compared to the density of the air.
- The pressure difference between the inside of the building and the outside of the building.

If the pressure difference is too great, flue gas will flow too quickly, allowing too much heat to escape out through the flue. If the pressure difference is too small, it may result in blowback that causes smoke and foul odors to enter the furnace room. To perform a ***draft test***, technicians use a ***draft gauge*** to measure the air pressure of the flue, which indicates the rate of flue gas flow. See **Figure 42-7**.

Draft is measured in inches of water column (in. WC). Oil furnaces usually require a chimney or flue draft of –0.02 in. WC to –0.03 in. WC. A technician must check the draft regulator prior to making any measurements or adjustments. A draft regulator is a device installed in the flue pipe that controls the amount of air drawn into the flue, usually from within the conditioned space. Often a draft regulator is a barometric damper with an adjustable weight used to determine the amount of airflow.

If the reading on the draft gauge is low, the weight should be moved to increase the draft. If the reading on the draft gauge is high, the weight should be moved to reduce the draft. Not all oil furnaces require draft testing. Oil furnaces with sealed combustion chambers often use a dedicated pipe for combustion air and do not always have a draft regulator.

Bacharach, Inc.

Figure 42-7. Draft gauge used to identify draft problems in residential and commercial heating systems.

Draft Test Procedure

In oil furnaces, draft measurements are taken in two locations: in the combustion chamber and in the flue. An ***overfire draft test*** measures the draft in the combustion chamber, and a ***flue draft test*** measures the draft in the flue. Overfire draft should be measured first.

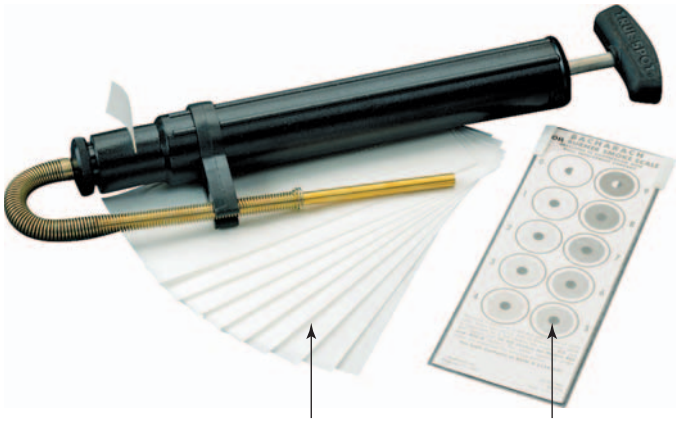
1. Increase the system thermostat temperature and let the furnace run for at least five minutes.
2. The overfire draft measurement is taken through air louvers or a bolt hole in the furnace door. The flue draft measurement is taken in the flue pipe between the draft regulator and furnace.
3. Unwrap the draft gauge hose and place the draft gauge on a level surface.
4. Calibrate the draft gauge to zero using the adjustment on the gauge.
5. Insert the draft gauge hose through the hole in the door or the hole in the flue pipe.
6. After 30 seconds, record the draft value measurement: _____.
7. Compare the measured draft value with the manufacturer's recommended values.

Copyright Goodheart-Willcox Co., Inc. 2017

If the measured draft value is below the recommended draft value, it means there is insufficient draft. Insufficient draft can occur when too many appliances, such as an oil furnace and a water heater, are connected to the same flue pipe. Obstructions such as soot, a bird's nest, and loose bricks in the chimney can restrict the flow of flue gases and cause insufficient draft as well. Homes with more airtight construction can also cause insufficient draft by preventing enough outside air from entering for combustion. This causes the pressure inside the building to drop below the pressure outside the building, which can result in blowback. Installing a pipe dedicated to bringing in fresh combustion air from outside is the best solution to this problem, **Figure 42-8**.

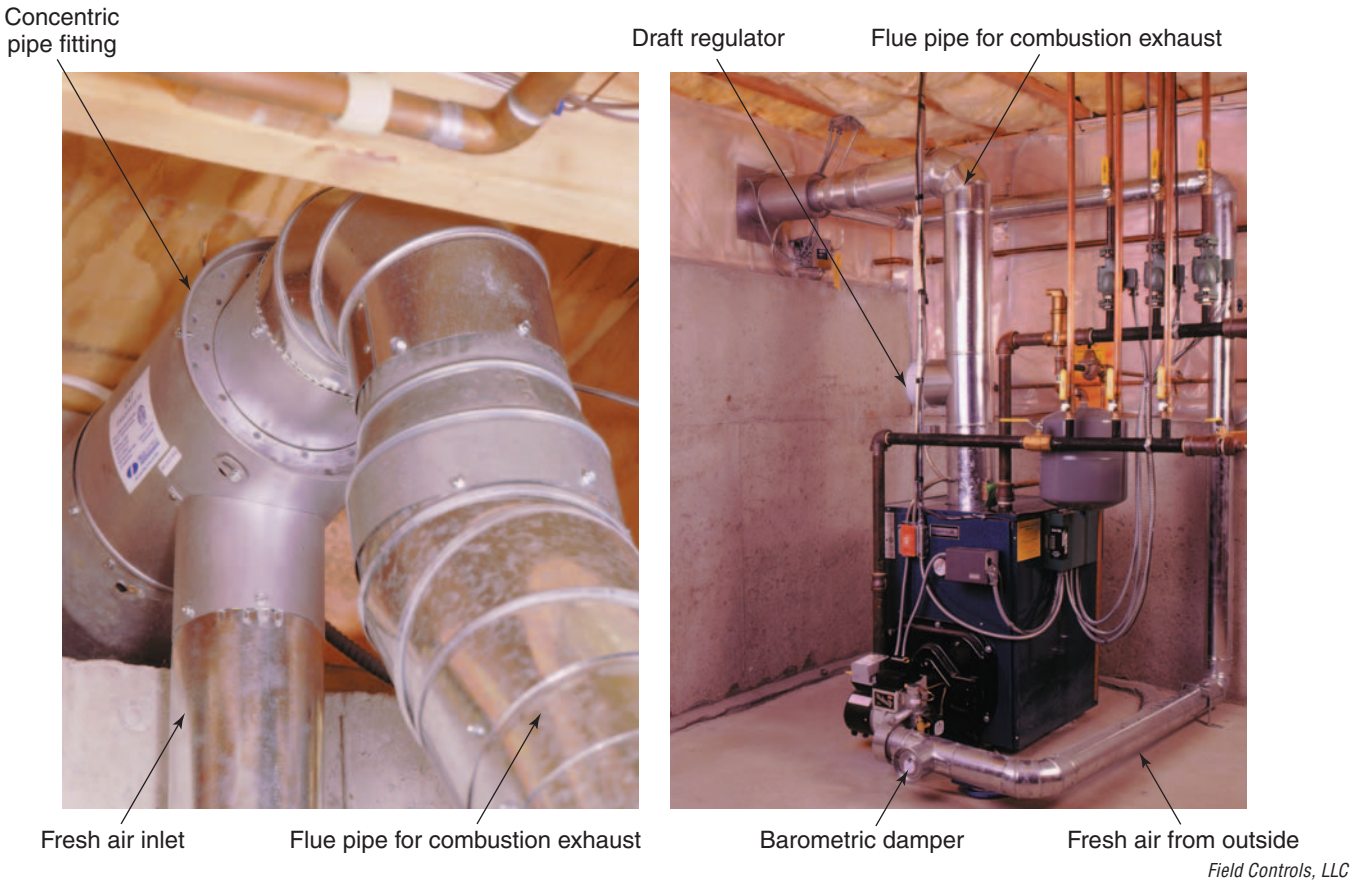
42.3.4 Smoke Test

In addition to performing a CO_2 test, a technician can also perform a smoke test as another method of gauging incomplete combustion. A ***smoke test*** involves drawing a sample of flue gas from the flue or combustion chamber while the furnace is running. This flue gas sample is passed through filter paper that becomes stained by the smoke. The stained paper is compared with premade samples, **Figure 42-9**.



Bacharach, Inc.

Figure 42-9. The test pump, filter paper, and premade stain samples used to perform a smoke test.



Field Controls, LLC

Figure 42-8. Using concentric piping (pipe-within-a-pipe), a single pipe body can supply fresh air for combustion and allow combustion exhaust to exit a building. This oil-fired boiler primarily draws in air from outside, but a barometric damper allows indoor air to be drawn in when necessary. A draft regulator is also installed on the flue pipe.

Copyright Goodheart-Willcox Co., Inc. 2017

Incomplete combustion causes fuel oil that is not fully consumed to turn into smoke, which can accumulate as soot in the heat exchanger. This soot forms an insulating barrier that reduces the amount of heat transferred to the conditioned space. Incomplete combustion not only reduces heat exchanger efficiency, but also results in the production of less heat for distribution.

Smoke Test Procedure

Before beginning a smoke test, install an unused piece of filter paper into the test pump.

1. Increase the system thermostat temperature and let the furnace run for at least five minutes.
2. Insert a stem thermometer into a hole in the flue pipe or into the combustion chamber. Check manufacturer literature for proper placement.
3. Monitor the stem thermometer. After five minutes, the flue temperature should level off. If it continues to rise, let the furnace continue to run.
4. After the temperature has leveled off, remove the stem thermometer. While the furnace continues to run, use the test pump to take a sample of flue gas from the hole in the flue pipe.
5. Remove the filter paper and compare it with the premade samples.
6. Follow any additional directions from the manufacturer of the smoke tester.

42.4 Fuel Line Components

While oil burners and their accessories make up the main operating components of an oil-fired heating system, a number of other active and passive components also aid in operation. Many of these components are found along the fuel supply line between the fuel oil tank and the oil burner.

Code Alert

Oil Piping Systems

Chapter 8 of NFPA 31 contains information on acceptable piping types and materials, acceptable fittings, and piping system design. There is also specific coverage of fill piping, vent piping, supply and return piping, auxiliary tank piping, piping cross-connected tanks, pumps, valves, gauges, other equipment, and testing supply piping.

There are two fuel line configurations: one pipe and two pipe. A ***one-pipe fuel delivery system*** uses a single fuel line between the fuel oil tank and the oil burner. Since many modern fuel units (fuel oil pumps) are able to pump more fuel oil than the oil burner requires, internal bypass valves in the fuel unit separate the extra oil pumped from the oil required by the burner. The amount of fuel oil necessary for burner operation is directed to the oil burner, and the rest of the fuel oil is directed back to the fuel unit's inlet through the unit's internal bypass valves, **Figure 42-10**.

One-pipe fuel delivery systems have air problems more often than two-pipe fuel delivery systems. Despite being more likely to experience air-related problems, a one-pipe fuel delivery system has certain advantages when compared to a two-pipe system. One-pipe fuel delivery systems require about half as much tubing as two-pipe fuel delivery systems. With less tubing to run, one-pipe fuel delivery systems require less installation labor and less initial investment in materials. This also reduces the risk that the fuel oil will begin chemically reacting with the copper tubing to form sludge. Sludge can clog filters, nozzles, and strainers.

A ***two-pipe fuel delivery system*** has a supply line from the fuel oil tank to the oil burner and a separate return line running from the oil burner back to the fuel oil tank. Each fuel line runs the entire length between the fuel oil tank and the oil burner. As a result, two-pipe fuel delivery systems require the fuel unit to repeatedly pump large amounts of fuel oil long distances, **Figure 42-11**.

Fuel oil is repeatedly circulated from the fuel oil tank to the oil burner until it is eventually burned in the combustion chamber. An average fuel unit in a two-pipe fuel delivery system pumps fuel oil a rate of approximately 15 gallons per hour (gph). For an oil burner with a nozzle that sprays oil into the combustion chamber at a rate of 1 gph, 15 gallons of oil are pumped and filtered for every one gallon of oil burned. This is inefficient and unnecessary.

In addition, the return line of a two-pipe fuel delivery system is pressurized. Since an oil burner would not be affected by a leak in the return line, this type of leak can continue unnoticed for quite some time. If this were to occur, it could result in significant damage and contamination, requiring a major cleanup. The major benefit of a two-pipe fuel delivery system over a one-pipe system is that a two-pipe system is self-priming and needs no bleeding if opened. If a one-pipe fuel delivery system is opened or the amount of fuel oil in the fuel tank is too low, the system must be bled to get rid of any air in the

Figure 42-10. A one-pipe fuel delivery system is used when the fuel oil tank is located above the oil burner, allowing oil to flow from the tank by gravity.

fuel line. For more information on fuel line materials and installation, see installation and service information later in this chapter.

Code Alert

Fuel Oil Piping and Storage Tanks

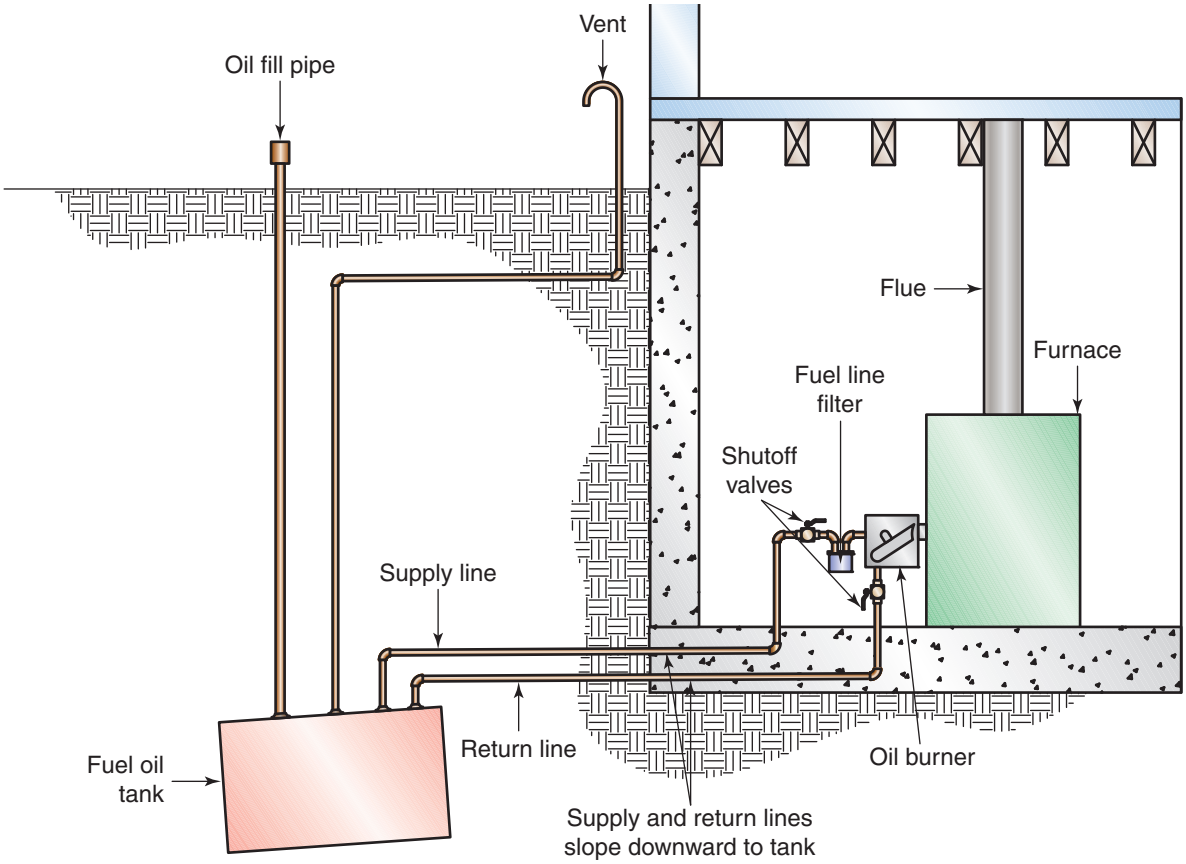
Local building codes specify requirements for fuel oil tank installation and removal. Codes also address acceptable equipment and materials for use in fuel supply, return, and vent piping; acceptable pipe joining methods; and gauge and valve requirements. Chapter 13 of the International Mechanical Code and Annex B of NFPA 31 cover acceptable tank installations.

42.4.1 Oil Deaerators

Some oil-fired heating systems suffer the symptoms of having air or other gases in the fuel line. These symptoms may be reduced oil pressure, smoky shutdowns, and oil burner lockouts. The system may just need to be bled to remove the air from the fuel line. However, if the air problems are persistent, the system may need to have an oil deaerator installed. An ***oil deaerator*** is a device that removes air and other gases from fuel oil, **Figure 42-12**.

Oil deaerators have three fuel line connections: an inlet from the fuel oil tank, an outlet to the oil burner's fuel unit, and a return inlet from the fuel unit. With the addition of a deaerator, a fuel unit may pump enough fuel oil to the burner and return the rest of the fuel oil to the deaerator to reduce air content. A deaerator's return inlet connection allows a one-pipe fuel delivery system to operate as a two-pipe fuel delivery system. Adding an oil deaerator to a system changes both one-pipe and two-pipe fuel delivery systems to the configuration shown in **Figure 42-13**.

Copyright Goodheart-Willcox Co., Inc. 2017



Goodheart-Willcox Publisher

Figure 42-11. A two-pipe fuel delivery system is used when the fuel oil tank is located below the oil burner. Fuel oil must be pumped to reach the oil burner.

Caution

Bypass Plug

When adding an oil deaerator to a one-pipe fuel delivery system, be sure to install the fuel unit's bypass plug. A fuel unit's ***bypass plug*** is a small plug that is threaded into the internal bypass between the fuel unit's inlet and return ports. It must be installed for a system with a deaerator to operate properly. The bypass plug stops excess fuel oil from flowing through the internal bypass back to the fuel unit's inlet, as it normally would in a one-pipe fuel delivery system. Instead, the bypass plug directs fuel oil out of the fuel unit's return port and to the return inlet on the oil deaerator.

An oil deaerator can be used in a two-pipe fuel delivery system to eliminate the long return line between the oil burner and fuel tank, avoiding the potential problems described in the previous section. Using a deaerator replaces the long return line to the tank with a shorter line to the deaerator, which is located closer to the oil burner. In two-pipe fuel delivery systems, the fuel unit's bypass plug should already be installed. Therefore, it should not be necessary to

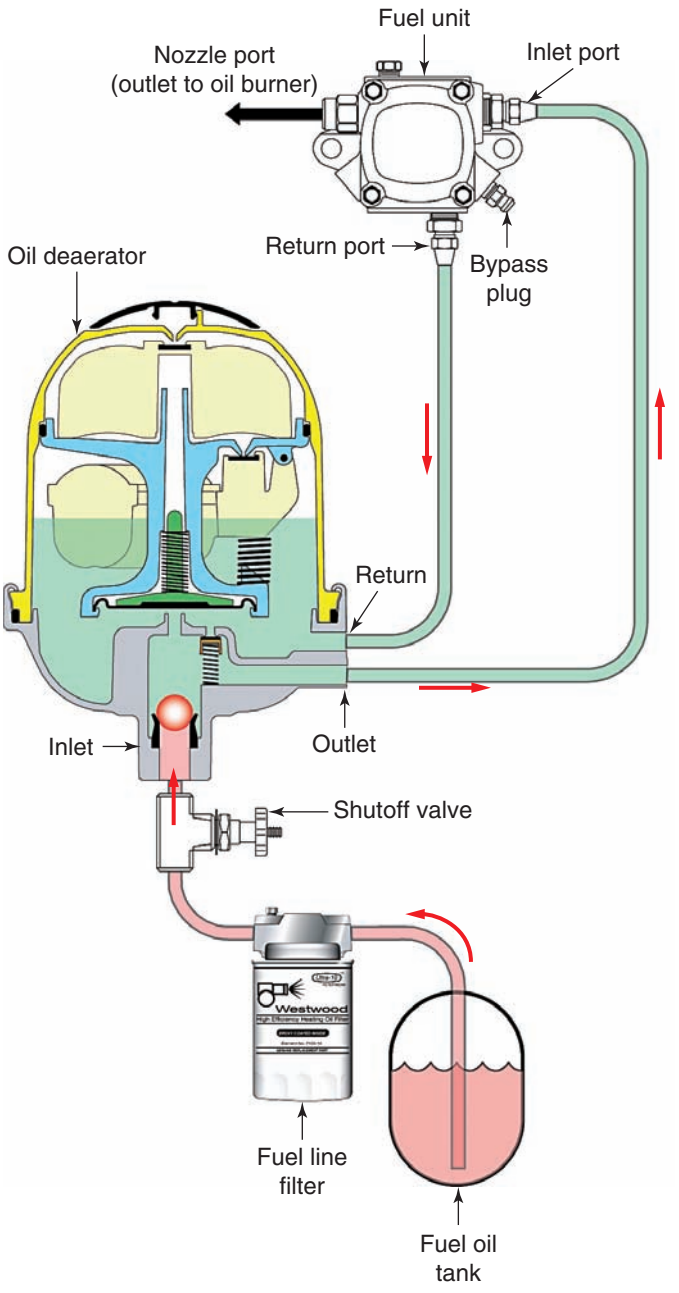
Westwood Products, Inc.

Figure 42-12. Oil deaerators may vary in appearance but typically have three ports: an inlet from the fuel tank, an outlet to the fuel unit, and a return inlet from the fuel unit.

Copyright Goodheart-Willcox Co., Inc. 2017

install a bypass plug in order to add a deaerator to a two-pipe fuel delivery system.

When an oil deaerator is added to a two-pipe fuel delivery system, the return line running from the oil burner to the fuel tank is disconnected and capped. The deaerator is connected in the supply line running from the fuel oil tank to the oil burner. Refer back to **Figure 42-13**. A short inlet line is run from the deaerator's outlet to the inlet port on the fuel unit. A short return line is then added from the fuel unit to the deaerator's return inlet. A fuel line filter should always be placed in the supply line between the fuel oil tank and the oil deaerator. The oil deaerator can become clogged and damaged if fuel oil entering it is not filtered.



Westwood Products, Inc.

Figure 42-13. Regardless of whether an oil deaerator is installed in a one-pipe or two-pipe fuel delivery system, the piping configuration is the same.

Caution

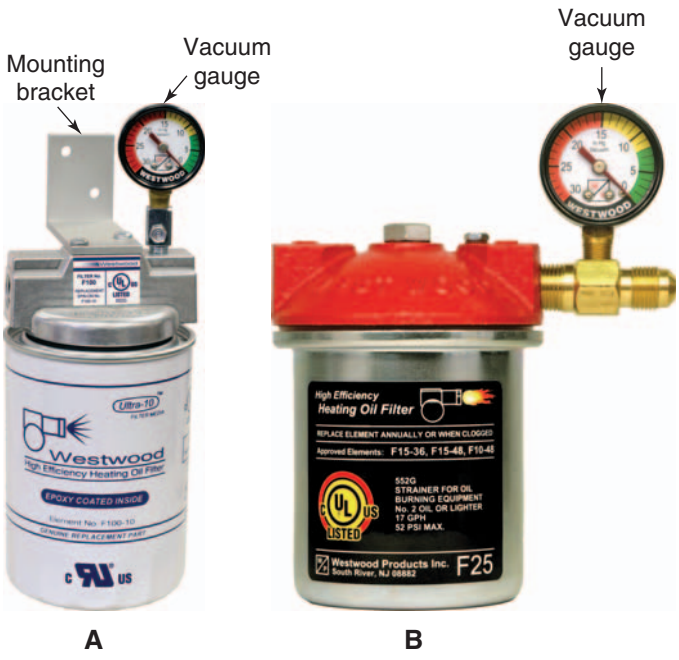
Filter Placement

Fuel line filters should not be installed between the oil deaerator and the oil burner. If a filter or any other component between the deaerator and oil burner were to become clogged, pressure could rise high enough to damage deaerator seals to the point of leaking. Although some deaerators have built-in filters, a technician should check manufacturer specifications to see if an additional fuel line filter is needed or recommended.

42.4.2 Fuel Line Filters

A ***fuel line filter*** removes impurities from fuel oil before the fuel oil reaches the oil burner for combustion. By removing the impurities from fuel oil, a fuel line filter promotes a cleaner burning flame, **Figure 42-14**.

Some fuel line filters have screens designed to catch solid matter. Others are designed to stop



Westwood Products, Inc.

Figure 42-14. Fuel line filters with pressure gauges. A—Type of filter that is replaced once it becomes clogged. B—Filter with a top that unscrews so that its filtering element can be replaced when it becomes clogged.

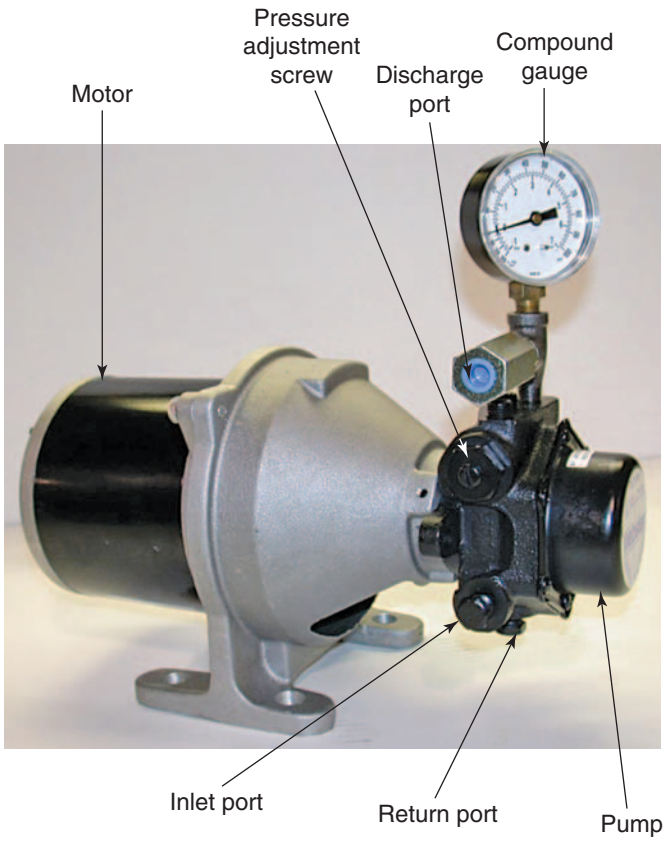
Copyright Goodheart-Willcox Co., Inc. 2017

water and sludge. These filters have inlets and outlets near the top of the canister, taking advantage of fuel oil's physical characteristic of being lighter than water and sludge. While water and sludge drop to the bottom of the canister, fuel oil flows on to the oil burner.

42.4.3 Booster Pumps

There are installations in which an oil burner's fuel unit cannot create enough suction to move fuel oil effectively from the fuel oil tank to the oil burner. This can happen if the fuel oil tank is excessively far from the oil burner, such as in larger commercial applications. It can also result from the fuel oil tank being considerably lower than the oil burner. Such installations require a ***booster pump***, which moves fuel oil from the tank to a fuel oil accumulator or reservoir tank nearer to the oil burner. From this reservoir tank, the fuel unit is able to supply fuel oil to the oil burner, **Figure 42-15**.

A booster pump should be located close to the fuel oil tank so that it functions to push, not pull, fuel oil to the reservoir tank. Low-voltage wiring is used between the oil burner and booster pump to control the booster pump motor relay.



Webster Fuel Pumps and Valves

Figure 42-15. A booster pump is used to move fuel oil from a fuel oil tank to a reservoir tank located closer to the oil burner.

Caution

Vacuum Safety Valves

When installing a booster pump, do not use a check valve in the fuel unit's inlet line in a one-pipe fuel delivery system or in the unit's return line in a two-pipe fuel delivery system. Check valves in such locations modify flow and elevate pressures, which can cause damage to fuel unit seals. Instead, install a vacuum safety valve in the fuel unit's inlet line to provide pressure relief for both the fuel unit and reservoir tank, **Figure 42-16**.

42.5 Oil Burners

An ***oil burner*** is a device that controls the burning of fuel oil to produce heat for a conditioned space using an oil-fired appliance. There are two types of oil burners: pot burners and gun burners. A ***pot burner*** is an oil burner that maintains a flame using a carburetor to feed the flame with vaporized fuel oil rising from a small pool of liquid fuel oil. Pot burners are rarely used, but they can be found on some older oil-fired unit heaters. The most widely used oil burners are gun burners.

A ***gun burner*** is an oil burner that uses a motor to operate a fan and a pump in order to deliver a pressurized mixture of air and fuel oil to a flame that is directed into a combustion chamber, **Figure 42-17**.

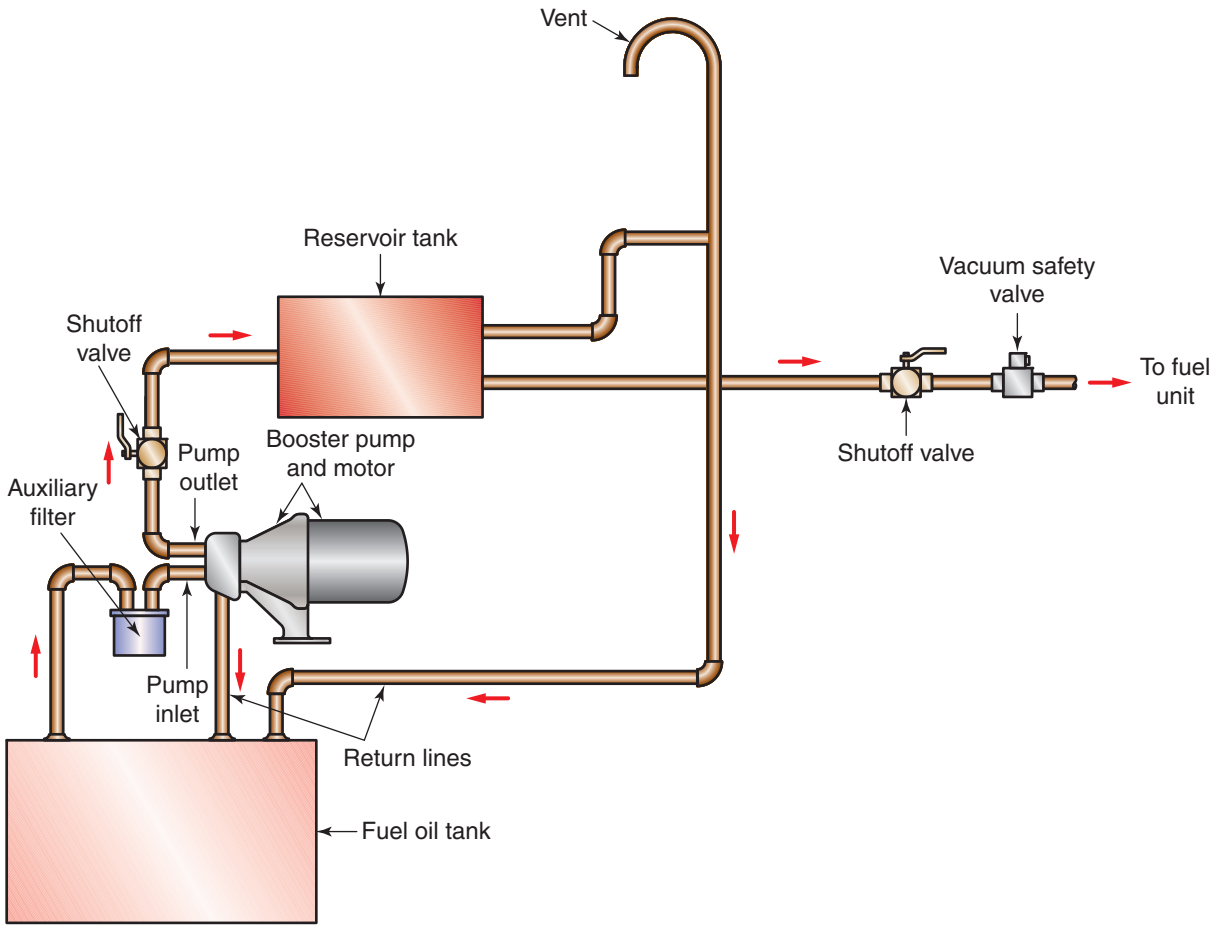
By forcing fuel oil through a specifically sized nozzle orifice under pressure, a gun burner atomizes the fuel oil, breaking it into finely divided particles. The fuel oil droplets are mixed with air from a fan and directed into the combustion chamber. Electrodes provide electric arcs that ignite the mixture of air and fuel oil.

Gun burners are designed to operate at either low pressure or high pressure. Older gun burners operate at a low pressure around 10 psi (70 kPa). Most gun burners manufactured since the 1960s operate at a high pressure. High pressures range from 100 psi to 300 psi (700 kPa to 2100 kPa). In most cases, when technicians use the term *oil burner*, they are referring to a high-pressure gun burner.

42.5.1 Oil Burner Construction

Oil burners contain a variety of components that contribute to producing an ideal flame. HVACR technicians must be familiar with oil burner parts, know how they are constructed into a single unit, and

Copyright Goodheart-Willcox Co., Inc. 2017



Goodheart-Willcox Publisher

Carlin Combustion Technology, Inc.

Figure 42-17. The main components of a typical gun burner used in residential furnaces.

understand what these parts do in the combustion process, **Figure 42-18**.

An ***air tube***, also called a *blast tube*, is the passage through which air from the burner fan is blown into the combustion chamber. It contains many oil burner components, as shown in **Figure 42-19**.

Fuel oil is pumped through the fuel line to a burner nozzle located at the end of the air tube. Electrodes used for ignition stretch through the air tube and are positioned near the front of the burner nozzle. A ***static pressure disk*** is mounted inside the air tube and disturbs airflow from the burner fan to create air turbulence for mixing air and fuel oil. A static pressure disk may also be called a *static disk*.

One of the most important components of an oil burner is the combustion head. A ***combustion head*** is a plate with slots and holes that are designed to promote ideal combustion by directing the airflow into the combustion chamber. It is located at the end of the air tube, dividing the space between the oil burner and combustion chamber. See **Figure 42-20**.

Carlin Combustion Technology, Inc.

Figure 42-20. The combustion head is located at the end of the air tube.

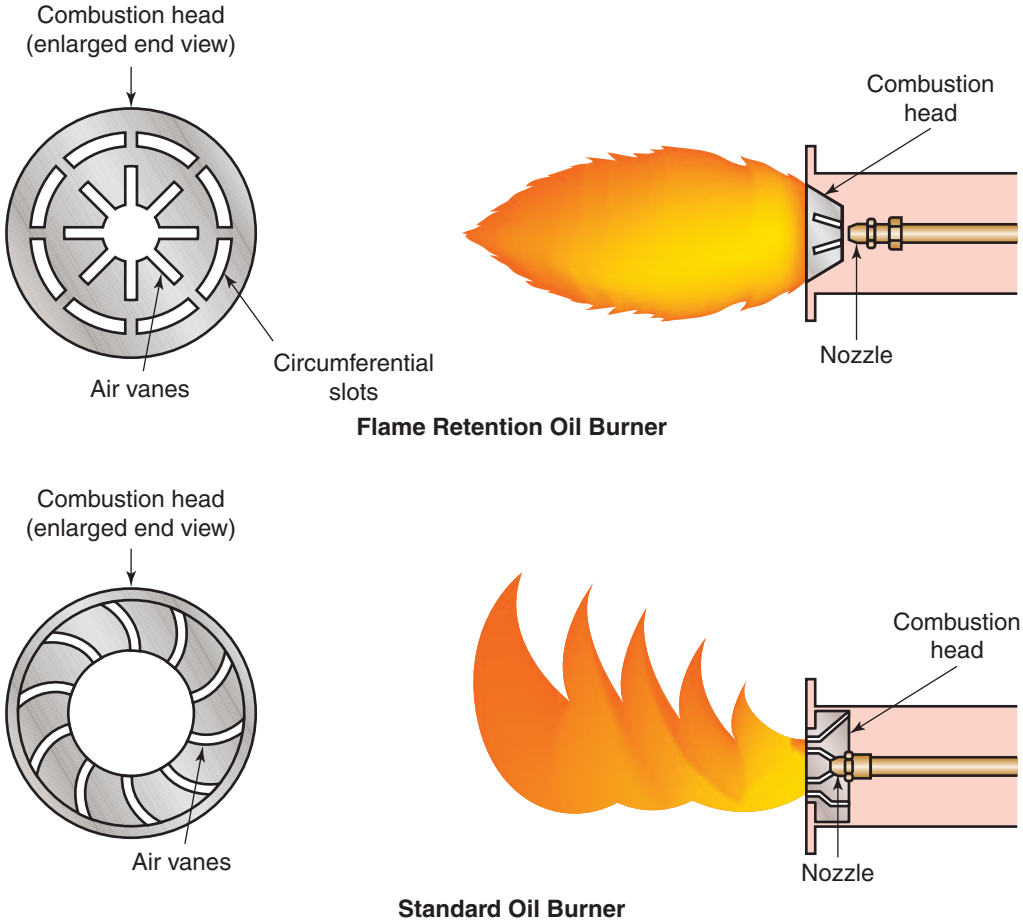
Pro Tip

Combustion Head Terminology

Combustion heads are known by several other names in the HVACR industry. Other terms include *end cone*, *burner head*, *fire ring*, and *retention ring*. Be aware of these different terms while speaking with parts clerks and other technicians.

The combustion head design determines whether an oil burner is a standard model or a flame retention model. A ***standard oil burner*** has a combustion head that directs combustion air to produce a somewhat lazy and unrestrained flame. A ***flame retention oil burner*** has a combustion head that directs combustion air in a manner that retains its flame, making it more compact, more efficient, cleaner, and hotter, **Figure 42-21**.

A flame retention oil burner feeds oil to the burner nozzle at high pressures, ranging from 100 psi to 300 psi (700 kPa to 2100 kPa). Air pumped through the air tube flows around every side of the nozzle as the air enters the combustion chamber. Usually, the air is



Goodheart-Willcox Publisher

Figure 42-21. The flame produced by a flame retention oil burner is more compact and controlled than the flame produced by a standard oil burner.

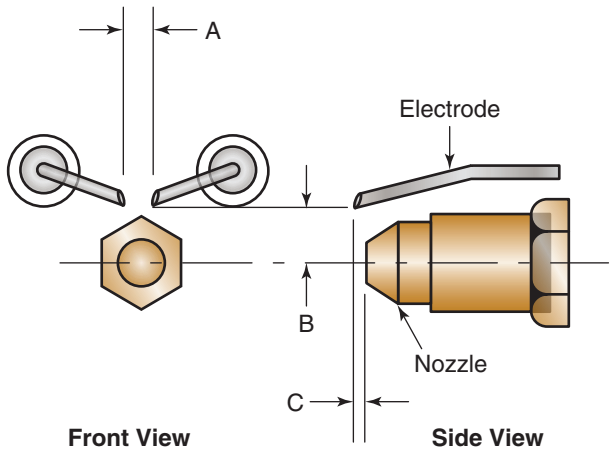
Copyright Goodheart-Willcox Co., Inc. 2017

twisted in one direction. The spray of fuel oil is given a twist in the opposite direction by the nozzle. Flame retention combustion heads are now widely used to replace standard combustion heads during service calls for maintenance and repair.

42.5.2 Electrodes

Two electrodes located near the front of the oil burner nozzle in the air tube conduct electric current provided by an ignition transformer or solid-state igniter to produce a high-voltage spark. The electrodes are made of stainless steel and mounted in ceramic insulators. No part of an electrode should be closer than 1/4″ (6 mm) to any metal part.

There are three important electrode-related gaps that need to be set in an oil burner. The ***electrode gap*** is the distance between the ends of each of the electrode tips. This should be 1/8″ to 3/16″ (3 mm to 5 mm). The ***above gap*** is the vertical distance between the center of the nozzle and the electrode tips. The electrode tips should be approximately 1/2″ to 5/8″ (13 mm to 16 mm) above the nozzle. The ***front gap*** is the horizontal distance between the front tip of the nozzle and the tips of the electrodes. For nozzles with a spray angle greater than 45°, the front gap should be approximately 1/2″ (13 mm). For 30° nozzles, the front gap should be 5/16″ (8 mm). See **Figure 42-22**. For each make and model of furnace, it is best to verify electrode and nozzle gap distances with the manufacturer's service manual.



R.W. Beckett Corporation

Figure 42-22. Oil burner nozzle and electrode gaps. A—The electrode gap is the distance between the two electrode tips. B—The above gap is the vertical distance between the electrode tips and the center of the nozzle. C—The front gap is the horizontal distance from the front of the nozzle to the tips of the electrodes.

Caution

Insulator Arcing

When servicing an oil furnace, make sure the electrode insulators are clean and free of soot. Soot is composed of carbon, which conducts electricity well. If soot builds up on insulators, the high voltage for the ignition spark can short across the insulators along areas covered in soot.

42.5.3 Oil Burner Nozzles

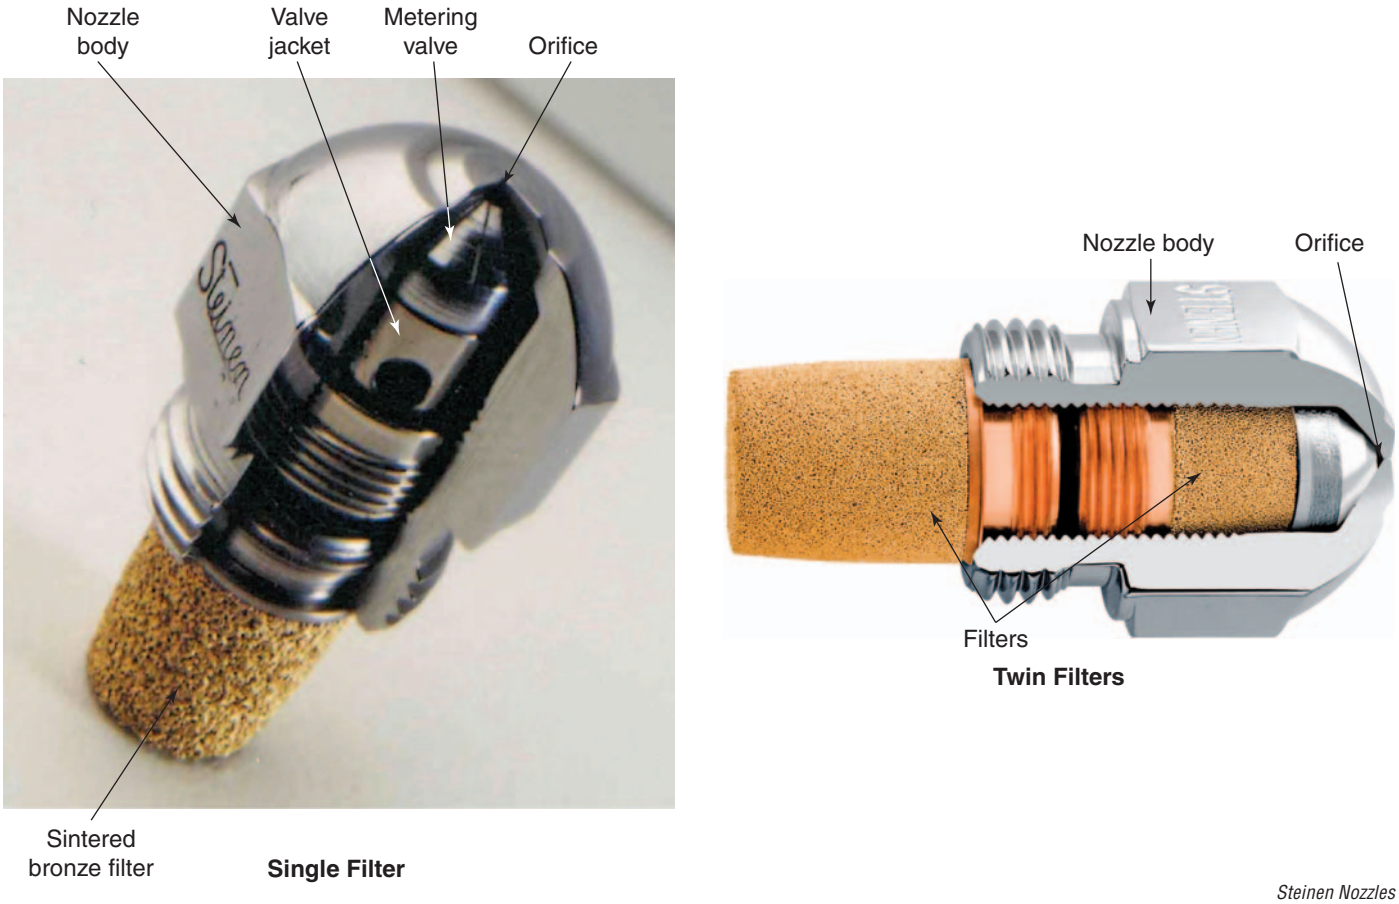
An ***oil burner nozzle*** is a metal piece with an orifice that controls the amount of fuel oil passing from the air tube into the combustion chamber. Nozzles are made of stainless steel or a combination of stainless steel and brass. These materials allow them to withstand the pressures, temperatures, and variety of fuels to which they are exposed. Each nozzle is supplied with a fine filter at its inlet. The filter is designed to prevent the possibility of dirt entering and plugging the nozzle, **Figure 42-23**.

Each nozzle is designed with very detailed specifications. Such precision is necessary for a nozzle to accomplish its three main roles: atomizing, metering, and patterning. Breaking up the fuel oil into tiny droplets is called ***atomization***. Since fuel oil will not burn as a liquid, atomization is used to cause the oil to vaporize rapidly so that it can be ignited. Fuel oil moving through an oil burner nozzle travels through very small holes. These holes are drilled at an angle to the nozzle. As the fuel oil travels through these holes, it is broken down into tiny droplets and given a twisting movement. Turbulent air mixes with the oil droplets as they leave the nozzle and enter the combustion chamber, where they are ignited to form a flame.

The amount of fuel oil delivered to the combustion chamber must be regulated. The amount of fuel is measured in gallons per hour (gph) at 100 psi. Nozzle orifice size and fuel oil pressure determine the rate at which fuel oil is delivered to the combustion chamber and, consequently, the rate at which heat is produced. The size of the burner nozzle must match the heating requirements of the conditioned space. If a nozzle is too small, the oil burner may not heat the space adequately. If a nozzle is too large, the oil burner may short cycle.

Directing atomized fuel oil droplets into the combustion chamber in a uniform spray pattern and at the correct spray angle is called ***patterning***. The correct spray pattern and angle is dependent on the design of the burner as well as the shape of the combustion chamber. Spray angles range from 30° to 90°. Round or square combustion chambers are usually fired with

Copyright Goodheart-Willcox Co., Inc. 2017



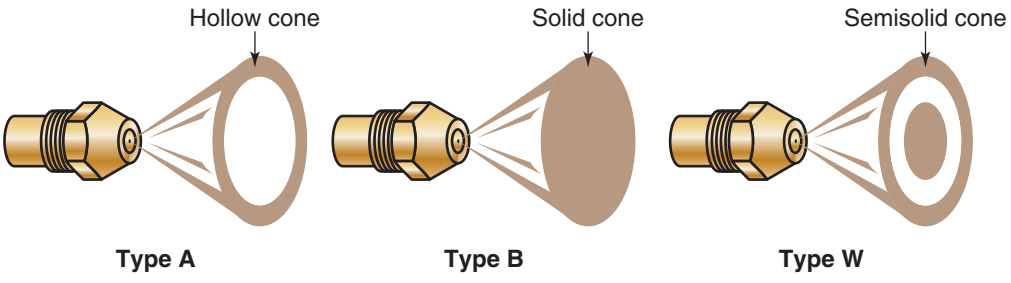
Steinen Nozzles

Figure 42-23. Oil burner nozzles may have a single filter or twin filters. Twin-filter nozzles provide increased filtering capacity.

70°–90° nozzles. Combustion chambers that are long and narrow are usually fired with 30°–70° solid cone nozzles. Fuel oil spray should not reach the electrodes or sides of the combustion chamber.

Burner nozzles are also made with different fuel oil spray patterns. Manufacturers assign identification letters or numbers to each nozzle. These numbers and letters vary. When replacing a nozzle made by one manufacturer with a nozzle made by a different manufacturer, refer to a manufacturer chart to cross-reference nozzles. Although there are many patterns available, the three most commonly used patterns are hollow cone (Type A), solid cone (Type B), and semi-solid cone (Type W), **Figure 42-24**.

A solid cone nozzle broadcasts fuel oil droplets uniformly throughout the cone shape. This nozzle is best when the air pattern of the burner is heavy in the center or if a long fire is required in the combustion



NORA

Figure 42-24. Nozzle construction determines the fuel oil spray pattern. Hollow, solid, and semisolid cones are the three main spray patterns.

Copyright Goodheart-Willcox Co., Inc. 2017

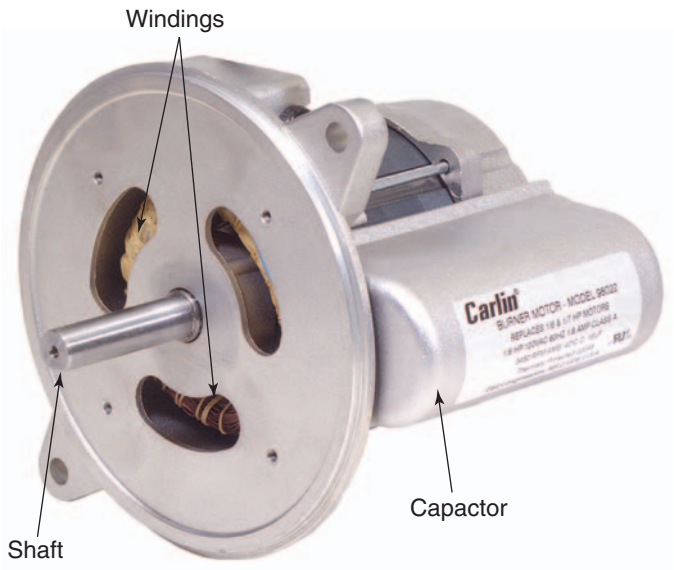
chamber. Solid cone nozzles are most often used for oil burners firing at a rate greater than 1 gph.

A hollow cone nozzle has little or no droplets in the center and the greatest amount of droplets at the outer edge of the spray. These nozzles are used for burners with a low firing rate, such as those firing at less than 1 gph. Hollow cone nozzle flames are often quieter than solid cone nozzles.

A semisolid cone nozzle is used with burners that can adapt to either solid or hollow spray patterns. Most manufacturers designate the appropriate nozzle to be used. A technician should follow this recommendation on nozzle selection and never install a nozzle with a firing rate higher than recommended.

42.5.4 Oil Burner Motors

An ***oil burner motor*** provides power for turning the fan and fuel unit (oil pump) in an oil burner assembly. Oil burner motors are either split-phase motors or permanent split capacitor (PSC) motors. The motor is mounted to the burner housing using a two-, three-, or four-bolt flange. The oil burner fan, which is attached to the motor shaft, can be easily accessed by removing the flange bolts. If a motor has to be replaced, it must be replaced with a new motor that has the same rotation direction, frame size, and rated full-load speed (RPM). An oil burner motor uses 120 V, 60 Hz electricity and is electrically connected to the oil burner's primary control unit, **Figure 42-25**.



Carlin Combustion Technology, Inc.

Figure 42-25. An oil burner motor.

42.5.5 Oil Burner Fans

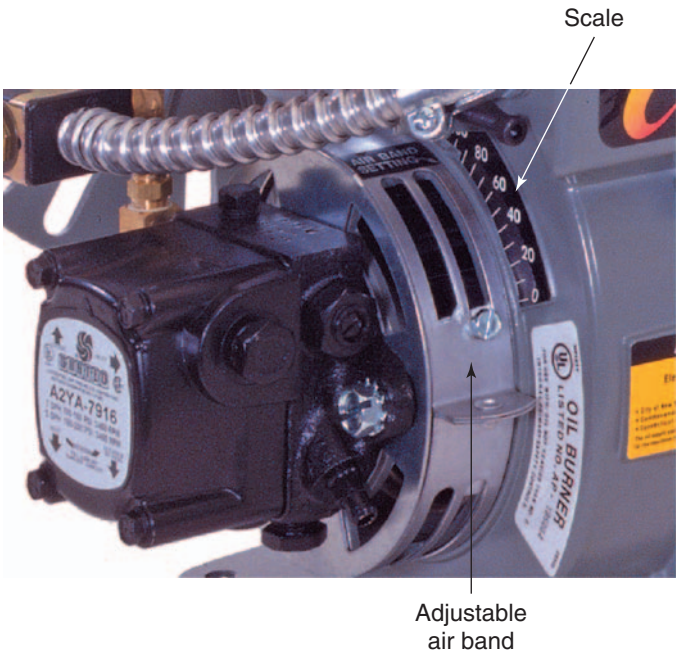
An ***oil burner fan***, or blower wheel, provides combustion air for the flame in the combustion chamber. The fan must also provide some excess air to ensure enough oxygen for complete combustion of the fuel oil. Designing the fan to deliver excess air also helps to ensure that complete combustion is maintained as the furnace gradually becomes dirty with use, reducing the fan's efficiency. Most oil burner fans have a squirrel cage design.

An ***adjustable air band*** is a metal band on an oil burner that is used to regulate the amount of air the burner fan can draw in and blow through the air tube. Air bands are also called *air inlet collars*, **Figure 42-26**.

Pro Tip

Air Band Adjustment

Adjusting an air band to obtain a proper flame can be misleading. A flame may look like it needs more air when it does not. This may be due to a dirty burner nozzle or fuel oil leakage during the Off cycle. Only adjust airflow after analyzing the products of combustion using test equipment, such as a combustion analyzer or combustion testing kit.



Carlin Combustion Technology, Inc.

Figure 42-26. As the air band is rotated, the indicator arrow points to the scale, which indicates the burner's airflow setting. The airflow setting is expressed as a percentage of total potential airflow.

11

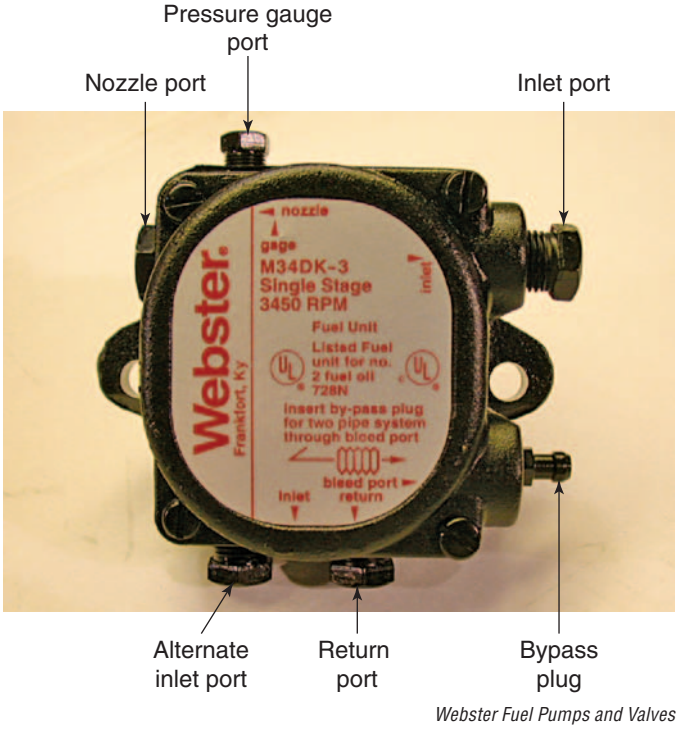
42.5.6 Fuel Units

A ***fuel unit*** is an oil burner subsystem consisting of a motor-driven pump that performs three tasks. Fuel units move fuel oil from the fuel oil tank to the oil burner, act as a secondary filter after the fuel line filter, and regulate the pressure of the fuel oil pumped to the oil burner. Like gas valves in gas furnaces, fuel oil pumps have developed into more complicated devices and taken on more roles. Just as gas valves have grown in function to become known as combination gas valves, fuel oil pumps have grown in function to become known as fuel units. See **Figure 42-27**.

A coupling connects the shaft of the oil burner motor to the shaft of the fuel unit pump. Therefore, the speed at which the oil burner motor rotates is the same speed at which the fuel unit pump rotates. Most fuel unit pumps are built to be driven at 3450 RPM. Some are designed to run at 1725 RPM while others can be driven at either speed. Fuel units are often preset to deliver fuel oil at 100 psi (700 kPa), which is the same pressure at which most oil burner nozzles are rated. Most fuel units have an adjustable oil pressure setting.

Fuel Unit Pumps

The most prominent part of a fuel unit is its pump. There are two types of fuel unit pumps: single stage and two stage. Selection of a single-stage pump or two-stage pump is determined by the limitations of the fuel oil itself. When fuel oil is subjected to excessive vacuum pressure, it starts to foam and change into a vapor. Oil foaming negatively affects system efficiency. Single-stage pumps can be used in both one-pipe and two-pipe fuel delivery systems where the pump's inlet vacuum pressure does not exceed 12 in. Hg vacuum. Two-stage pumps can operate under a vacuum pressure as high as 17 in. Hg vacuum. As a result, two-stage pumps create greater suction than single-stage pumps and are used to pull fuel oil from fuel oil tanks that are located far away from or below the oil burner.



Webster Fuel Pumps and Valves

Figure 42-27. A single-stage fuel unit that runs at 3450 RPM. Each port is identified using arrows.

Single-stage pump operation is shown in **Figure 42-28**. Fuel oil enters the single-stage unit and fills the front chamber. Rotating blades filter the fuel oil as it passes from the front chamber to the suction side of the gears. The oil then goes from the lower suction side to the upper pressure side of the gears and flows into the pressure-regulating valve. At a predetermined pressure, the valve piston moves, forcing the fuel oil to flow out the nozzle port. In a one-pipe fuel delivery system, surplus fuel oil returns to the front chamber through the surplus return passage. If a single-stage pump is used in a two-pipe fuel delivery system, surplus fuel oil is piped back to the fuel oil tank through the return port.

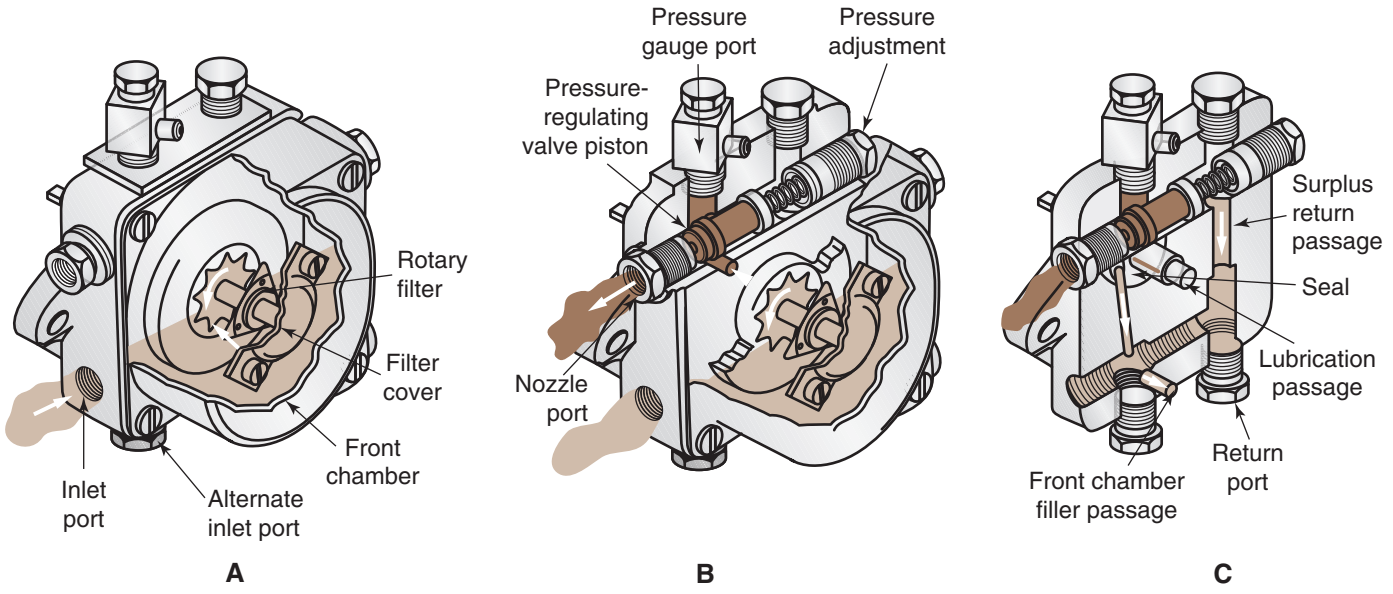
Two-stage pumps have two sets of gears. One set pulls fuel oil from the fuel oil tank into a strainer. The second set of gears removes fuel oil from the strainer chamber and pumps it to the nozzle port. Excess fuel oil is returned to the strainer chamber in some pumps or returned back to the fuel oil tank in others.

Fuel Unit Operation

To quickly and cleanly end oil burner operation, fuel units use a solenoid valve for quick fuel oil shutoff. This prevents residual oil from being pumped, which can cause soot or smoke formation. The solenoid valve is located at the fuel unit's nozzle port and is wired in parallel with the oil burner motor. Therefore, as soon as a system thermostat signal tells the oil burner to stop operation, the motor stops driving the pump and the solenoid valve closes to block fuel oil from moving into the combustion chamber. The power requirements for these solenoid valves vary, and some manufacturers produce solenoid valves that can operate at different voltage settings. Always check before replacing or servicing.

Sensing devices are also installed to minimize the spraying of fuel oil into the furnace when there is no flame. These sensing devices, such as stack relays and cad cell relays, stop fuel unit operation in case of an ignition failure or if the flame goes out. They often work with the primary control unit, which is discussed in greater detail in the following section.

Copyright Goodheart-Willcox Co., Inc. 2017



Webster Fuel Pumps and Valves

Figure 42-28. Single-stage pump operation. A—Fuel oil is drawn through the inlet port into a storage chamber in the front of the fuel unit. B—A gear set pumps the oil to a certain pressure, and a pressure-regulating valve directs some of it to the oil burner nozzle for combustion. C—Surplus fuel oil is bypassed to the pump inlet or is piped back to the fuel oil tank through the return port.

42.6 Primary Control Units

Each and every oil furnace is operated by its ***primary control unit***, which is a type of control device that starts and stops the oil furnace while monitoring variables for safe operation. A primary control unit is mounted on an oil burner and is often labeled with the words *Primary Control*. Some primary control units include an internal troubleshooting feature that causes an LED light to flash in case of an error, **Figure 42-29**.

Start-up begins with a call for heat from a system thermostat. When the thermostat places a call for heat, the primary control unit signals each device in a specific sequence. First, the primary control unit turns on the burner motor and ignition transformer. This initiates the flow of air and fuel oil and ignites the flame.

During operation, the primary control unit relies on sensing devices to detect the flame. The two types of oil furnace sensing devices are stack relays and cad cell relays. A stack relay senses with a heat-sensitive bimetal element, and a cad cell relay senses with a light-sensitive cad cell. If the oil burner does not ignite or if the flame is extinguished, the primary control unit's sensing device will trip. A tripped sensing device requires manually resetting the control unit.

Honeywell, Inc.

Figure 42-29. A primary control unit is responsible for turning an oil burner on and off.

Copyright Goodheart-Willcox Co., Inc. 2017

Caution

Resetting Primary Control Units

Prior to pushing a primary control's reset button, always check that the combustion chamber is not saturated with oil.

Stopping can be caused by several events. For normal operation, stopping occurs when the desired temperature has been met and the thermostat no longer calls for heat. Stopping can also occur due to the control unit sensing a furnace malfunction, such as the flue temperature rising too high or the flame going out.

Pro Tip

Gas and Oil Furnace Controls

An oil furnace primary control unit is equivalent to a gas furnace ignition control module. Both devices sequence the operation of the individual components in a furnace to control ignition and monitor operation. Primary control units are used in oil furnaces, and ignition control modules are used in gas furnaces.

42.6.1 Stack Relays

Older oil furnaces may use a stack relay rather than a cad cell as the primary sensing device. A ***stack relay*** is a heat-sensing device that consists of a bimetal element, at least one relay coil, a heat-operated safety switch, and the different electrical contacts that the bimetal element and relay coil operate. A stack relay may also be called a *stack switch*. It is mounted in the flue of an oil furnace close to the exhaust opening where it senses the heat produced by fuel oil combustion. See **Figure 42-30**.

Caution

Stack Relay Location

There should be no dampers or other devices between a furnace's flue gas and a stack relay's bimetal element. Blocking a stack relay's sensing element can disrupt oil furnace operation.

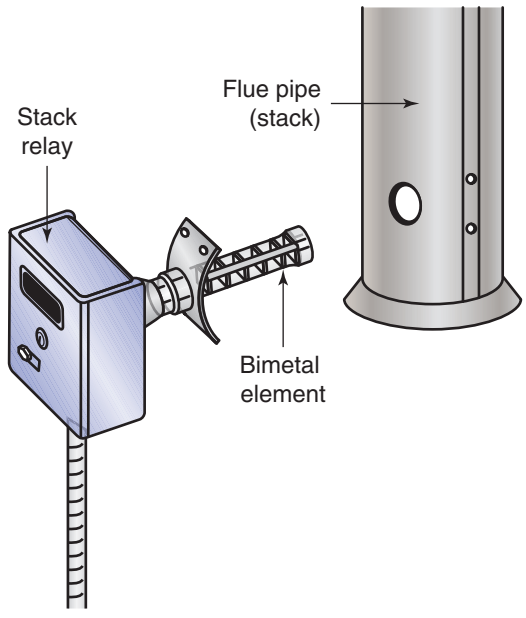
An ignited flame in a combustion chamber produces heat that a stack relay senses. If a stack relay does not sense successful ignition (usually within 15 seconds), it will open an electrical contact to cut the power to the oil burner. This shuts off the system and avoids a potentially dangerous condition.

The bimetal element of a stack relay is the stack relay's heat-sensing component. Heat from an oil furnace flame deforms the bimetal element. This movement is used to open and close at least two sets of electrical contacts: hot contacts and cold contacts. The hot contacts close when they are hot, and the cold contacts close when they are cold.

When an oil furnace operates and produces enough heat, the bimetal element reacts by closing the hot contacts and opening the cold contacts. After an oil furnace has stopped operating, accumulated heat begins to dissipate. After the furnace has lost enough heat, the bimetal element returns to its original shape, so that the hot contacts open, and the cold contacts close. During most of the Off cycle, the cold contacts remain closed, and the hot contacts remain open.

The hot and cold contacts are not the only electrical contacts in a stack relay. The relay coil (1K) in a stack relay also controls at least two sets of contacts (1K1 and 1K2). When a thermostat calls for heat by closing its switch, the relay coil responds by closing two sets of contacts. One set of relay contacts (1K1) closes to provide power to the oil burner, ignition circuit, and oil burner solenoid valve. This pumping and ignition of the fuel oil begins the combustion process. The other set of relay coil contacts (1K2) also closes but does not yet conduct any current, **Figure 42-31A**.

As fuel oil burns and warms the flue, the heat produced deforms the bimetal element, which closes the hot contacts and opens the cold contacts. Once the hot contacts have closed, current begins to flow through the hot contacts and the second set of relay coil contacts (1K2) and continues to flow through the relay coil (1K), **Figure 42-31B**.



Goodheart-Willcox Publisher

Goodheart-Willcox Publisher

Figure 42-31. The sequence of operation in a stack relay control circuit. Initial Call for Heat Operation—The 1K1 contacts close to power the oil burner motor, the ignition circuit, and the oil burner solenoid valve. The 1K2 contacts also close but do not conduct current, as the hot contacts remain open. Current flows through the relay coil, safety switch, safety switch heater, and cold contacts. Confirmed Ignition Operation—When enough heat is sensed by a stack relay's bimetal element, the cold contacts open, and the hot contacts close. The safety switch heater no longer conducts current or produces heat, but the relay coil remains energized through the hot contacts.

Both sets of relay coil contacts remain closed. The first set of contacts (1K1) continues to allow current flow to power the oil burner and other line power components. The second set of contacts (1K2) allows current to flow through the relay coil (1K), which keeps the furnace on until the thermostat is satisfied or a malfunction is sensed.

With the cold contacts open, the safety switch heater is out of the circuit and no longer producing heat in the stack relay. If the oil pumped into the furnace had not ignited and provided enough heat to cause the bimetal element to close its hot contacts and open its cold contacts, the safety switch heater would have remained in the circuit. After a specified period of time, the safety switch heater would have opened the safety switch, which would have de-energized the relay coil, shutting off the oil burner.

As long as an oil furnace produces heat, the bimetal element keeps its hot contacts closed to power the relay coil and run the oil burner. Once the desired temperature has been reached, the thermostat opens a switch that de-energizes the relay coil, which turns off the oil burner. The furnace also cycles off if the oil burner flame is extinguished or some other malfunction is sensed.

Copyright Goodheart-Willcox Co., Inc. 2017

Stack relay circuits may have additional contacts and coils for additional control and different types of ignition. **Figure 42-31** shows just one way that a stack relay may be wired. Stack relays were very popular years ago and may still be found in older oil furnaces. An oil furnace with a stack relay as its primary sensing device may be due for replacement with a high-efficiency system.

42.6.2 Cad Cell Relays

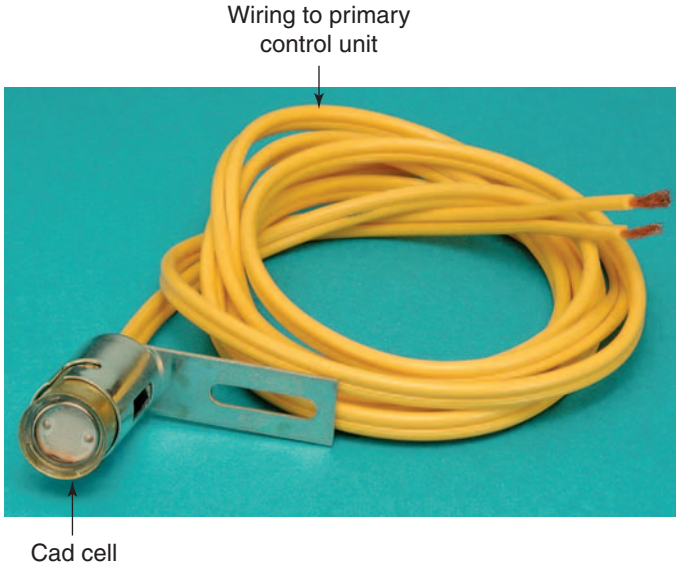
A ***cad cell*** is a light-sensitive semiconductor used to visually detect the flame of an oil burner. A cad cell is a semiconductor device that has a coating of cadmium sulfide, which is a material with light-sensitive electrical properties. When cadmium sulfide is in darkness, it has a high resistance to electrical current. When it is exposed to light, it has a much lower resistance. A cad cell has two wires that connect to a primary control unit, which contains the relay and control circuitry, **Figure 42-32**.

A cad cell is wired to a circuit so that its changing resistance can be used to determine when an oil burner is producing a flame. Cad cells have no mechanical moving parts and are very dependable as flame detectors. They have a much quicker reaction time than a stack relay, which has moving mechanical parts.

When an oil burner ignites, light from the flame causes its cad cell's resistance to drop, allowing current to flow through the cad cell. When the cad cell has low resistance, current is diverted around a triac and safety switch heater in the control circuit. This allows oil furnace operation to continue as the safety switch heater is no longer energized, **Figure 42-33**.

If there is no flame, no light will be produced, so the resistance of the cad cell remains high. This allows the triac and safety switch heater to conduct current, causing the safety switch to open to shut down the furnace, **Figure 42-33**. The reset button must be pressed on the primary control unit before the furnace can be returned to operation.

Cad cells are primarily installed in the air tube of an oil burner. Always follow burner manufacturer recommendations regarding cad cell location, as a cad cell must be very carefully mounted. The cad cell must be lined up to see the oil burner flame, **Figure 42-34**.



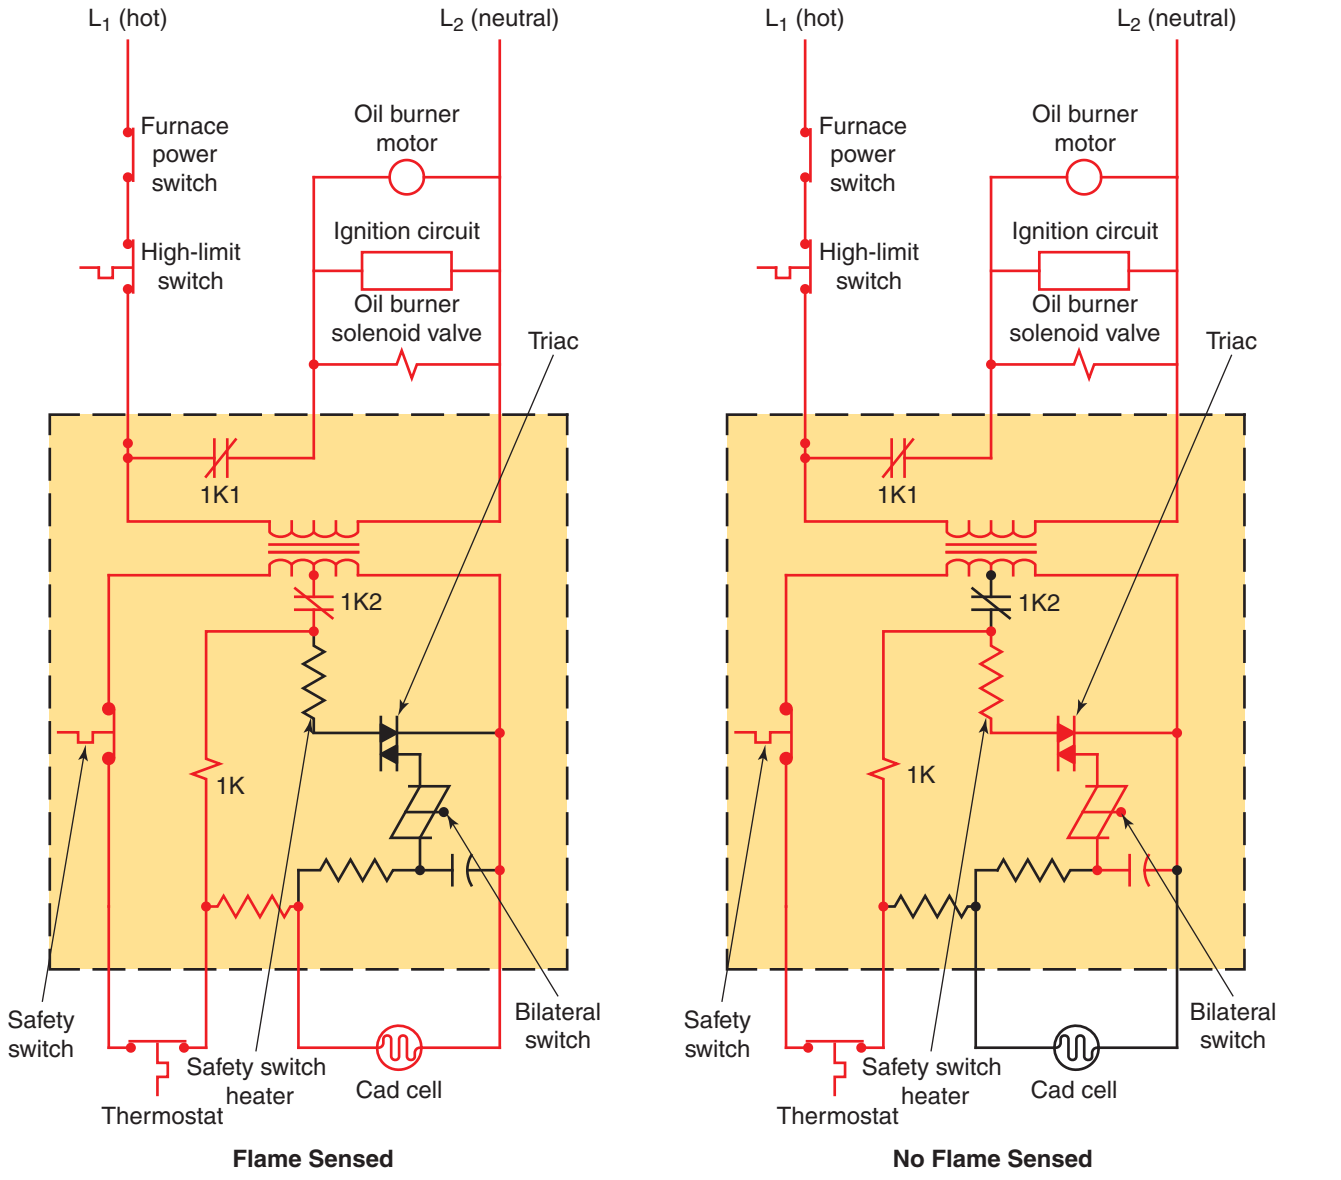
White-Rodgers Division, Emerson Climate Technologies; Honeywell, Inc.

Figure 42-32. A cad cell and primary control unit make up a cad cell relay, which is used to monitor the presence of a flame in an oil furnace.

42.6.3 Ignition Control

A primary control unit governs an oil furnace's ignition. The majority of oil furnaces have gun burners that are lit by electrical ignition. Electrical ignition is accomplished by applying a high voltage to a circuit with a small gap between the ends of two electrodes. A spark is generated in the gap, near the outlet of the oil burner's air tube and nozzle. The electrode ends are positioned in front of and above the nozzle. The atomized fuel oil swirls out of the nozzle and mixes with the turbulent air from the oil burner. At the same time, a spark jumps between the electrode ends and ignites the mixture of air and fuel oil.

Copyright Goodheart-Willcox Co., Inc. 2017



Goodheart-Willcox Publisher

Figure 42-33. The sequence of operation in a cad cell control circuit. Flame Sensed—With a flame present, the cad cell's resistance is low. Current flows through the cad cell and around the triac and safety switch heater for normal operation. No Flame Sensed—When no flame is present, the cad cell's resistance is high. This forces current through the triac and safety switch heater, which will eventually cause the safety switch to trip open.

11

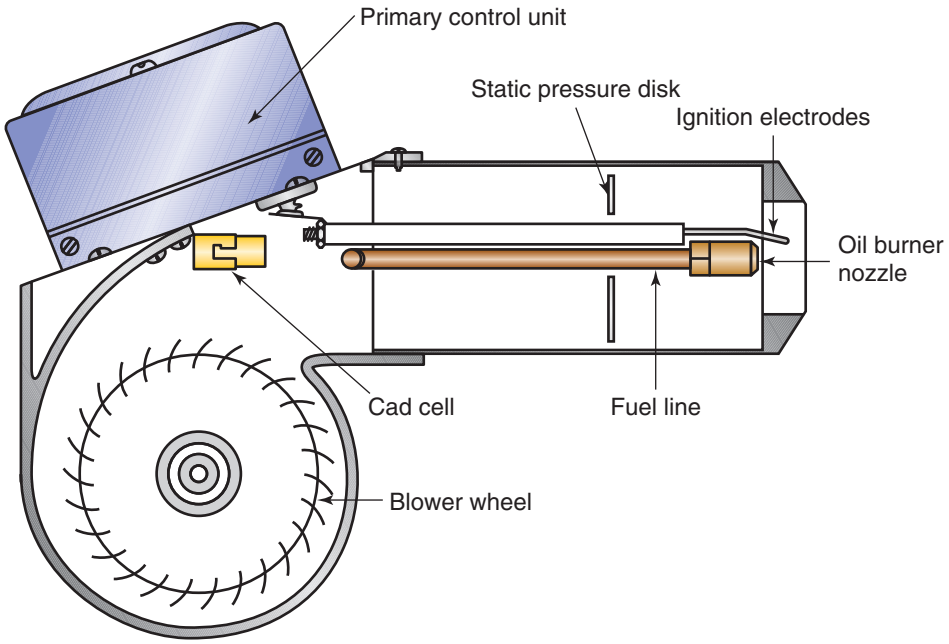
The high-voltage spark may occur only as the furnace begins operation or may continue firing throughout the operation of the furnace. ***Interrupted ignition*** applies a high voltage to the electrodes for only a brief period at the beginning of oil burner operation. It relies on the flame to continue burning after electric current has stopped creating sparks between the electrodes. ***Intermittent ignition*** applies a high voltage to the electrodes throughout oil burner operation. As the furnace continues to operate to produce heat for the conditioned space, intermittent ignition continues to apply a high voltage for igniting the oil burner's flame. When an ignition source is always present, as in a standing pilot, it is referred to as continuous ignition or constant ignition.

Pro Tip

Ignition Terminology

Be aware that in the field, interrupted ignition is sometimes erroneously referred to as intermittent ignition, and intermittent ignition is sometimes erroneously referred to as continuous ignition. Be certain that the proper type of ignition is known.

Copyright Goodheart-Willcox Co., Inc. 2017



White-Rodgers Division, Emerson Climate Technologies

Figure 42-34. A cad cell must be mounted with a direct line of sight to the oil burner flame.

Generally, there are two different devices that can be used to generate the high voltage necessary to create the electric arc in an oil-fired appliance. These devices are an ignition transformer and a solid-state igniter.

Ignition Transformers

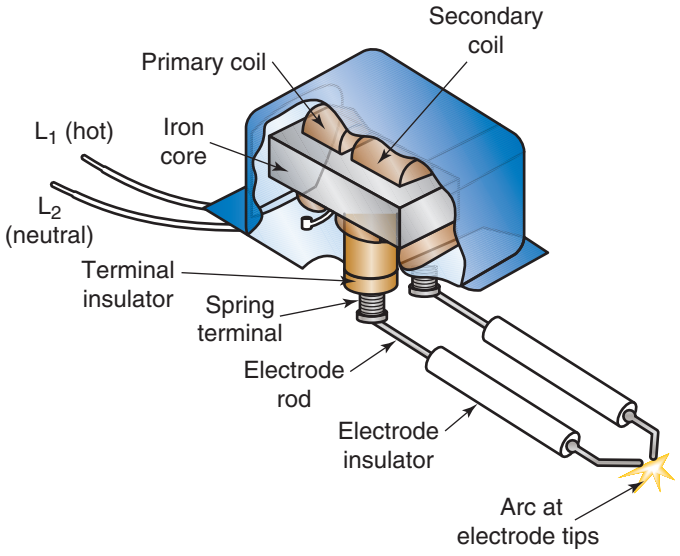
In an oil furnace, an ***ignition transformer*** is a transformer that steps up a line voltage of 120 Vac to a higher voltage. The high voltage arcs across a gap between two electrodes where it ignites the fuel oil exiting the air tube of the oil burner. An ignition transformer is an example of a step-up transformer. See **Figure 42-35**.

An oil furnace's primary control unit regulates the operation of an ignition transformer. Line voltage connects to an ignition transformer's primary winding terminals. The voltage produced across the secondary winding steps up from a line voltage of 120 Vac to a value ranging from 10,000 Vac to 14,000 Vac.

When an ignition transformer with a secondary winding rated at 10,000 Vac or 12,000 Vac needs to be replaced, an ignition transformer with a secondary winding rated at 14,000 Vac should be installed. This is especially advisable in situations involving cold combustion air or cold fuel oil or when voltage drops are known or suspected.

Solid-State Igniters

Newer oil furnaces typically have oil burners that use solid-state igniters for their ignition. A ***solid-state igniter*** is a device that uses electronic circuitry to produce the low-current, high-voltage electricity necessary for creating a spark across the electrodes of an oil burner, **Figure 42-36**.



NORA

Figure 42-35. Cutaway of an ignition transformer showing the transformer's components.

Solid-state igniters produce a high-voltage output that ranges from 14,000 Vac to 20,000 Vac. These igniters produce higher voltages while using less power than ignition transformers. The increased voltage increases the spark temperature, so the spark can vaporize and ignite more of the fuel oil.

Carlin Combustion Technology, Inc.

Figure 42-36. A solid-state igniter used to ignite an oil burner.

42.6.4 Primary Control Unit Functions

An oil furnace's primary control unit monitors variables and initiates individual devices for ignition. A primary control unit relies on different functions to control furnace operation according to certain lengths of time or certain measurable variables. HVACR technicians need to understand the following functions of a primary control unit in order to properly troubleshoot and repair malfunctions:

- ***Standby***. The time when an oil furnace is not burning fuel oil for heat is called standby. This is because the oil furnace's primary control unit is standing by for a call for heat from a system thermostat.
- ***Preignition***. When a call for heat is acknowledged, preignition occurs. During preignition, the primary control unit energizes the igniter to establish an electric arc before the oil burner motor provides the mixture of fuel oil and air for combustion.
- Pre-purge. Also called valve-on delay, pre-purging occurs before ignition. The oil burner motor turns the burner fan, but the fuel supply line solenoid valve on the fuel unit remains closed. Because the solenoid valve blocks the fuel line, the burner fan can purge the combustion chamber and heat exchanger of any lingering fumes from previous cycles and bring in fresh air for combustion. Since the fuel supply line solenoid is closed, the burner motor can operate the fan without operating the pump. This allows the motor to operate the fan without filling the combustion chamber with unburned fuel oil.
- ***Ignition carryover***. Ignition carryover is the length of time (in seconds) that an igniter will continue to spark after a flame has been sensed. A system's igniter continues to spark in order to ensure a flame is well established. This control unit function is only for interrupted ignition, as intermittent ignition continues sparking throughout a furnace's heating cycle.
- Post-purge. Also called *burner off delay*, this is the time during which the oil burner motor continues to power the oil burner fan after the fuel unit's solenoid valve closes. With no fuel oil being pumped into the combustion chamber, post-purging allows the burner fan to clear any remaining fumes from the combustion chamber and heat exchanger.
- Trial for ignition (TFI). Like gas furnace ignition control modules, oil furnace control units have a trial for ignition, which is the limited amount of time to ignite a burner flame. A trial for ignition is only a number of seconds. It may also be called *lockout time* or *safety lockout time*.
- ***Flame failure response time (FFRT)***. Related to an oil furnace's trial for ignition is its flame failure response time (FFRT), which is the amount of time for a primary control unit to sense that there is no flame when a thermostat is calling for heat. If the flame failure response time takes too long, unburned fuel oil can start soaking or filling the combustion chamber. If the flame failure response time is too brief, the primary control unit can lock out a system unnecessarily.
- ***Recycle time***. For a given call for heat, an oil furnace primary control unit may attempt to ignite several times before locking out. Recycle time is the amount of time in seconds before an igniter attempts ignition again after a failed ignition attempt. Often, the primary control unit only allows an igniter to attempt ignition a set number of times.
- ***Recycle limit***. The recycle limit, or *limited recycle*, is the number of times a furnace will try to ignite for a single call for heat before locking out. The primary control unit limits the number of times a furnace attempts ignition. If the furnace fails to ignite after this number has been reached, the primary control unit locks out the system.
- ***Reset limit***. The reset limit is the number of times a primary control unit can be reset from a lockout. After the reset limit has been reached, a simple push of a button will not reset the furnace. Resetting the furnace requires a longer procedure

Copyright Goodheart-Willcox Co., Inc. 2017

that HVACR technicians should perform rather than untrained building owners. This function allows a technician an opportunity to diagnose the root problem of the lockout. Reset limit may also be called *limited reset*, *restricted lockout*, or *lockout*.

42.7 Oil Furnace Exhaust

The products of combustion from an oil furnace must be properly vented to avoid contaminating the air in a conditioned living space. However, before the flue gases are vented, the heat in the flue gases must be captured by the heat exchanger and transferred to the conditioned air (or water in an oil-fired boiler). Heat transfer and venting of the products of fuel oil combustion begin in a system's combustion chamber.

42.7.1 Combustion Chambers

Combustion chambers play an important role in ensuring efficient heating and fuel oil combustion. The combustion chamber is the area in which the mixture of air and fuel oil burns to produce a flame. It may also be referred to as a *firepot*. Combustion chambers come in a variety of shapes and heights. It is the technician's job to know about a furnace's combustion chamber and be able to find an oil burner nozzle to match with the combustion chamber. The nozzle determines the spray pattern and amount of fuel oil blown into the combustion chamber, so it is an extremely important part of the system. If a nozzle is not correctly matched to the combustion chamber, it can cause the vaporized carbon in the fuel oil to transform into smoke and soot prior to burning. A combustion chamber must heat up quickly, reflect heat back to the burning zone, and quickly cool after burner shutdown.

Five common materials used in combustion chamber construction are insulating firebrick, common or hard brick, metal, ceramic, and molded composites. The combustion chamber is also lined with a fire-resistant material called ***refractory material***. The most efficient chamber shape is round or oval. Square or rectangular chambers are inefficient due to the corners as they require additional air for complete combustion. The burner nozzle should be centered halfway between the top and the bottom of the chamber.

Code Alert

Combustion and Ventilation Air

Chapter 5 of NFPA 31 covers air for combustion and ventilation of oil-fired appliances.

42.7.2 Oil Furnace Venting

Since excess air must be used to ensure complete combustion, a considerable amount of nitrogen is in the flue gas. Some oxygen, carbon dioxide, water, and impurities in the flue gas also go up the flue pipe (stack). About 2000 ft^3 of air (providing 400 ft^3 of oxygen) is used per gallon of fuel oil. This 2000 ft^3 of air includes the minimum amount of air necessary for combustion and the excess air necessary for complete combustion. Flue gas may be moved up the stack in the following ways:

- Natural convection—common in residential and small commercial units.
- Forced draft—by forcing the flue gases up the stack with a fan or blower.
- Induced draft—by drawing the flue gases up the stack.

Oil furnaces must maintain a consistent draft for efficient operation. Inconsistent draft or insufficient draft can cause problems. Draft is affected by a number of conditions, such as outdoor temperature, flue height, and flue temperature. Most vent systems produce excess levels of draft during certain times of the year. However, even slight variations in draft can directly influence combustion air intake.

A draft regulator is a device installed in a flue that is used to control draft. A bypass, or air-bleed, draft regulator is the most commonly used type of draft regulator. These are usually barometric dampers installed in the flue stack. When draft becomes excessive, a counter-weighted swinging door opens, allowing ambient air to enter the flue. This air mixes with the flue gases and cools them. This reduces the temperature difference between the flue gases and the outside air, which reduces draft. As the draft decreases, the damper door closes as needed. Always follow manufacturer instructions regarding draft, **Figure 42-37**.

Code Alert

Oil Furnace Flue Exhaust

The International Mechanical Code (IMC) states that oil-fired appliances must be vented according to NFPA 31, *Standard for the Installation of Oil-Burning Equipment*.

42.8 Oil-Fired Heating System Service

Oil-fired heating systems provide heat through the combustion of fuel oil. Areas of interest include fuel

Field Controls, LLC

Figure 42-37. A flue stack fitting with a barometric damper to act as a draft regulator. The door of a draft regulator opens and closes to keep the draft at the desired pressure.

oil storage tanks, fuel line piping, burners, operational controls, the combustion chamber and heat exchanger, and the flue.

42.8.1 Storage Tank and Fuel Line Installation

Installation of an oil-fired heating system includes a 200 gallon to 1,000 gallon storage tank. A fuel line connects the storage tank and the oil burner. Fuel lines are often copper, but they can be made of any material and build that is approved by agencies having authority.

Code Alert

Fuel Oil Line Materials

Section 1302 of the IMC specifies acceptable types of fuel oil piping and tubing material. These include brass pipe and tube, copper and copper-alloy pipe, copper and copper-alloy tube (Types K, L, or M), steel pipe and tube, and approved types of nonmetallic piping. All piping and tubing must be rated for its intended use and manufactured to specified standards.

Fuel lines should be sized according to manufacturer specifications. Review all system literature to determine fuel line size according to system capacity. The fuel lines must be able to convey enough fuel oil to match the maximum operating output of an oil-burning appliance.

Code Alert

Sizing for System Capacity

Section 1305.1 of the IMC states that a fuel oil system must be sized for the maximum capacity of fuel oil required for a fuel-burning appliance. The smallest size a supply line can be is 3/8″ (9.5 mm) inside diameter nominal pipe or 3/8″ (9.5 mm) outer diameter tubing. The smallest size a return line can be is 1/4″ (6.4 mm) inside diameter nominal pipe or 5/16″ (7.9 mm) outside diameter tubing. Copper tubing must have 0.035″ (0.9 mm) nominal and 0.032″ (0.8 mm) minimum wall thickness.

Several in-line components are installed between a fuel storage tank and the burner. These in-line components belong in the supply line, not the return line. A manual shutoff valve and a fuel filter are two of the components that should be installed in the supply line.

Code Alert

In-Line Valves

Sections 1307.1 and 1307.2 of the IMC require that a shutoff valve be installed between a fuel storage tank and a burner. While a shutoff valve is required to be in the supply line, Section 1305.4 of the IMC prohibits valves from being installed in the return line of an oil-fired appliance. A supply line must have a shutoff valve, and a return line cannot have any valves.

In one-pipe fuel delivery systems, the storage tank feeds fuel oil to the oil burner by gravity. Typically, the storage tank is located in the same room as the furnace. The storage tank should be at least 7′ (2 m) away from the furnace and should be elevated less than 25′ (7.5 m) above the oil burner. See **Figure 42-38**. This elevation keeps the fuel line pressure below 10 psi (70 kPa). Otherwise, a pressure-reducing valve must be used.

In two-pipe fuel delivery systems, the storage tank is typically placed outside the building, either aboveground or belowground. Regardless of whether the storage tank is aboveground or belowground, it can be placed either above the oil burner or below the oil burner. These installations should have the tank located within a reasonable distance of the oil burner to minimize the pressure drop in the fuel line between the tank and the oil burner inlet.

For fuel lines, runs of 50′ to 100′ (15 m to 30 m) should use 3/8″ (10 mm) copper tubing. Runs of 200′

Figure 42-38. An indoor installation with a one-pipe fuel delivery system. Note the required components in the fuel line and the minimum distance between the furnace and tank.

to 300′ (60 m to 90 m) should use 1/2″ (13 mm) copper tubing. The manufacturer's specifications should be checked if the fuel oil must be raised above the tank.

For storage tank installations both aboveground and belowground, the tank should be installed with a slight pitch toward the fill pipe end and away from the fuel line connection. This provides a low spot in the tank for dirt and water to collect.

There are several requirements for a fuel oil storage tank's vent pipe. Its purpose is to keep the inside of the tank at atmospheric pressure but still prevent intrusion of foreign materials. In order to vent properly, the opening needs to meet certain size requirements.

Code Alert

Oil Tank Vent Size

NFPA 31 provides requirements for fuel oil tank openings for filling and venting. Vent openings must meet a minimum size requirement to prevent abnormal pressures from building up in the tank, **Figure 42-39**.

In order for an oil tank vent to prevent intrusion of foreign materials, certain designs are required. The end of the vent pipe must be designed with a 180° bend to keep out dirt and rain. It must have an opening away from gutter downspouts, roof edges, and other

Minimum Tank Vent Openings

Capacity of Tank (gallons)	Diameter of Vent (nominal size, inches)
660 or less	1 1/4
661 to 3,000	1 1/2
3,001 to 10,000	2
10,001 to 20,000	2 1/2
20,001 to 35,000	3

Goodheart-Willcox Publisher

Figure 42-39. This table shows the minimum diameter vent opening that can be used on fuel oil tanks by capacity.

Copyright Goodheart-Willcox Co., Inc. 2017

blockages. The vent opening should be above the highest possible snowfall.

Code Alert

Oil Tank Vent Termination

Section 1305.7 of the IMC explains oil tank vent requirements. The vent must terminate with a weatherproof vent cap. It should have a free open area equal to the cross-sectional area of the vent pipe. It can have a screen, but that screen cannot be finer than No. 4 mesh.

Oil tank fill piping also has certain requirements. The cap on the oil fill pipe should always be in place, except when filling the tank. It should be designed to discourage tampering. The cap helps keep the fuel oil clean and reduces the chances of fire or explosion. See **Figure 42-40**.

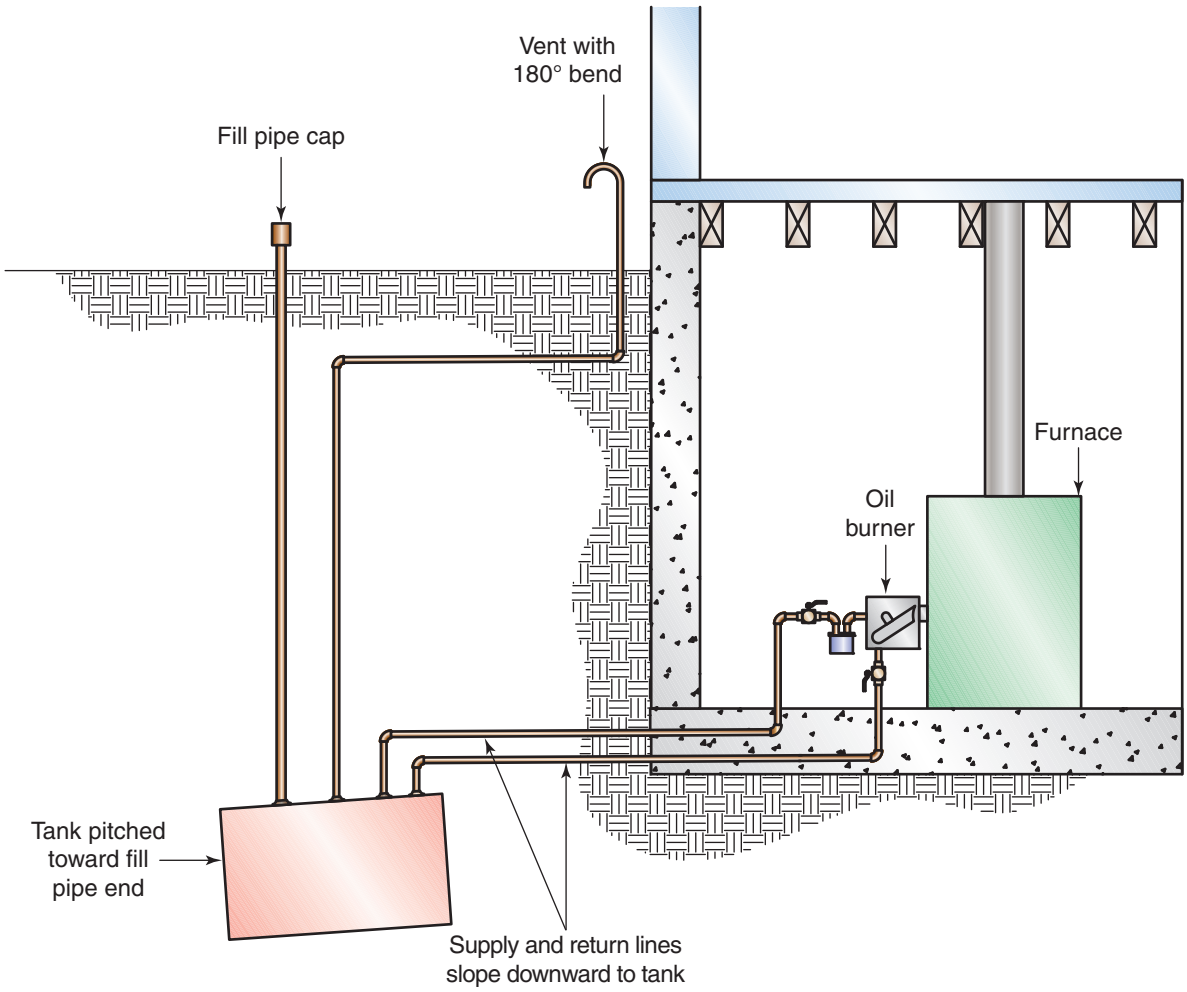
With underground tanks, measures should be taken to ensure that no groundwater can seep into the tank. Underground tanks require a suitable gasket around any plugs to prevent water seepage. The plug and gasket must be tight and kept in good condition. Before each fill-up, or at least annually, check the tank with water-sensing paste. The paste changes color when water is present. Any water accumulation should be pumped out. A leaking tank must be replaced in accordance with local and other codes.

Code Alert

Oil Tank Installation

NFPA 31 includes installation requirements for tanks used to store and supply liquid fuel for liquid fuel-burning appliances.

Underground tanks require all threaded joints to be sealed with a temperature-resilient compound. Never use Teflon® tape. Loose or poorly sealed joints allow groundwater to infiltrate the storage tank.



Goodheart-Willcox Publisher

Figure 42-40. An underground installation with a two-pipe fuel delivery system. Note the fill pipe, the vent, and the pitch of the storage tank and fuel lines.

Code Alert

Oil Piping Connections

Section 1303 of the IMC covers acceptable types of joints and connections used for the different piping and tubing materials that may be used in fuel oil line systems.

During installation, keep the tubing ends sealed with tape to keep dirt and moisture out. Remove the tape when connecting the tubing. The 3/8″ or 1/2″ (10 mm or 13 mm) copper tubing is often attached using fittings with standard 45° flares.

Tanks located aboveground may also generate water problems through condensation. To alleviate this problem, paint the tank silver to reflect the sun's rays and reduce thermal expansion. Locate the tank in a shaded area, if possible, and install the tank so the fill pipe end is pitched below the end with the fuel line connections. During warm weather, keep the tank filled to reduce air space at the top and minimize condensation.

The fuel lines in storage tanks should be mounted so the tubing opening is 3″ to 4″ (75 mm to 100 mm) above the bottom of the tank. The return line, if the system has one, does not need to go near the bottom of the tank for lighter oils (No. 1 or No. 2 fuel oil). For heavier fuel oils, however, the return line should go within 4″ to 5″ (100 mm to 130 mm) of the bottom of the tank to help keep the oil more fluid.

Code Alert

Fuel Line Support

The IMC includes minimum requirements for pipe support. See **Figure 42-41**.

42.8.2 Oil Burner Installation

Oil burner installation must be made in accordance with local codes and manufacturer instructions. The burner must be the correct height above the bottom of the combustion chamber. Burners are mounted either on adjustable legs or on a flange that is bolted to the furnace.

Code Alert

Oil Burner Installation

Chapter 10 of NFPA 31 provides guidelines related to the installation of oil burners and oil-burning appliances.

Before an oil burner is started, the fuel line must be completely purged of air. Air in the fuel line will form bubbles, which could result in fuel unit malfunctions, blowbacks, and flame failures. In an oil furnace, ***blowback*** is the ignition of a large amount of vaporized fuel oil that blows soot backward out of the combustion chamber.

Oil furnaces with two-pipe fuel delivery systems are designed to bleed their own fuel lines. Air is automatically eliminated through the return line. However, air can still be trapped in high spots in the fuel lines. Furnaces with one-pipe fuel delivery systems require the system to be bled manually. A leak in the fuel line almost always causes air-related troubles.

Piping Support and Spacing

Piping Material	Maximum Horizontal Spacing (feet)	Maximum Vertical Spacing (feet)
Brass pipe	10	10
Brass tubing (1 1/4″ and smaller)	6	10
Brass tubing (1 1/2″ and larger)	10	10
Copper or copper-alloy pipe	12	10
Copper or copper-alloy tubing (1 1/4″ and smaller)	6	10
Copper or copper-alloy tubing (1 1/2″ and larger)	10	10
Steel tubing	8	10
Steel pipe	12	15

Goodheart-Willcox Publisher

Manually Bleeding an Oil Furnace

To manually bleed an oil furnace with a one-pipe fuel delivery system, locate the bypass plug (bleed screw) mounted in the fuel unit housing. Usually, this plug seals the bleed port, which is sometimes the same as the pressure gauge port.

1. Using pliers or a crescent wrench, loosen the bypass plug halfway.
2. Attach a 1/4" pliable tube to the bleed port. Direct the tubing into a large container that is placed below.
3. Using a wrench, loosen the bypass plug the rest of the way to open the bleed port completely.
4. Turn the furnace on. A flow of air and fuel oil should exit the fuel unit.
5. Once a steady stream of oil is present, turn off the furnace.
6. Oil should stop flowing. Remove the pliable tube from the bleed port and wipe it clean.
7. Reinstall the bypass plug and tighten it with a wrench.
8. Restart the furnace.

42.8.3 Oil Furnace Maintenance

Oil furnaces must be properly maintained to ensure peak performance. An experienced technician should check, clean, and adjust a system each year. Oil furnaces require additional cleaning in comparison to gas furnaces. Soot can form in the heat exchanger and burner, blocking some of the passageways. Large amounts of soot buildup can stop a furnace from functioning and cause combustion gases to be forced back into the conditioned space. Soot contains sulfur, so an unpleasant odor may be present in such cases. Technicians should perform the following procedures during the yearly maintenance inspection:

- Inspect the manual shutoff valve and fuel line filter. Replace filter or filter cartridge.
- Check fuel line connections for tightness.
- Replace burner nozzle assembly according to manufacturer recommendations. For peak performance, the burner nozzle is typically replaced yearly.
- Check that the electrodes are clean and positioned correctly in relation to the burner nozzle.
- Clean or replace the fuel unit strainer.
- Insert a pressure gauge into the fuel unit's pressure gauge port. Start the burner and adjust the pressure setting to the manufacturer's specifications (usually about 100 psi or 700 kPa).

Oil burner nozzles require special care and attention. They are designed with precision to provide the proper amount of fuel oil for complete combustion. Improper handling can cause damage, which can lead to equipment failure. Below are some general guidelines for working with oil burner nozzles:

- Never interchange the inner parts of a nozzle with those from another nozzle.
- Never attempt to clean an oil burner nozzle. Brushes and cleaning products will damage the nozzle's machined surfaces.
- Keep a nozzle in its box until it is time to install the nozzle.
- Pick up nozzles by their hex flats. Never touch the strainer or orifice.
- If a nozzle is dirty or plugged, replace it.
- Be careful not to twist the air tube or move the air tube out of line.
- Always use a nozzle-changing tool for removing oil burner nozzles.
- Always replace a nozzle with an exact replacement. Use the same orifice, spray angle, and spray pattern as originally used.

Other tasks related to oil furnace maintenance involve the effect of one component on another. For instance, because flame retention oil burners produce hotter flames and use less combustion air than standard oil burners, check the combustion chamber materials and condition each time such a system is serviced. See **Figure 42-42**.

Safety Note

Combustion Chamber Explosions

If enough fuel oil and air collect in the combustion chamber and ignite, there may be a puff of flame or an explosion. The explosion can be forceful enough to wreck the building and injure or kill occupants. If fuel oil is found in a combustion chamber during inspection, shut off valves and vent the combustion chamber. Remove the fuel oil by means of a suction pump and rags until all danger of oil fumes is gone.

42.8.4 Troubleshooting Oil Furnaces

Operation of an oil furnace can be monitored using an integral monitoring device. The monitor is connected to the oil burner's primary control unit to measure various system parameters, such as cad cell resistance, cycle time, voltage to the burner,

Copyright Goodheart-Willcox Co., Inc. 2017

Ullman Devices Corporation

Figure 42-42. Telescoping mirrors used to inspect a combustion chamber and heat exchanger.

temperature of the flue stack, and flame quality. See **Figure 42-43**.

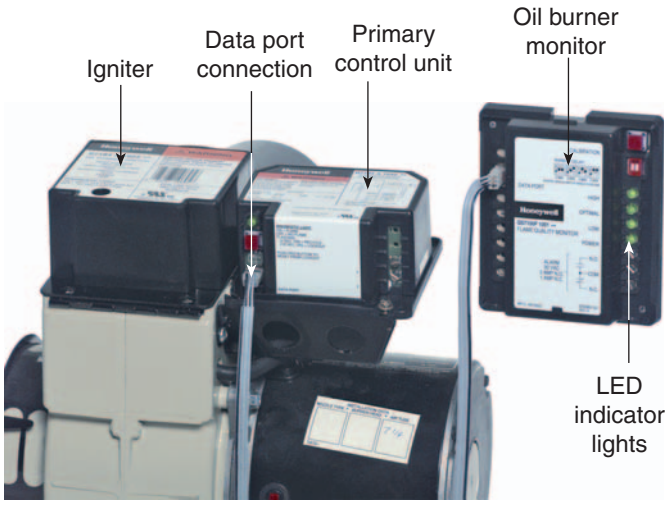
Many monitoring devices provide diagnostic trouble codes that assist a technician in troubleshooting an oil furnace. The device may be left on the jobsite to monitor operating cycles to determine whether a furnace is operating within specifications. This provides a technician with a log of data collected over time that can be used to analyze how a furnace is operating. This is especially useful in systems that are experiencing intermittent problems. Other instruments are designed for testing individual oil burner components, **Figure 42-44**.

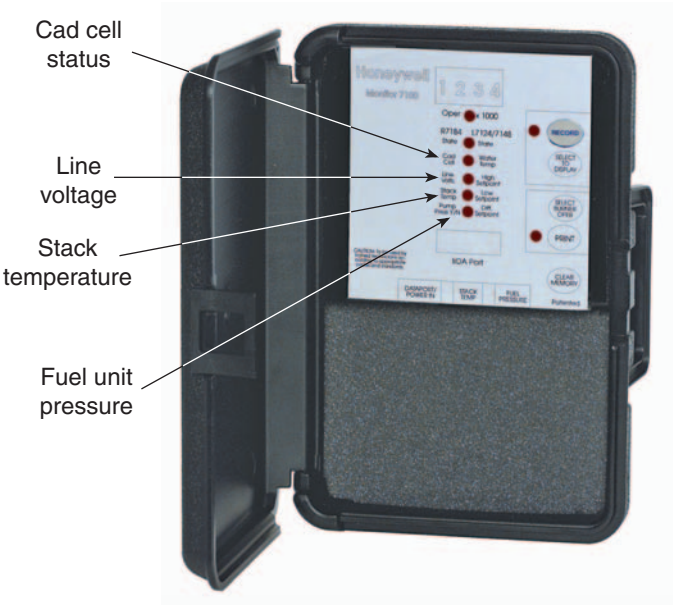
Proper flame appearance in an oil furnace is luminous (mainly yellow), **Figure 42-45**. If there is insufficient combustion air, the flame turns dull orange or red, and there may also be smoky tips to the flame. Soot deposits in a combustion chamber typically collect when the furnace first starts. The more often the furnace starts, the greater the soot deposits are. A correctly sized oil burner that operates less frequently will deposit less soot in the furnace and stack.

Sometimes, a blowback will blow soot into a building's conditioned space. This often requires major cleaning. Delayed ignition and blowback may be due to any of the following:

- Electrodes improperly spaced.
- Nozzle spray pattern distorted away from electrodes.
- Weak ignition transformer.
- Poor insulation on the electrodes.

In no case should the electrode ends be touching the oil spray. If they do, the electrodes will become





Honeywell, Inc.

carbon coated. Observe ignition and nozzle spray action to check for normal operation. Poor fuel oil delivery may be the result of clogging. The main fuel line filter, the fuel unit filter, or the nozzle filter may be partially clogged. Check all three filtering devices when servicing the system. **Figure 42-46** outlines common oil burner problems.

Flame failure may be caused by one or more of the following:

- Storage tank out of fuel oil.
- Storage tank not vented.
- Clogged filter in fuel line.
- Ice in fuel line.
- Loose fuel line connection (air in line).
- Dirt in fuel line.
- Water in fuel line.
- Loose wiring or connections.
- Motor not running (check reset button).
- Defective fuel unit.
- Fuel unit pump losing prime.
- Changing pressure or low pressure at fuel unit pump (slipping coupling).
- Clogged burner nozzle.
- Damaged burner nozzle.
- Improperly installed bypass plug.

Oil Burner Problems and Causes	
Problem	**Possible Cause**
Burner does not start.	1. Relay does not close (will not close or contacts dirty). 2. Safety lockout stays open. 3. Bad relay coil. 4. Low voltage. 5. Open high-limit control. 6. Broken wires or loose connections. 7. Relay transformer open. 8. Thermostat open (dirt on contacts, loose or dirty connections). 9. Stack switch open. 10. Heat-sensing contacts out of place or open. 11. Motor overload open (burned out or has dirty contacts).
Burner starts, but locks out.	1. No fuel oil out of nozzle. • Clogged. • Pressure too low. • Fuel unit not working. • Loose motor coupling. • Air leaks in fuel line. • Fuel line shutoff valve closed. • Strainers or screens clogged (filter, fuel unit screen, or nozzle strainer). • The pressure regulator in the fuel unit is stuck open. • Vent on storage tank closed. • Empty storage tank. 2. Fuel oil coming out of nozzle, but no ignition. • Electrodes not positioned correctly. • Insulators cracked. • Ignition wires are worn, are loose, or have dirty connections. • Transformer/igniter not operating. • Primary wires are worn, are loose, or have dirty connections. • Low line voltage. 3. Fuel oil to nozzle, ignition OK, but no flame. • Clogged nozzle. • Clogged nozzle strainer. Nozzle loose. • Pressure too low. • Fuel oil too heavy (wrong oil or too cold). • Excessive air or too much draft. • Electrodes in wrong position. 4. Flame burns only a few seconds. • Flame sensor not in correct position. • Stack switch not operating correctly. • Excessive air or air too cold. • Flame is too lean.
Burner cycles, but not on lockout.	1. Thermostat differential too close. 2. Anticipator set too close. 3. Limit switch set too low. 4. Overfiring (reaching high-limit temperature too quickly).

Goodheart-Willcox Publisher

Figure 42-46. Common oil burner problems, symptoms, and possible causes. *(continued)*

Copyright Goodheart-Willcox Co., Inc. 2017

Burner emits smoke, soot, odors, or pulsating sound.	1. Wrong oil pressure. 2. Flame touches combustion chamber. 3. Not enough draft. • Dirty chimney. • Draft regulator is out of adjustment or is stuck open. • Dirty flue. • The combustion chamber or the heat exchanger leaks. 4. Poor mixing of air and fuel oil. • Nozzle is worn, loose, dirty, or leaking. • Oil pressure too low or too high. • Poor air velocity and turbulence. • Not enough air (shutter closed too much, fan binding, or tight bearings).
Burner puffs back.	1. Water in fuel oil. 2. Delayed ignition. • Electrodes not positioned correctly or loose. • Insulators carbonized. • Nozzle is worn, loose, dirty, or leaking. • Voltage drop when burner starts. • Oil pressure too low or too high. • Transformer leads loose or dirty. • Transformer not operating correctly. • Excessive air or high draft.
Burner is making noise.	1. Loose fan. 2. Loose shutter. 3. Worn fuel unit pump. 4. Dirty strainer. 5. Air in fuel line. 6. Transformer hum. 7. Draft regulator vibrates. 8. Motor coupling worn. 9. Motor and pump not lined up correctly. 10. Relay contacts not seating tightly. 11. Fuel line restricted. 12. Motor mounting loose. 13. Tight motor bearings. 14. Tank hum.
Burner's fuel oil consumption is too high.	1. Nozzle is worn, loose. 2. Combustion chamber is dirty. 3. Too much combustion air (heat escapes up flue due to high flow of flue gases). 4. Poor mixing of air and fuel oil. 5. Not enough draft over fire. 6. Air leaks into combustion chamber. 7. Oil pressure too high or too low. 8. Overfiring, as noted by a high stack temperature.

Goodheart-Willcox Publisher

Figure 42-46. Continued.

Copyright Goodheart-Willcox Co., Inc. 2017

Having no spark across the electrodes may be caused by the following:

- Loose wiring.
- Bad ignition transformer.
- Low voltage to electrode.
- Crack in electrode insulator.
- Electrodes carbonized.
- Electrode spacing too far or too close.

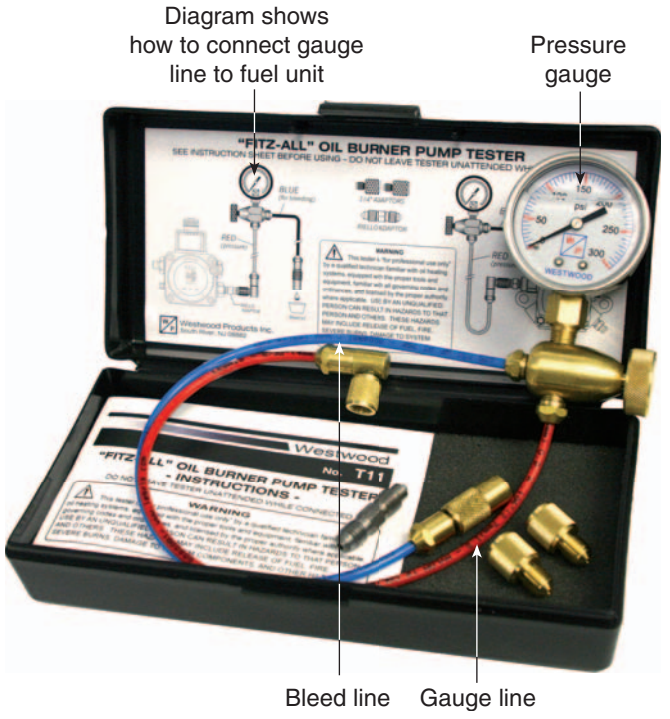
Fuel oil on the floor of a furnace room is dangerous. A leak may be caused by loose fittings or unions, a damaged fuel unit pump seal, or air in the fuel line. If a leak is suspected of being caused by air, check for air in the system by connecting a pressure gauge at the fuel unit's pressure gauge port, **Figure 42-47**.

If the gauge needle fluctuates, it signifies that there is air in the system. For small leaks, put a tube from the bleed port in a bottle of oil. Bubbles will indicate an air leak in the fuel line. Once the source of the leak is determined, repair or replace the damaged part.

Safety Note

Blowing Out Fuel Lines

If a fuel line is dirty or clogged, blow it out with nitrogen gas. Never use compressed air or oxygen because a violent explosion may result. Also, always use a pressure regulator and a pressure-relief valve when blowing out fuel lines.



Westwood Products, Inc.

Figure 42-47. A pressure gauge designed to be connected to a fuel unit's pressure gauge port.

Fuel Oil Additives

In noncondensing oil furnaces, flue gases must be warm. Otherwise, condensation will form in the flue, which can cause severe corrosion. One corrosive agent that may form is sulfuric acid (H_2SO_4). It corrodes steel rapidly; discolors brick and stone; and sticks to the heat exchanger, flue pipe, and inside of the chimney, producing a scaly yellow-red crust. This decreases furnace efficiency, restricts airflow, and increases smoke production. Using a fuel oil with low sulfur content reduces sulfuric acid formation. Another way to combat the formation of sulfuric acid is to use fuel oil additives. Fuel oil additives reduce the sulfur content in the flue gas and the amount of visible smoke produced. Fuel oil additives also reduce deposits in the combustion chamber, heat exchanger, and flue.

If water is present in fuel oil, it can allow bacteria to grow and multiply. Sludge, which clogs filters and nozzles, may be caused by bacteria. A fuel oil additive can be added to the main storage tank to kill the bacteria. Moisture also retards combustion and may even cause a flame to go out. Moisture in fuel oil may pose a more difficult problem than a single dose of fuel oil additive can solve. Two filters may be necessary on problematic installations. A large bypass filter can be installed at the storage tank, and a no-bypass filter can be installed at the burner. A no-bypass filter does not allow fuel oil to pass through the filter when the filtering element inside is full.

Testing Ignition Devices

Ignition transformers and solid-state igniters occasionally wear down and break. Manufacturers have developed instruments for testing solid-state igniters that often can be calibrated to also test ignition transformers, **Figure 42-48**. However, instruments made to test the operation of ignition transformers generally should not be used to test solid-state igniters, **Figure 42-49**. This is because solid-state igniters have a high-frequency output of 20,000 Hz whereas ignition transformers have a frequency output of only 60 Hz. Always follow manufacturer instructions for testing procedures.

Caution

Testing Solid-State Igniters

Prior to testing a solid-state igniter, be certain the manufacturer approves such a test. Be careful not to short the terminals as this can destroy the internal circuitry of the igniter.

Chapter Review

Summary

- Oil furnace operation begins when a system thermostat calls for heat. The furnace's primary control unit responds by opening a solenoid valve in the fuel line, energizing the oil burner's motor, and applying a high voltage across electrodes to ignite the fuel oil. Once the heat from fuel oil combustion has begun to build up in the heat exchanger, an indoor blower circulates heated air to the conditioned space.
- Fuel oil is a form of refined petroleum with various grades. Flash point and ignition point are indicators of a fuel oil's ability to vaporize and burn. A fuel oil's viscosity plays a part in determining what size burner nozzle should be used in an oil burner.
- To properly diagnose incomplete combustion and to determine combustion efficiency, a technician conducts a CO_2 test, stack temperature test, draft test, and smoke test. Both CO_2 tests and smoke tests are used to identify whether incomplete combustion is occurring. A draft test gauges the rate of flue gas flow through the stack. Stack temperature is an indicator of combustion efficiency.
- A one-pipe fuel delivery system relies partially on gravity to deliver fuel oil and is used when the fuel oil tank is above the oil burner. One-pipe fuel delivery systems tend to experience more air-related problems, but they require less tubing and installation labor.
- A two-pipe fuel delivery system has separate supply and return fuel lines. Two-pipe fuel delivery systems pump more fuel oil than is necessary, sending back some fuel oil to the tank through the return line. However, two-pipe lines require no bleeding when they are opened and exposed to air.
- An oil deaerator removes air from fuel oil to help prevent reduced oil pressure and oil burner lockouts. A fuel line filter removes impurities from fuel oil before it reaches the oil burner. If an oil burner is located too far from the fuel oil tank, a booster pump is used to pump fuel oil to a reservoir tank located closer to the burner.
- An oil burner is a device that controls the burning of fuel oil.
- Oil burner nozzles are designed to spray a specific amount of fuel oil into the combustion chamber at a specific angle and in a specific pattern at a standard pressure.
- An oil burner motor provides mechanical power to a fan and fuel unit in the oil burner assembly.
- The two types of oil furnace sensing devices are stack relays and cad cell relays. A stack relay uses a bimetal element mounted in the flue of a furnace to sense the heat produced by fuel oil combustion. A cad cell relay uses a light-sensitive semiconductor to determine when an oil burner is producing a flame.
- Interrupted ignition produces a spark for only a brief period at the beginning of oil burner operation. Intermittent ignition produces a spark across the electrode gap throughout oil burner operation.
- A primary control unit starts and stops an oil furnace while monitoring variables for safe operation. Functions such as pre-purge, post-purge, trial for ignition (TFI), flame failure response time (FFRT), and recycle limit help ensure safe ignition and operation of an oil furnace.
- An oil-fired heating system's storage tank may be installed aboveground, belowground, or inside a building's basement. A vent pipe must keep the inside of the tank at atmospheric pressure and must meet certain code requirements. The tank should have a slight pitch toward the fill pipe end to provide a spot for dirt and water to collect.
- Air in fuel lines can stop fuel oil from being pumped, cause flame failures, or result in blowbacks. To remove air from the fuel lines of a one-pipe system, bleed the lines through the bleed port or pressure gauge port on the fuel unit until a steady stream of fuel oil comes out.
- Routine oil-fired heating system maintenance includes fuel line and shutoff valve inspection, filter replacement, nozzle replacement, and oil pressure measurement and adjustment. When troubleshooting a problem, a technician should use monitoring devices and diagnostic trouble codes to pinpoint the cause.

Review Questions

Answer the following questions using the information in this chapter.

1. Which of the following is *not* an action that an oil furnace's primary control unit performs in response to a call for heat?
   A. Closing a damper in the flue to build pressure in the combustion chamber.
   B. Opening a solenoid valve in the fuel line.
   C. Signaling the igniter to send high-voltage electricity to the electrodes.
   D. Turning on the oil burner motor.
2. A fuel oil's viscosity primarily plays a part in determining _____.
   A. air band adjustment
   B. burner nozzle orifice size
   C. flue pipe size
   D. oil tank vent pipe size
3. The heating value of No. 2 fuel oil ranges from _____ per gallon.
   A. 240 Btu to 480 Btu
   B. 14,000 Btu to 20,000 Btu
   C. 12,000 Btu to 14,000 Btu
   D. 137,000 Btu to 141,800 Btu
4. The amount of noncombustible contaminants in fuel oil is referred to as the fuel oil's _____.
   A. ash content
   B. carbon residue
   C. distillation quality
   D. sediment
5. A flame that is _____ may be the result of incomplete fuel oil combustion.
   A. dull orange or red
   B. mainly yellow and luminous
   C. mostly blue with red or orange feathering
   D. white
6. When taking combustion efficiency measurements, _____ is the acceptable range of carbon dioxide in the flue gas.
   A. 0% to 5%
   B. 8% to 12%
   C. 25% to 28%
   D. 42% to 47%
7. Stack temperature is determined by subtracting the temperature of the _____ from the temperature of the flue gas in the flue pipe.
   A. combustion air
   B. combustion chamber
   C. flame
   D. oil storage tank
8. An oil-fired appliance may use a(n) _____ in its flue pipe to help control the amount of air drawn into the flue.
   A. air tube
   B. barometric damper
   C. booster pump
   D. combustion head
9. When determining an oil-fired appliance's combustion efficiency, the test that involves drawing a sample of flue gas from the flue or combustion chamber and passing it through filter paper is the _____.
   A. CO_2 test
   B. draft test
   C. oil filter test
   D. smoke test
10. A(n) _____ allows a one-pipe fuel delivery system to operate as a two-pipe fuel delivery system.
    A. booster pump
    B. combustion air tee
    C. fuel line filter
    D. oil deaerator
11. A booster pump should be located close to the _____.
    A. cad cell
    B. fuel oil tank
    C. oil burner
    D. reservoir tank
12. The purpose of a(n) _____ in a gun burner is to disturb airflow from the blower fan to create air turbulence for mixing air and fuel oil.
    A. air tube
    B. combustion head
    C. electrode
    D. static pressure disk
13. When servicing an oil burner, the main reason that a technician should clean soot off of the electrodes' insulation is because _____.
    A. dirty electrodes upset customers
    B. soot accumulates quickly and can completely block an air tube's airflow
    C. soot conducts electricity and could short out the high-voltage signal
    D. soot eats right through electrode insulation in a matter of days

Copyright Goodheart-Willcox Co., Inc. 2017

14. The purpose of an oil burner nozzle is to _____.
    A. atomize the fuel oil
    B. regulate the amount of fuel oil delivered to the combustion chamber
    C. spray atomized fuel oil in a specific pattern
    D. All of the above.
15. A standard pressure setting on fuel units on oil burners and the pressure at which most oil nozzles are rated is _____.
    A. –0.02 in. WC
    B. 10 psi
    C. 30 psi
    D. 100 psi
16. The purpose of an adjustable air band is to _____.
    A. adjust the direction of rotation of air in the air tube
    B. provide air to cool the burner motor's windings
    C. reduce air turbulence in the air tube
    D. regulate the amount of air the burner fan can draw in
17. Fuel units perform all of the following tasks, *except* _____.
    A. act as a secondary filter after the fuel line filter
    B. actuate the draft regulator upon a call for heat
    C. move fuel oil from the tank to the burner
    D. regulate the pressure of oil pumped to the burner
18. Which of the following statements regarding stack relays is *not* true?
    A. The hot and cold contacts are operated by a bimetal element.
    B. The safety switch heater keeps the safety switch open whenever the cold contacts are closed.
    C. The stack relay's cold contacts open when heated sufficiently.
    D. Sufficient heat from flue gases closes a stack relay's hot contacts.
19. Which of the following statements regarding cad cell relays is true?
    A. A cad cell relay is typically installed in the flue.
    B. A cad cell relay reacts more quickly than a stack relay.
    C. A cad cell relay uses a bimetal element to determine flue temperature.
    D. The cadmium oxide coating of the cell allows it to change resistance in response to minor fluctuations in temperature.
20. An ignition system that provides a spark for only a brief period at the beginning of oil burner operation is called _____ ignition.
    A. continuous
    B. intermittent
    C. interrupted
    D. one-shot
21. The ignition device most commonly used in new oil furnaces is a(n) _____.
    A. glow coil
    B. ignition transformer
    C. pilot light
    D. solid-state igniter
22. The term *ignition carryover* refers to _____.
    A. the maximum amount of time allowed for an ignition attempt
    B. the period of time that an igniter is energized before the burner provides fuel oil for combustion
    C. the period of time that an igniter will continue to spark after a flame has been sensed
    D. the period of time that must elapse between a failed ignition attempt and another ignition attempt
23. Which of the following statements regarding combustion chambers in oil furnaces is *not* true?
    A. A burner nozzle should be positioned facing vertically upward from the bottom center of a combustion chamber.
    B. Combustion chambers are lined with a refractory material.
    C. A combustion chamber of a certain size and shape must have a burner nozzle with a spray pattern to match it.
    D. All of the above.

Copyright Goodheart-Willcox Co., Inc. 2017

24. Oil furnace draft is affected by several conditions, including all of the following, *except* _____.
    A. flue height
    B. flue temperature
    C. oil tank temperature
    D. outdoor temperature

25. A shutoff valve must be placed in the _____ of an oil-fired appliance.
    A. flue piping
    B. fuel return line
    C. fuel supply line
    D. tank vent piping

26. Which of the following practices should *not* be employed on a fuel oil tank's vent?
    A. Include a screen on the vent that is no finer than No. 4 mesh.
    B. Maintain an open area equal to the cross-sectional area of the vent pipe.
    C. Secure a vacuum seal plug to prevent moist air from entering the tank.
    D. Terminate with a weatherproof vent cap.

27. Which of the following is *not* a guideline for handling oil burner nozzles?
    A. Always use a nozzle-changing tool to remove burner nozzles.
    B. If a nozzle is dirty, clean it.
    C. Never touch a nozzle's strainer or orifice.
    D. Pick up nozzles by their hex flats.

28. Blowback in an oil furnace may be caused by all of the following, *except* _____.
    A. improperly spaced electrodes
    B. an overfilled storage tank
    C. poor insulation on the electrodes
    D. a weak ignition transformer

29. If there is no spark at an oil furnace's electrodes, it may be caused by all of the following, *except* _____.
    A. carbonized electrodes
    B. improper electrode spacing
    C. an improperly installed bypass plug
    D. loose wiring

30. In oil-fired heating systems, fuel oil additives may be used to do all of the following, *except* _____.
    A. eliminate the need to replace fuel line filters
    B. kill sludge-forming bacteria
    C. minimize the formation of smoke and other corrosive agents
    D. reduce combustion chamber deposits

CHAPTER 43 Electric Heating Systems

Chapter Outline

43.1 Principles of Electric Resistance Heating
43.2 Electric Heating Elements
- 43.2.1 Open Wire
- 43.2.2 Open Ribbon
- 43.2.3 Tubular Cased Wire

43.3 Electric Heating Systems
- 43.3.1 Electric Furnaces
- 43.3.2 Duct Heaters
- 43.3.3 Fan Heaters
- 43.3.4 Electric Baseboard Heating Units
- 43.3.5 Electric Radiant Heat
- 43.3.6 Electric Heat for Deicing and Snow Melting

43.4 Electric Furnace and Duct Heater Controls
- 43.4.1 Airflow Switches
- 43.4.2 Sequencers
- 43.4.3 Electromagnetic Contactors
- 43.4.4 Mercury Contactors
- 43.4.5 Safety Controls

43.5 Electric Baseboard Heating Unit Controls
43.6 Electric Heat Construction Practices
- 43.6.1 Heat Loss
- 43.6.2 Humidity and Ventilation

43.7 Electric Heating System Service
- 43.7.1 Installing Heating Elements
- 43.7.2 Installing Baseboard Heating Units
- 43.7.3 Electric Heating System Maintenance and Troubleshooting

Learning Objectives

Information in this chapter will enable you to:

- Identify the advantages and disadvantages of electric heating systems compared to combustion heating systems.
- Calculate an electric heating system's heat production when given the system's wattage or voltage and amperage values.
- Describe the three types of electric heating elements.
- List examples and applications of convection electric heating systems.
- Compare and contrast direct and indirect radiant heating systems.
- Explain the purpose of sequencers and different contactors used in electric heating systems and how they function.
- Describe the operation of airflow and safety control devices in electric heating systems.
- Explain how controls are used in electric baseboard heating and some of their requirements.
- Summarize construction practices used for buildings with electric heating systems.
- Install, maintain, test, and troubleshoot electric heating systems.

Review of Key Concepts

Reviewing these concepts from earlier chapters will help you understand new concepts presented in this chapter:

- Voltage is electrical pressure that causes current (electron flow) in a closed circuit. Voltage is measured in volts. Current is the flow of electrons and is measured in amperes. (Chapter 12)
- Resistance is the name of the electrical property that measures how much a material resists the flow of electrons through it. (Chapter 12)
- The harder it is for electrons to move through a material, the greater the heat generated in that material. For example, iron and steel have greater resistance than copper, so they produce more heat when current passes through them. (Chapter 12)
- The relationship of voltage, current, and resistance in an electrical circuit is explained mathematically in Ohm's law: current × resistance = voltage. (Chapter 12)
- The relationship of power, current, and voltage in an electrical circuit is explained mathematically in Watt's law: current × voltage = power. (Chapter 13)
- Series circuits provide current with a single path to follow, whereas parallel circuits allow current to flow along two or more electrical paths. (Chapter 12)
- A multistage thermostat can vary an electric furnace's heating capacity by controlling the number of electric heating elements that are energized in order to produce more or less heat. (Chapter 36)
- Heating systems that rely on natural convection to distribute heated air function on the principle that heated air is lighter than cool air, which means heated air rises and cool air drops. (Chapter 38)
- Control devices used to detect blower operation include sail switches, end switches, and pressure switches. (Chapter 41)
- Fuses, circuit breakers, thermistors, and other devices are used to protect circuits from current overloads and overheating. (Chapter 13)
- Exfiltration is air naturally leaving a building through doors, windows, and other construction joints. (Chapter 28)
- A heat recovery ventilator (HRV) is a heat exchanger that passes incoming fresh air and outgoing stale air through a series of parallel passages so that incoming air is closer to the temperature of outgoing air. An energy recovery ventilator (ERV) operates in the same manner as an HRV, but has an additional component that also allows it to transfer humidity in addition to heat. (Chapter 28)

Introduction

Electricity is a form of energy that can be easily changed to another form of energy for a useful purpose. For instance, electrical energy can be easily changed to magnetic energy to produce mechanical motion in motors and solenoids. In heating systems, electrical energy can be changed directly to heat energy. This is done by passing electrons through electric heating elements. The electrical resistance of the heating elements produces heat, which can be distributed for various purposes, including climate control.

Heat distribution in electric heating systems is accomplished through convection or radiation. Convection systems use electric heating elements to warm a distribution medium, such as air or water. Examples of convection electric heating systems are forced-air electric furnaces, duct heaters, electric baseboard heating units, fan heaters, and electric boilers. Radiant heating systems directly warm occupants or warm a central mass that radiates heat to other objects, including occupants. Examples of electric radiant heating systems include infrared heaters and electric heating elements embedded in floors or in panels mounted on walls or ceilings.

43.1 Principles of Electric Resistance Heating

Electric resistance heating is the process of producing heat by conducting electricity across electric heating elements. An electric heating element is made from metal that generates heat as electrons overcome the metal's electrical resistance. Heating elements are sized and designed to permit a certain current to flow to produce a certain amount of heat. In this way, a known amount of electrical energy is being changed into a known amount of heat energy. The relationship between electrical energy in watts and heat energy in Btu/hr is shown in the following equations:

1 watt = 3.413 Btu/hr
100 watts = 341.3 Btu/hr
1,000 watts (1 kW) = 3,413 Btu/hr

HVACR technicians working with electric heat need to be mindful not only of watts and Btu/hr, but also of voltage and amperage. The high electrical power consumption of electric heat means that supply voltage levels affect the amount of current drawn and the gage of wiring used. The Watt's law equation shows the relationship among current, voltage, and electrical power:

$$P = I \times E$$

P = power (watts)
I = current (amperes)
E = electromotive force or voltage (volts)

Example:

Using the above equation, an HVACR technician can keep track of power, voltage, and current in electric heat applications. For example, what is the maximum amount of heat energy that can be produced by an electric heater circuit with a 20 A maximum capacity and a 240 V supply?

Solution:

Before calculating heat energy, determine the heater circuit's electrical power in watts by multiplying voltage and amperage.

$$P = I \times E$$
$$P = 20 \text{ A} \times 240 \text{ V}$$
$$P = 4{,}800 \text{ W}$$

After determining electrical power, multiply the wattage by 3.413 to determine the amount of heat energy in Btu/hr.

$$4{,}800 \text{ W} \times 3.413 = 16{,}382 \text{ Btu/hr}$$

An electric heating system can produce a certain number of Btu per hour (Btu/hr). A certain number of Btu per hour must be produced in order to maintain a certain temperature in a building. Thus, an electric heating system installed in a building must be able to produce more than the minimum number of Btu per hour needed to maintain the building's temperature.

Example:

If a home needs 50,000 Btu/hr for heating, how much electrical power per hour will the home need to consume?

Solution:

To convert Btu/hr to electrical power, divide 50,000 Btu/hr by 3,413. This converts Btu/hr to electrical power in kilowatts.

$$50{,}000 \text{ Btu/hr} \div 3{,}413 = 14.65 \text{ kW}$$

The calculated value is the minimum heat-producing capacity that a system can produce to maintain temperature. Therefore, the combined heat capacity of the electric heating elements used in the system should meet or exceed this value to ensure that temperature can be maintained.

Upon confirming that an electrical system can provide enough power to the heating system to produce the Btu per hour required to keep a building comfortable, an HVACR technician can consider other decision factors, such as the cost to operate the heating system and the labor and supplies required for wiring the system. Electric utility companies charge for electricity consumption based on kilowatt-hours. A technician can determine an electric heating system's cost of operation using the utility company's kilowatt-hour rates.

43.2 Electric Heating Elements

Electric heating elements are conductors through which electrical current is passed in order to produce heat. Electric heating elements may have fins or other attachments to increase their surface area and promote heat transfer. Elements are divided into three basic types:

- Open wire.
- Open ribbon.
- Tubular cased wire.

43.2.1 Open Wire

The term ***open wire*** describes uninsulated electric heating wires. Open wire heating elements are used in duct heaters, electric furnaces, and some heat pump air handlers. These wires are often formed into coils,

Copyright Goodheart-Willcox Co., Inc. 2017

allowing more wire to be used in a smaller space. The more wire used in a given location, the more heat that can be produced. Coiled wire also helps the manufacturer attain a controlled resistance. Open wire heating elements usually consist of nickel chromium (nichrome) wire that is mounted on ceramic or mica insulation, **Figure 43-1**.

43.2.2 Open Ribbon

The term ***open ribbon*** describes uninsulated electric heating elements that are composed of flat strips. Some open ribbons are made from a mesh of metal foil that is formed into thin strips. Like open wires, open ribbons are made of nichrome and are mounted similarly in appliances. With a thin, flat surface, a ribbon design provides more surface area for air contact than a straight, uncoiled open wire.

Safety Note

Heating Element Shock

Open wire and open ribbon elements must be carefully protected. They cannot be allowed to contact any metal objects, else they could short out or energize the object. Open electric elements should be kept out of reach of people to prevent electrical shocks and short circuits.

43.2.3 Tubular Cased Wire

A ***tubular cased wire*** consists of a nichrome heating element surrounded by a magnesium oxide powder and enclosed in a heat- and corrosion-resistant steel tube. Tubular cased wires are sometimes referred to as calrod heating elements. The tubular casing protects against electrical shock while still allowing the element to reach high temperatures. Tubular cased wires are sometimes placed in fin-type aluminum castings. This increases the heating surface and reduces the danger of excessively high temperatures. A common application of tubular cased wire is in electric appliances, such as ranges and washing machines. See **Figure 43-2**.

43.3 Electric Heating Systems

Electric heating systems can vary greatly in size and application. These systems may be used for heating operations in industrial processes, such as the fast drying of paints or the melting of low-temperature metals or metal alloys. Electric heat may also be used for domestic and commercial cooking and baking. Different electric heating systems meet the needs of consumers through various applications.

In residential applications, electric heating may be used as the primary heating system, or it may be used

Copyright Goodheart-Willcox Co., Inc. 2017

as an auxiliary heating system. Electric heat is often used to provide heat in sections of buildings that are not easily heated, such as in building additions and in areas where using the primary heating system would be unsafe. If a primary heating system does not have enough capacity to heat a building well and a replacement system would be too costly, electric heat can supplement the present system.

43.3.1 Electric Furnaces

An ***electric furnace*** consists of a central air handler with electric heating elements that are used to warm circulating air for a conditioned space. Electric current that passes through the heating elements produces the heat for distribution. Electric furnaces have capacities ranging from 34,000 Btu/hr (10 kW) to 120,000 Btu/hr (35 kW), **Figure 43-3**.

Electric furnaces usually have several heating elements or banks of elements. Each element consumes from 5 kW to 10 kW of electrical energy to produce between 17,000 Btu/hr and 34,000 Btu/hr of heat. Each heating element is energized in a specific order by a sequencer. The sequencer energizes each heating element one after the other about 30 seconds apart. This gap in time helps to minimize an electric furnace's initial current draw, which may cause a noticeable disturbance in a building's electricity use, such as a lowering or flickering of lights. Sequencers are covered in greater detail later in this chapter.

Electric furnaces are typically controlled by a low-voltage thermostat with two or more heat stages. A heat stage is an appliance setting at a certain level of heat output. For example, stage 1 may produce a low or middle amount of heat production, during which only one-half of the heating elements are energized. Stage 2 may be the full level of heat production, during which all of the heating elements are energized. With programmable thermostats, these heat stages are put into operation from 0.5°F to 1.5°F (0.3°C to 1°C) apart. In older thermostats operated by a bimetal coil and mercury switch, however, the temperature difference between the two heat stages is set at 1.5°F (1°C). The first stage brings on at least 50% of the furnace's capacity, and the second stage energizes all the heating elements for the furnace to operate at 100% capacity.

Code Alert

Electric Furnace Sizing

ACCA Manual S requires that furnaces be sized no greater than 140% of the heat load (that is, no more than 40% oversized). Often, an oversized furnace must be selected due to limitations in available furnace capacities. Choosing a multistage unit offsets some of the disadvantages of needing to use an oversized unit.

Thinking Green

Heat Stages

Staging the amount of heat using a thermostat helps balance heat load and heat loss. When the heat load is low, a furnace operates on the first stage, which saves energy and reduces power consumption.

Electric furnaces are often smaller than oil and gas furnaces of similar heating capacities. Also, electric furnaces do not require connections to a gas line or oil line. Electric furnaces do not remove moisture from the air, so a humidifier is seldom necessary with electric heat. Since electric heating elements are not position-sensitive, electric furnaces can be installed as upflow, downflow, or horizontal furnaces. These characteristics allow electric furnaces to be installed in more compact and diverse places than oil or gas furnaces.

Caution

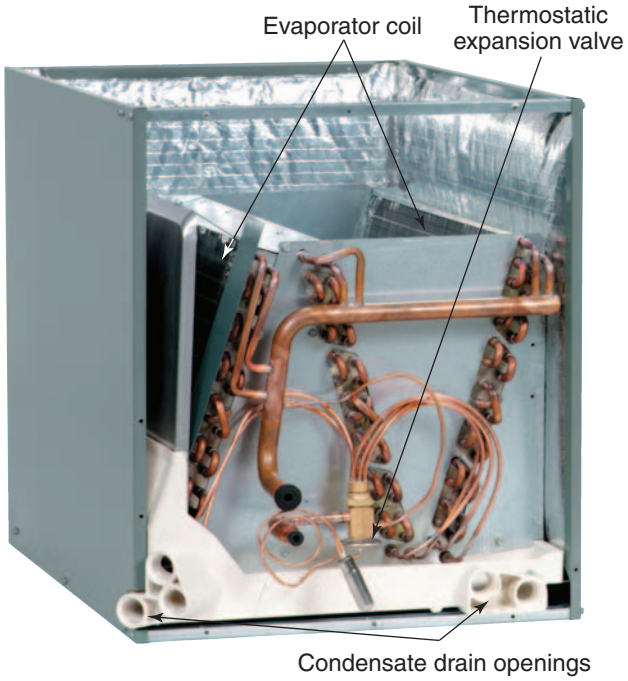
Electric Furnace Orientation

While electric heating elements are not position-sensitive, some control devices, such as mercury contactors and some types of relays, are position-sensitive and need to be installed in a certain orientation to operate properly. Also, some manufacturers may require certain control devices to be located below or to one side of heating elements, rather than above where they may trip off the system unnecessarily. Before installing an electric furnace in a downflow or horizontal flow position, check its control components and manufacturer literature to see if any part will need to be positioned in a certain orientation for proper operation.

An electric furnace is a convenient option to provide building heat in many applications. However, since an electric furnace can only produce heat and cannot absorb heat, a technician may install an evaporator coil onto the air handler that connects to a remote condensing unit for use in the cooling season, **Figure 43-4**.

43.3.2 Duct Heaters

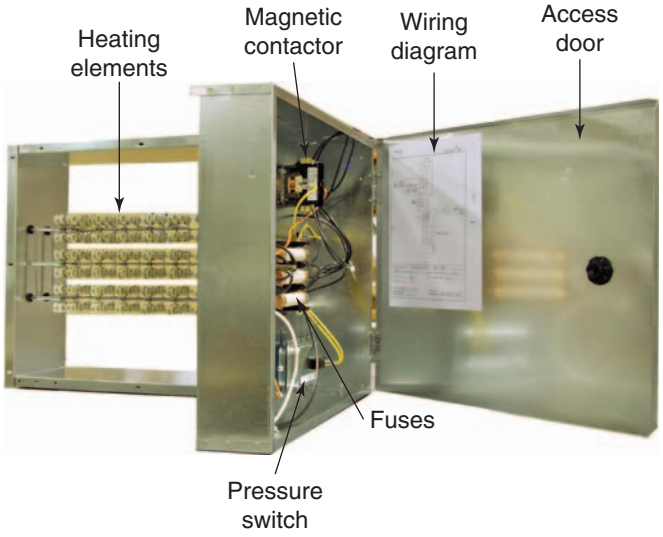
A ***duct heater*** is an array of electric heating elements contained in a single unit that can be installed in a run of ductwork. A system thermostat or a zone thermostat is used to control duct heater operation, **Figure 43-5**.



Rheem Manufacturing Company

Figure 43-4. An evaporator coil already in a sheet metal body ready to be added onto an air handler.

Rather than having a forced-air electric furnace as a primary heating system, a building may have a central air handler with duct heaters heating individual rooms. When used as the primary heating system, electric duct heaters provide individual room temperature



Tutco, Inc.

Figure 43-5. A duct heater with its access door open, revealing the heating and control components.

Copyright Goodheart-Willcox Co., Inc. 2017

control. Individual room thermostats allow occupants to govern duct heater operation, providing a form of zone control.

Duct heaters may be designed to slide into a slot opening in the side of a run of ductwork, or they may be installed at a flanged opening between two sections of ductwork, **Figure 43-6**.

Duct heaters may also be used to supplement other heating systems, such as forced-air heat pump systems during very cold weather. When weather conditions only permit a heat pump to produce somewhat warm air or when a heat pump is in defrost mode, duct heaters provide supplementary heat to boost the temperature of circulated air. Duct heaters also work well as supplementary heat for room or building additions and other conditioned spaces that are difficult to regulate.

Even when duct heaters are used as a supplementary heating system, the principle of zone control may be applied, especially in large commercial buildings with long runs of ductwork. For instance, a temperature sensor near the primary heat source may end the call for heat early, leaving remote rooms located at the end of long runs of ductwork cooler than rooms closer to the system's heat source. On the other hand, a temperature sensor near the end of a long run of ductwork may leave the heat on longer than normal to warm the more remote rooms. This results in the rooms closer to the heat source being warmed too quickly before the remote rooms have been warmed. Installing and properly controlling duct heaters near the end of the duct run solves this problem by supplying additional warmth to these remote rooms, producing a more uniform temperature throughout the whole building.

In some cases, duct heaters may also be used during the cooling season. In a large building in which cold air quickly cools the rooms located near the cooling coils, the thermostat may not turn off the cooling cycle until more remote rooms have been cooled. As a result, rooms closer to the cooling coils become too cold while rooms farther from the cooling coils are just moderately cool. A duct heater located in the ductwork to a quickly cooled room can raise the temperature of the incoming air using a room thermostat for control. Such installations are not very common but may be desirable to produce more uniform cooling and temperature control throughout a building.

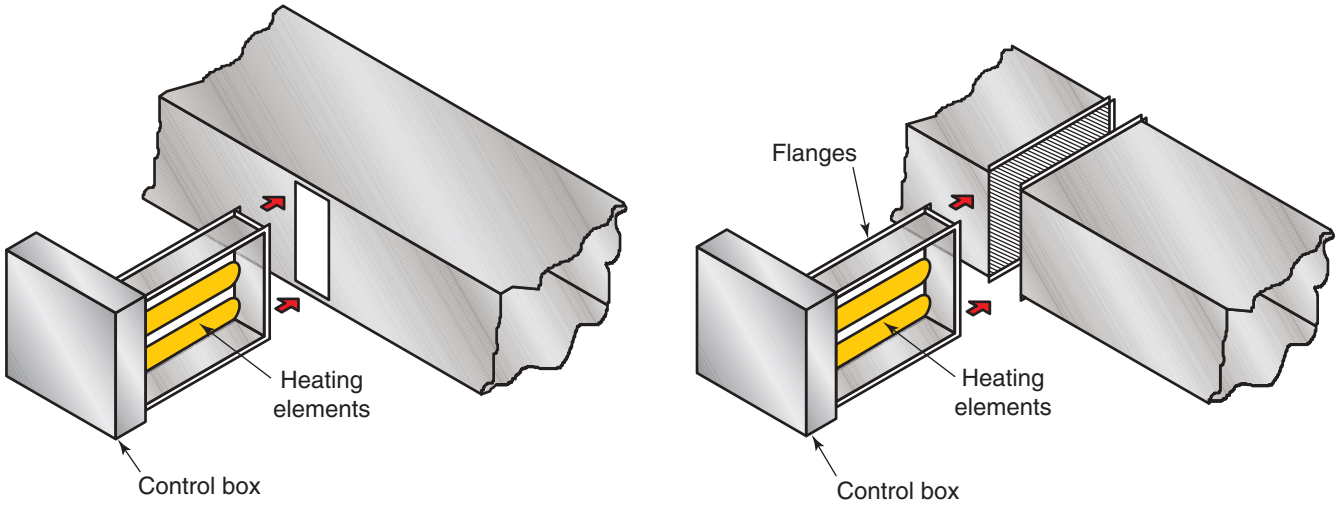
Code Alert

Duct Heaters

Section VI of Article 424 of the National Electrical Code (NEC) covers the requirements for duct heaters. Important topics covered include airflow, fan circuit interlock, limit controls, location of disconnection means, condensation compatibility, installation requirements, and use with air conditioner and heat pump systems. Section M1407 of the International Residential Code (IRC) provides duct heater installation requirements for one- and two-family dwellings.

43.3.3 Fan Heaters

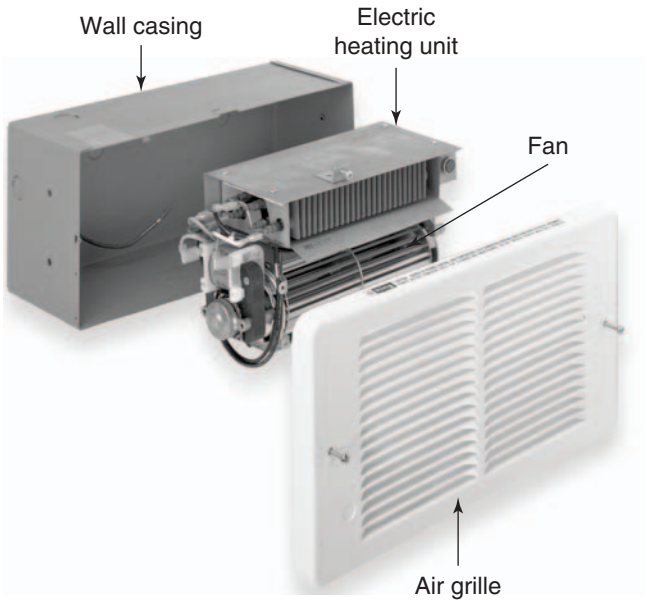
A ***fan heater*** is a type of convection heater that uses electric heating elements to produce warm air, which is distributed to a conditioned space by a fan.



Tutco, Inc.

Figure 43-6. Diagrams showing how slip-in and flanged duct heaters are installed.

Copyright Goodheart-Willcox Co., Inc. 2017



King Electrical Mfg. Co.

Figure 43-7. A fan heater installed in a metal casing designed to be mounted in a wall opening.

While small, portable fan heaters are available, permanently installed fan heaters are mounted in a casing in a wall opening, usually a few feet up from the floor, **Figure 43-7**.

Fan heaters are typically used as a supplementary heat source, such as building entryways. Often, fan heaters are built to look like little more than wall vents, **Figure 43-8**.

43.3.4 Electric Baseboard Heating Units

An ***electric baseboard heating unit*** consists of an electric heating element in a casing that is mounted close to the floor on a wall, usually under windows. These units are shaped much like a regular baseboard, **Figure 43-9**.

An electric baseboard unit's casing is designed to efficiently move air over the heating element by natural convection. Air expands and becomes lighter when heated. As a result, warm air rises as it exits a baseboard heating unit. Cool air, which is heavier, settles to the lower opening of a baseboard heating unit and enters the unit to replace the rising heated air. See **Figure 43-10**.

Baseboard heating units are available in lengths ranging from approximately 36″ to 100″ (0.9 m to 2.5 m). Some baseboard units have only one heating element, while others have two or more elements connected in parallel. For instance, a stairstep baseboard heating unit has several heating elements in a stair arrangement. Stairstep units direct airflow so that air near the wall is cooler than air farther from the wall. See **Figure 43-11**.

Baseboard heating units run on 240 V more often than on 120 V. This is because if two baseboard units are rated for the same wattage, a baseboard unit running on 240 V pulls half the current as a baseboard unit running on 120 V. An advantage of using a higher voltage to pull fewer amps is in material cost. The fewer amps a circuit requires, the smaller the wire gage can be. More amps require a higher gage wire. In most cases, the higher the wire gage, the more expensive it is. For most baseboard

Copyright Goodheart-Willcox Co., Inc. 2017

unit installations, it is good practice to keep the current load to 20 A or less per circuit. As a result, the use of 240 V circuits, where practical, is desirable.

Example:

If a room needs 10,000 Btu/hr to remain comfortable, a technician may install a baseboard heating unit rated at 3,600 W. According to calculations, the unit would produce sufficient heat (3,600 W × 3.413 Btu/hr = 12,287 Btu/hr). However, the wiring to the room is rated for 25 A. Should a technician install a 3,600 W baseboard unit rated at 120 V or 240 V?

Solution:

To determine which baseboard heating unit to use, calculate each unit's current draw using the formula for electrical power ($P = I \times E$). First, rearrange the equation to solve for current, then substitute the known values for power and voltage:

Baseboard unit rated at 120 V:

$$I = \frac{P}{E}$$
$$= \frac{3{,}600 \text{ W}}{120 \text{ V}}$$
$$= 30 \text{ A}$$

An electrical power of 3,600 W at 120 V will draw 30 A of electrical current. The electrical wiring to the room's baseboard units is only rated for 25 A. Calculate the current drawn for the baseboard units at 240 V:

Baseboard unit rated at 240 V:

$$I = \frac{P}{E}$$
$$= \frac{3{,}600 \text{ W}}{240 \text{ V}}$$
$$= 15 \text{ A}$$

Since a baseboard unit rated at 120 V and 3,600 W would pull 30 A, it cannot be used with the present wiring, which has a maximum current rating of 25 A. A baseboard unit rated at 240 V and 3,600 W will work well in this application because it draws only 15 A.

Code Alert

Allowable Ampacity

Electrical wiring is designed and manufactured for specific applications and for use at maximum allowable ampacity levels. Current flowing through electrical wiring generates heat. Insulation around wiring prevents current from causing fires and from conducting outside a circuit. Table 310.15(B)(16) of the National Electrical Code (NEC) lists allowable ampacities for different types and sizes of wire.

Caution

Baseboard Unit Voltage Ratings

Baseboard units are generally designed to operate at either 120 V or 240 V. These values are not interchangeable. Connecting a 240 V circuit to a baseboard unit rated at 120 V will ruin the baseboard unit. Always check with manufacturer specifications to be certain of a baseboard unit's rated voltage level.

43.3.5 Electric Radiant Heat

Electric radiant heat describes systems that use heating elements to radiate heat that primarily warms objects instead of air. Radiant heat may be produced by methods other than electricity, such as a fuel gas flame. In this section, however, we will focus on electric radiant heat, which is generally used in two different ways: directly and indirectly.

Direct Radiant Heat

For ***direct radiant heat***, the heating elements are mounted in a fixture that focuses the heat energy emitted by the elements on the objects to be warmed. In other words, the heat energy primarily warms the objects it directly strikes rather than the air. The assembly of heating elements mounted in a fixture may be called a *radiant heater*, a *radiant lamp*, an *infrared heater*, or a variety of similar names.

Glass panel heaters are also available. A glass panel heater has heating elements installed on the back of borosilicate glass, which is then covered with a reflective surface. The elements operate at about 500°F (260°C). The glass surface is about 350°F (180°C). It gives off about 60% radiant and 40% convective heat.

Radiant heaters emit infrared light to warm objects in their line of sight. See **Figure 43-12**. Objects absorb the infrared light energy and become warmer. However, radiant heat decreases as the distance increases between a radiant heater and the object it is warming. For instance, an object twice as far from a radiant heater will receive only one-fourth as much heat. A simple example of a small radiant heater is a toaster. The nichrome wires conducting electricity radiate heat to toast foods inside.

Radiant heat rays, if focused on a person who has several square feet of surface area to absorb the rays, will keep that person quite comfortable, even if the ambient air temperature is below the comfort range. An example of where direct radiant heat is a viable heating option is in a large warehouse with a few small areas where employees work. While it would be costly to heat the entire warehouse using a forced-air heating system, direct radiant heat can be used to warm the few small areas where employees usually work.

Copyright Goodheart-Willcox Co., Inc. 2017

Olena Zaskochenko/Shutterstock.com

Figure 43-12. A radiant heater, or infrared heater, used to heat small areas.

Radiant heaters may have a 45°, 60°, or 90° reflection angle, depending on the size of the area that needs to be heated, **Figure 43-13**.

Code Alert

Residential Radiant System Installation

Section M1406 of the International Residential Code (IRC) provides requirements for installing electric radiant heating systems in one- and two-family dwellings.

Indirect Radiant Heat

For ***indirect radiant heat***, heating elements produce heat that warms a large surface, such as a floor or a panel on a ceiling or wall, which then radiates its heat to the solid objects in a conditioned space. Thus, the heating elements indirectly heat the objects in a conditioned space. In most cases, the heating elements are embedded in a floor, wall, or ceiling or in a panel attached to one of these surfaces. Since indirect radiant heat warms a surface before warming the conditioned space or occupants, it is also called *surface radiant heat*.

Heavy insulation installed on one side of the heated surface prevents heat from escaping into unconditioned spaces or into conditioned spaces in a different zone. The other side of the heated surface faces the conditioned space. When energized, the heating elements warm the surface in which they are embedded. The amount of heat radiated by an indirect radiant heating system can provide a very comfortable living environment, even in a location where the temperature of the air is lower than usual, such as 66°F (19°C). A thermostat mounted on a wall controls room temperature by changing the amount of current passing through the heating elements. **Figure 43-14** illustrates a typical radiant ceiling panel installation.

Code Alert

Electric Space-Heating Cables

Section V of Article 424 of the National Electrical Code (NEC) covers the requirements for electric space-heating cables. Important topics covered include cable color identification codes (by voltage level), clearances, restricted areas, and use in concrete, poured masonry, dry board, and plaster.

Electric radiant floor heating is also used in both residential and commercial applications. This method uses heating elements embedded beneath a floor's surface. The heating elements are typically made of conductors with a diameter of 1/8″ (3 mm) and a center-to-center distance of 3″ (76 mm). Controlled by a wall-mounted thermostat and a temperature sensor

Figure 43-14. Radiant heat is supplied by electric heating elements embedded in ceiling panels. Heavy insulation is needed with a radiant ceiling panel installation to prevent heat from escaping to an unconditioned attic.

embedded in the floor, the heating elements have an output of about 12 W/ft² (130 W/m²). To minimize the time required to heat a room, high-emissivity insulation, such as polyurethane foam or mineral wool and reflective foil, should be installed. This also helps to control the direction of heat flow.

Electric radiant floor heating can be used as a supplementary heating system or as a primary heating system with separate circuits for zone control. Although radiant floor heating primarily warms objects through radiant heat, it also provides convective heat by warming the ambient air somewhat. As a result, radiant floor heating has excellent heat distribution compared to convective heating methods, such as forced air. Compared to baseboard heating units, indirect radiant heat produces much less room temperature variation. Temperature variation between the floor and ceiling with baseboard heating units can be between 4°F and 15°F (2°C and 8°C). With indirect radiant heating systems, temperature variation between the floor and ceiling is between 4°F and 5°F (2°C and 3°C).

In certain installations, radiant floor heating can be used to store heat in a large mass for a slow, gradual release over time. If electricity is billed by time of use, the heating elements can be used during non-peak billing times to store thermal energy in a concrete slab beneath a floor's surface. Depending on the thermal mass of the floor, heat can be provided to a house for 8–10 hours after the system cycles off during peak billing hours.

Code Alert

Electric Radiant Heat

Section IX of Article 424 of the National Electrical Code (NEC) covers the requirements for electric radiant heat. Important topics covered include installation requirements, use in concrete or poured masonry, and use under floor covering.

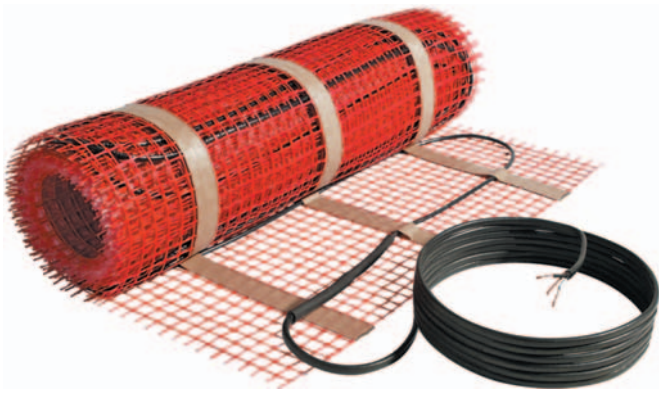
43.3.6 Electric Heat for Deicing and Snow Melting

Besides climate control, electric heat can be used to melt snow and ice. For ground protection, the heating elements are installed under asphalt, concrete, or stonework. See **Figure 43-15**. Insulation should be laid on the ground before the installation to prevent downward heat loss.

Code Alert

Outdoor Deicing

Article 426 of the NEC covers fixed outdoor electric deicing and snow-melting equipment. This includes both embedded and exposed deicing equipment. Embedded equipment is considered electric heating in driveways, walkways, steps, and other related areas. Exposed equipment is considered drainage systems, bridge structures, roofs, and other structures.



King Electrical Mfg. Co.

Thinking Green

Radiant Snow Melting

Installation of indirect radiant heat for snow-melting applications eliminates the negative environmental impact caused by the use of chemicals or rock salt to melt snow and may reduce long-term snow removal costs. However, as the outdoor temperature drops, more power must be used. From 14°F to –40°F (–10°C to –40°C), the output ranges from 19 W/ft² to 46 W/ft² (200 W/m² to 500 W/m²) respectively.

Heating elements may also be placed on roofs to prevent snow accumulation and around downspout pipes to prevent ice blockage.

Code Alert

Considered Continuous Load

Section 426.4 of the NEC states that fixed outdoor electric deicing and snow-melting equipment is considered as a continuous load. The NEC defines ***continuous load*** as "a load where the maximum current is expected to continue for 3 hours or more." Articles 210.19(A) and 210.20(A) require that circuits powering only a continuous load (for example, a circuit dedicated to deicing equipment) must have properly sized conductors and overcurrent protection of 125% of the continuous load.

43.4 Electric Furnace and Duct Heater Controls

Electric furnaces and duct heaters use many of the same control devices. A primary control, such as a thermostat, senses room temperature and signals for operation to begin. Before energizing the electric heating elements, however, both electric furnaces and duct heaters check for airflow. If there is no airflow from an indoor blower fan, the heating elements may build up too much heat. Confirming airflow minimizes the risk of high heat damaging the heating elements.

43.4.1 Airflow Switches

Some devices commonly used to confirm airflow are pressure switches, sail switches, and fan interlock relays. A pressure switch actuates based on air pressure. It may actuate based on a rise in pressure, a drop in pressure, or a difference in pressure. For example, by measuring air pressure before and after a duct heater, a pressure switch can detect airflow, **Figure 43-16**.

A sail switch, which appears as a switch assembly with a paddle or flipper attached, responds to the flow of air. A fan interlock relay locks out heating element operation until a blower fan turns on. Regardless of the type of control, pressure switches, sail switches, and fan interlock relays all perform the same function of checking for airflow before allowing the heating elements to be energized.

To prevent heating elements from overheating during shutdown, airflow should continue even after the room temperature set point is reached and the thermostat has ended its call for heat. This is done with a heat-sensitive switch, such as a bimetal disc, that is wired in parallel with the primary control. Even if the primary control opens to turn off power to the blower at the end of a heating cycle, this switch senses the heat in the duct heater or furnace and remains closed to keep the blower operating as the heating elements de-energize. Once the heating elements have been turned off and enough heat has dissipated, the switch opens to turn off the blower fan.

Pro Tip

Duct Heater Airflow

When installing a duct heater, be certain to compare airflow measurements with the manufacturer's specifications. Although a pressure switch or sail switch may detect airflow and close for heater operation to begin, it may close at an airflow level that does not meet the duct heater's minimum airflow requirement. This can lead to the heating elements overheating and breaking. A broken heating element results in reduced heat production and may also lead to a short circuit or other dangerous electrical conditions, such as ductwork that is electrically live. A live duct can lead to a dead technician.

43.4.2 Sequencers

Electric furnaces and duct heaters usually have more than one electric heating element. Heating elements draw high current, which can be disruptive to other electric appliances in a building and can blow a fuse or trip a circuit breaker. Therefore, each heating element is energized one at a time. A ***sequencer*** is a device that closes and opens its electrical contacts on a time delay for energizing a series of electrical loads in sequence. It is used to control when each heating element is energized. Sequencers are manufactured either as single, stand-alone units or as units with multiple sequencers. In an installation with multiple heating elements, one or more sequencers control the heating elements. Typically, each individual sequencer in the unit energizes its own heating element, **Figure 43-17**.

A sequencer consists of several sets of electrical contacts, a coil (wire heater), and a heat-sensitive switch. For its heat-sensitive switch, a sequencer uses a bimetal element to open and close its sets of contacts. In a sequencer with three sets of contacts, one set is rated for high current and is used to energize an electric heating element in a furnace or duct heater. Another set of contacts is used to keep the blower fan energized. The third set of contacts is rated for low current and is used to energize the next sequencer coil in the control circuit, **Figure 43-18**.

Some sequencers are equipped with five sets of contacts, allowing them to control three heating elements, the blower fan, and the low-voltage circuit connected to the next sequencer.

At the beginning of a heating cycle, a sequencer's contacts are open. When a thermostat calls for heat, the sequencer's coil is energized. The voltage applied to a sequencer across the coil produces heat at a rate that actuates the bimetal element in a specified period of time. After the specified period of time, the coil produces enough heat to close the contacts regulated by the bimetal element. One set of contacts closes to energize the first heating element. Another set of contacts closes to energize the coil of the next sequencer. This action continues until all the heating elements are energized.

Often, a blower fan relay is wired in parallel with the first sequencer in a unit. In this case, the blower fan turns on before the first heating element is turned on. If a fan relay is not wired in parallel with the first sequencer, the blower fan is controlled

Figure 43-18. Wiring diagram showing a sequencer's coil and auxiliary contacts connected to the control circuit. The sequencer's blower contacts and heating element contacts are connected to the power circuit.

by one set of contacts in the first sequencer. In this case, the blower fan and first heating element turn on at the same time.

The way an electric furnace or duct heater shuts down depends largely on a system's thermostat and the wiring of the control circuit. One method has all the control circuit's current, including the sequencer current, running through the thermostat. This method is not always desirable as the level of current may be higher than a thermostat's current rating. Most 24 V thermostats have a 1 A maximum current rating.

With the thermostat controlling the current in the control circuit, all the heating elements in the furnace or duct heater turn off at once. When the thermostat ends its call for heat and opens its contacts in the control circuit, all the sequencers and their coils become de-energized and begin to cool down immediately. Since all the sequencer coils cool at the same rate, all the heating elements in the furnace or duct heater shut off at once, **Figure 43-19A**.

An alternative wiring method has the thermostat and most of the sequencers wired in parallel in the thermostat, **Figure 43-19B**. The only sequencer that is wired in series with the thermostat is the first sequencer that begins operation. With the thermostat wired in series with only the first sequencer, each heating element in the furnace or duct heater turns off one at a time. When the thermostat ends its call for heat, it de-energizes the first sequencer's coil. After the first sequencer's cooling down period, its contacts open to de-energize two things: the sequencer's corresponding heating element and the second sequencer's coil. After the second sequencer's coil cools down, it opens its contacts to de-energize the corresponding heating element and the third sequencer's coil. In this sequential manner, each sequencer turns off its corresponding heating element one at a time. Such an arrangement requires a heat-sensing device in parallel with the fan coil contact. This blower off-delay keeps the blower operating through sequencer shutdown until heat production is reduced to a safe level.

Figure 43-20. Electric heating elements equipped with circuit breakers as overcurrent protection.

Pro Tip

Sequencer Terminology

Sequencers may be called by several different names in the HVACR industry, such as *heat sequencers*, *sequencer relays*, *step controllers*, and *stage controllers*.

43.4.3 Electromagnetic Contactors

Instead of sequencers, electromagnetic contactors may also be used to open and close the circuit feeding the heating elements. With contactors, however, all of the heating elements are energized simultaneously unless separate contactors with time-delay functions are used for each element. Check that the contactors are designed to carry the amount of current that is conducted by a duct heater or furnace. For more information on contactors, review Chapter 16, *Electrical Control Systems*.

43.4.4 Mercury Contactors

Electromagnetic contactors are seldom used in electric furnaces and duct heaters because the hard hitting of the contacts produces a sound that reverberates through the ductwork into conditioned spaces. As a result, contactors are usually used in commercial systems where they are not attached to the ductwork. To eliminate this sound, some older units may be equipped with a mercury contactor. A ***mercury contactor*** is a switching device that immerses its electrodes into a small pool of mercury for electrical contact. This device fulfills the same function as an electromagnetic contactor but does so silently. Solid-state relays are another alternative to electromagnetic contactors for noiselessly switching furnaces and duct heaters on and off.

43.4.5 Safety Controls

In the event that a circuit pulls too much current, such as from a short in the circuit, circuit breakers open or fuses blow to break the circuit and stop the high current, **Figure 43-20**. Excessively high current can be dangerous to technicians and damaging to property. However, not all duct heaters are required to have fuses. Those that do have fuses usually have them in the control box.

In addition to having overcurrent protection devices, duct heaters and electric furnaces have other safety controls to protect them from overheating. Overheating can occur for a variety of reasons. For instance, a blower motor can burn out and stop circulating air, which would lead to a buildup of excessive heat. Supply and return air ducts can be blocked by large objects, which would also reduce airflow and cause excessive heat buildup. There are numerous other circumstances that can cause an unsafe rise in heat capable of damaging electric heating components. Safety controls used to prevent such occurrences are called high-temperature safety cutoffs or high-limit switches.

A high-temperature safety cutoff is usually a bimetal disc or a fusible link. A bimetal disc is composed of two dissimilar metals that react to temperature by changing shape, which opens or closes an electrical switch. A bimetal disc is wired in the control circuit to turn off power to the electric heating elements. Some electric furnaces or duct heaters use two bimetal discs that are calibrated at two different temperature settings. The first bimetal disc is set to trip open the heating elements at a certain high temperature, and the second bimetal disc is set to trip open at a higher temperature than the first bimetal disc. The first bimetal disc usually resets automatically when the temperature drops below the calibrated set point. However, the second bimetal disc requires manual resetting. This is intentional so that a service technician will realize there is some problem in the system causing the rise in temperature that needs to be fixed.

Aside from a bimetal disc, an electric furnace or duct heater may also use a fusible link as a high-temperature safety cutoff. A ***fusible link*** is a heat-sensitive device that opens an electric circuit when the temperature rises too high. Like a bimetal disc,

Copyright Goodheart-Willcox Co., Inc. 2017

a fusible link is wired to turn off the electric heating elements. Unlike a bimetal disc, however, a fusible link cannot be reset. A fusible link must be replaced once it has been opened. Rather than just replacing a fusible link, a service technician should investigate why the temperature rose too high, **Figure 43-21**.

43.5 Electric Baseboard Heating Unit Controls

Electric baseboard heating units are controlled by their own thermostats. Since each room in a building would have its own baseboard heating unit with its own thermostat, occupants can regulate each room's temperature independently without adjusting the temperature of the entire building. The independent adjustment of individual baseboard units is an easy form of decentralized zone control that does not require extra controls or automatic duct dampers.

Although some baseboard heating units can run on 120 V, the majority run on 240 V. Producing heat through electrical resistance requires a significant amount of current. As a result, baseboard heating units are often wired on their own separate, dedicated circuits to avoid drawing too much current that could result in voltage drops or damage to property. No lights, appliances, or electrical sockets should be placed on these circuits, only the baseboard unit. Some manufacturers include outlets on their baseboard units, **Figure 43-22**. Review the owner's manual before connecting to these outlets.

Code Alert

Baseboard Receptacle Outlets

Section 424.9 of the NEC states that electrical receptacle outlets included as part of a baseboard heating unit shall not be connected to the heater circuit. This means that the heating elements will be on a completely separate circuit from the electrical outlets in the same assembly.

Thermostats for baseboard units may have a single-pole or double-pole switch. A single-pole thermostat

DiversiTech Corporation

Figure 43-21. A fusible link acts as a high-temperature safety cutoff by opening the circuit that de-energizes the electric heating elements in an electric furnace or duct heater.

Cadet Manufacturing Co.

Figure 43-22. Since electrical outlets should not be installed above baseboard heating units, manufacturers may produce baseboard units that include installed outlets.

Copyright Goodheart-Willcox Co., Inc. 2017

opens only one leg of the 240 V circuit. Baseboard heat uses two hot legs to get 240 V. Using a single-pole switch is generally considered less safe than a double-pole thermostat, so single-pole thermostats are used less frequently. A double-pole thermostat opens both legs of the 240 V circuit, reducing the risk of grounds or shorts.

Code Alert

Thermostats as Disconnecting Means

Section 424.20 of the NEC provides requirements for using a thermostat as a controller and also as a disconnecting means in fixed electric space-heating equipment, such as baseboard heaters. These must meet four requirements as follows: (1) Have a marked "off" position. (2) Must directly open all ungrounded conductors when manually placed in the "off" position. (3) Designed so that the circuit cannot be automatically energized after the device has been manually placed in the "off" position. (4) Located as specified in Section 424.19. If a thermostat does not meet these requirements, a separate disconnecting means must also be installed in the circuit.

There are two main ways of wiring thermostats for an electric baseboard heating unit. One way incorporates the thermostat into the baseboard unit. Built-in thermostats are generally used for baseboard units that are plugged into a dedicated wall outlet, **Figure 43-23**.

The second way is to use a wall thermostat to control the baseboard heating unit. Wall thermostats are generally used to control baseboard units that are hardwired to the building's electrical system.

Code Alert

Wiring Baseboard Units

When wiring 240 V for electric heat, check local electrical codes to see which color wires should be used and how to indicate that a circuit is 240 V. Local authorities may have different methods of addressing this issue.

43.6 Electric Heat Construction Practices

Electric heating systems are considered less complicated than other forms of heat generation for climate control. The principles of heat generation are straightforward, and the methods of heat distribution are simple. Some advantages of electric heating systems include the following:

- Lower initial purchase price and installation cost.
- Electric heating equipment normally requires less space than other heating equipment.
- No ductwork required for certain applications, such as baseboard heating units and fan heaters.
- Electric heating systems are 100% efficient because no heat is lost to the products of combustion as in other heating systems.

Nonprogrammable Bimetal Thermostat

Electronic Programmable Thermostat

Cadet Manufacturing Co.

Figure 43-23. Two types of thermostats that are built into baseboard heating units.

Copyright Goodheart-Willcox Co., Inc. 2017

- The highest temperatures produced are below the ignition temperature of most materials. Therefore, electric heating systems are considered safer and less of a fire hazard than other heating systems.
- Due to the absence of combustion gases, there is less danger of toxic conditions arising indoors, and no flue or chimney is needed.
- Many types of electric heat allow individual room temperature control, giving a building zoned climate control. Conditioning only rooms that have occupants instead of an entire building reduces energy consumption and energy costs.
- Very clean operation (no soot or combustion by-products).

Electric heating systems also have some disadvantages:

- The cost per unit of heat is often higher than for other fuels. However, this varies depending on city, county, or state. Costs of fuels change frequently, making some more expensive than others.
- The consumption of more kilowatt-hours of electricity than a heating system that uses a different heat source.
- Humidity control problems may occur.
- Additional wiring and electrical circuits are required.
- The danger of working on high-voltage wiring that draws a lot of current.

Diversity in equipment manufacturing allows electric heat to be used as the primary heating system for an entire building or as a supplementary heating system in smaller applications. Various applications of supplementary heat include a wall-mounted fan heater near an entryway, radiant heat panels built into a wall or ceiling, and baseboard heating units installed along walls. Supplementary electric heat is often used to condition building additions, such as added bedrooms or utility rooms. The original heating system may not have enough capacity to carry the extra load of heating any additions, or extending the original heating system to the addition may be difficult or expensive. Electric heat may also be used to heat a room that is rarely in use, thereby reducing overall energy consumption.

Problems in buildings with electric heat usually involve the need for insulation or ventilation. The lack of proper insulation or ventilation results in problems such as excess relative humidity and longer system run times. These problems may be more prevalent or apparent in buildings that were originally built with heating systems other than electric. The building should be modified to reduce heat transfer and air exfiltration.

43.6.1 Heat Loss

To reduce heat loss and exfiltration, insulate walls and ceilings as thoroughly as possible. Preventing heated air inside a building from exiting reduces the time and necessity for electric heat to operate. Since it usually costs more to produce a unit of heat using just electricity than it costs with most other types of fuels, reducing the amount of time that an electric heating system needs to run substantially minimizes operating costs.

Basement walls or the floor slab of buildings without a basement must be insulated. The floor slab should be insulated according to the chart shown in **Figure 43-24**. Use only insulation approved for below-grade use. Basement walls should have 2″ to 4″ (5 cm to 10 cm) of insulation. Windows should be double-glazed. Wood or plastic window and door frames are preferred, rather than metal. Walls should have 4″ (10 cm) of insulation and ceilings should have 7″ (18 cm).

Thinking Green

Heating Degree-Days

The *International Energy Conservation Code* (*IECC*) specifies both the R-value and the minimum insulation depth from the top of a slab based on an area's heating degree-days. For more information on heating degree-days and the degree-day method of calculating heating costs, see Chapter 46, *Energy Conservation*.

Floor Slab Insulation Depths and R-Values

Heating Degree-Days	Minimum Insulation Depth	R-Value
0–2,499	None required	None required
2,499–4,500	2′	4
4,500–6,000	4′	5
6,000–7,200	4′	6
7,200–8,700	4′	7
8,700–10,000	4′	8
10,000–12,400	4′	9
12,400–14,000	4′	10

US Department of Energy

Copyright Goodheart-Willcox Co., Inc. 2017

During daylight hours, solar heat can be used to supplement electric heat. When possible, open curtains and blinds on east, south, and west windows to allow sunlight to radiate warmth into a building. Although electric heating systems require a well-insulated and tight structure, this design may add to ventilation problems.

43.6.2 Humidity and Ventilation

Relative humidity control in electrically heated buildings is different than in buildings with combustion heating systems. With combustion heating systems, a fairly large quantity of air passes through the furnace and out of the stack. However, electric heating produces no draft. It does not pull excess water vapor out and replace it with drier outside air. With combustion heating systems, makeup air enters the building through a makeup air unit or through leakage around the doors, windows, and cracks in the floor. With most electrically heated structures, building construction permits little infiltration of this nature. Therefore, without the replacement of humid air with dry air, indoor relative humidity may reach uncomfortable or unhealthy levels.

Water vapor formed in the conditioned space of a well-insulated and tightly constructed building cannot easily escape. Relative humidity builds up from cooking, laundry, bathing, pets, occupants, and other sources. Dehumidifying and ventilation equipment may be needed. Depending on the climate zone in which a building is located, a heat recovery ventilator (HRV) or an energy recovery ventilator (ERV) can be used to ventilate a tightly constructed building with minimal heat loss. HRVs and ERVs consist of specially designed heat exchangers that allow outgoing conditioned air to increase the temperature of incoming outdoor air. This allows fresh outdoor air to replace stale indoor air without much heat loss.

43.7 Electric Heating System Service

Electric heating systems provide heat through electric resistance heating. Although electric heating systems do not have combustible fuels or high-pressure fluids, they do require technicians to work safely with high-voltage and high-current circuits. Technicians must take extra precautions to avoid touching components that may be energized and surfaces that may be hot (temperature). Areas of interest include electric heating elements, wiring, and operational controls.

43.7.1 Installing Heating Elements

Electric heating elements must be installed according to electrical codes and manufacturer recommendations. The heating element installation must be carefully checked and inspected. The power circuit providing electrical service to the heating elements must use the appropriate wire gage for the voltage and amperage of the circuit. The heating element circuit must have fuses or circuit breakers and adequate high-limit switches. All safety control devices must be designed for the correct voltage and current. Unit heaters should not be installed close to flammable materials or surfaces.

Safety Note

Heat and Electric Shielding

Electric furnaces must be shielded electrically and heat protected. All metal parts of the furnace must be grounded. Check an electric furnace installation to ensure it is fire safe.

Code Alert

Spacing and Clearance

Section 424.13 of the NEC requires fixed electric space-heating equipment to be installed with required spacing between itself and adjacent combustible material, unless listed for other requirements. Section M1306 of the International Residential Code (IRC) provides required clearances of mechanical appliances from combustible construction. Note that clearance reductions are possible based on manufacturer instructions and Table M1306.2 in the IRC. Other code considerations are working clearances necessary for regular service and maintenance of an appliance.

When replacing a heating element, confirm its part number, size, resistance (in ohms), current capacity (in amps), and voltage (120 V or 240 V). A heating element must always be replaced with a heating element that has an identical kilowatt rating. Substituting heating elements with higher kilowatt ratings or with elements of a different design may result in unsafe operation of a furnace. Heating elements with lower kilowatt ratings will reduce output and may result in unsatisfactory operation of the furnace, **Figure 43-25**.

Copyright Goodheart-Willcox Co., Inc. 2017

DiversiTech Corporation

Figure 43-25. Electric heating element replacement kit with insulators and hardware.

Testing Heating Elements

To test an electric heating element, a technician uses a multimeter to see if the heating element has continuity or is grounded. Refer to furnace wiring diagrams while following this procedure.

1. Shut off all power to the furnace.
2. Remove all wires from the heating element terminals.
3. Using the continuity check function on the multimeter, test from terminal to terminal of the heating element.
4. The multimeter should show continuity. If not, replace the heating element assembly.
5. Next, test from the heating element terminal to ground.
6. There should be no continuity. If there is, the element is grounded and must be replaced.

43.7.2 Installing Baseboard Heating Units

In most cases, a baseboard heating unit should be mounted on a wall. If the unit is built into the wall, dust in the heated air coming from the unit may cause streaking, which means the wall will need frequent cleaning using a vacuum, duster, or rag. A baseboard heating unit's air passages must be clear to prevent poor airflow because the heating element can become overheated if the air passages are blocked.

Typically, each baseboard heating unit or the baseboard units in a single room are controlled by an individual thermostat. This arrangement permits individual room temperature control. Baseboard heating units are easy to install and take up a minimum amount of space. Since there are no moving parts, they are noiseless. Heating units contain a high-limit switch, which is a safety control. A high-limit switch opens the electrical circuit if any part of the heating unit rises above normal temperature. High-limit switches are not always sold separately. If such a high-limit switch fails, replace the baseboard heating unit.

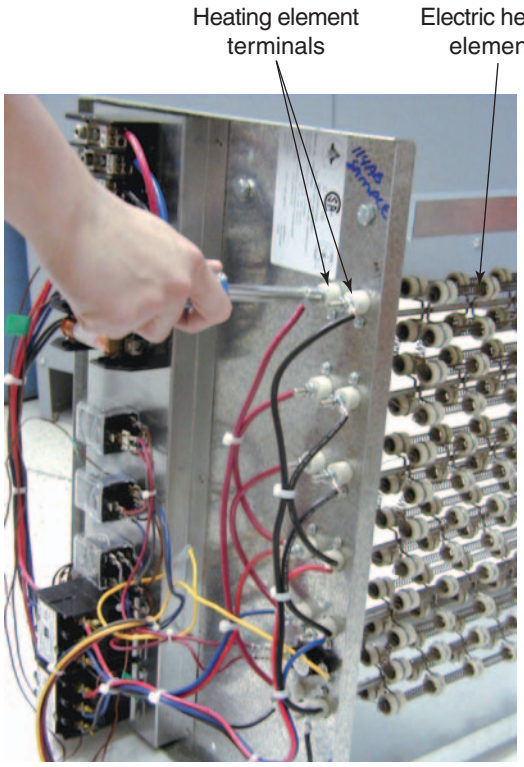
Replacing Baseboard Heating Units

1. Turn off power to the heating unit at the circuit breaker.
2. Remove screws from brackets on the top and sides of the unit.
3. Gently pry the heating unit from the wall. A flat bar may need to be used.
4. Remove the screws from the rear of the wiring box and pull the wiring box cover off.
5. Unscrew wire nuts in the wiring box connecting the ground wire and any additional wires to the wall.
6. Position the new baseboard heating unit next to the wall.
7. Remove screws from the new unit's wiring box.
8. Connect the ground wire and any additional wires to the wall by following the manufacturer's instructions.
9. Screw wire nuts over wiring connections.
10. Secure the new heating unit in place using screws.
11. Turn the circuit breaker on.

43.7.3 Electric Heating System Maintenance and Troubleshooting

Electric heating systems require less maintenance compared to combustion heating systems because they do not produce soot or smoke. However, grilles, ducts, heating elements, and fins should still be cleaned at least once each year. Air passages around the heating elements must be kept clean using brushes and vacuums. Any loose electrical terminals should be tightened, and any corroded terminals should be cleaned. See **Figure 43-26**. Use an ohmmeter or multimeter to check for high-resistance connections.

Copyright Goodheart-Willcox Co., Inc. 2017



Cadet Manufacturing Co.

Figure 43-26. A technician tightening electric heating element terminal connections.

Safety Note

Flammable Fluid Cleaners

Never use flammable fluids to clean electric heating systems.

The thermostat and sequencer circuits are common causes of electric heating system problems. See **Figure 43-27**. If a circuit does not function, use the following questions to diagnose the cause of the electrical circuit malfunction:

- Is there power to the fuse or circuit breaker box?
- Are the fuses in good condition and are all connections tight?
- Is the thermostat operating? (Check cut-in and cut-out temperatures.)
- Is the high-limit switch operating? (Check cut-in and cut-out temperatures.)
- Are the sequencers in good condition and operating?
- Are the relay or contactor contacts clean and operating?
- Does the electric heating element circuit have continuity?

Electric Heat Troubleshooting

Problem	Possible Cause
Blower turns on and off.	1. If the heating elements heat and cool as the blower runs and stops, the thermostat is short cycling. The anticipator rating may be too high. 2. High-limit switch may be opening and closing. 3. Incorrect low voltage. 4. Motor overload may be opening and closing.
Blower runs, but there is not enough heat.	1. Dirty filters. 2. Voltage too low. 3. Only some heating elements are energized. 4. Open fuse or circuit breaker. 5. Heating element burned out. 6. Sequencer switch not operating. 7. Second stage of two-stage thermostat not operating (second-stage adds to heating capacity).
No power or low voltage.	1. Sequencer switch defective (open). 2. Thermostat open. 3. Low line voltage. 4. Low transformer output voltage.
Motor not operating, but there is proper voltage at motor.	1. Defective motor (open circuit). 2. Defective overload (open circuit). 3. Defective motor capacitor (shorted or open).

Chapter Review

Summary

- Electric heat is produced by electric current flowing through a resistance element. A technician can calculate an electric heating system's wattage and heat production. For wattage, multiply voltage and amperage. One watt of electrical power equals 3.413 Btu/hr, and one kilowatt equals 3,413 Btu/hr. By dividing the number of Btu per hour (Btu/hr) needed to maintain a building's temperature by 3,413, a technician can calculate how much electrical power in kilowatts is needed to produce this heat.
- There are three basic types of electric heating elements: open wire, open ribbon, and tubular cased wire. Open wire and open ribbon elements are mounted on insulators while tubular cased wire is enclosed in a steel tube to prevent electrical shock.
- Electric heat may be used as a building's primary heating system or as a supplementary heating system. Convection heating systems warm air and move it throughout a conditioned space. Convection systems include electric furnaces, duct heaters, fan heaters, and baseboard heating units.
- Radiant heating primarily heats objects, including occupants, within a conditioned space, instead of heating the air. Direct radiant heat focuses heat from its source directly on objects in its line of sight. Indirect radiant heat warms a large surface, such as a wall or ceiling panel, that radiates heat to other objects. Electric heat can also be used to melt snow and deice walkways and driveways.
- Before energizing heating elements, electric furnaces and duct heaters confirm airflow using a control device, such as a pressure switch or sail switch. Safety control devices such as circuit breakers and fuses are used to protect against excessively high current. Other safety control devices include bimetal discs and fusible links, which protect against overheating by turning off power to the heating elements.
- Sequencers are used to energize electric heating elements one at a time. A sequencer typically has three sets of contacts: one to energize the heating element, one to energize the blower fan, and one to energize the next sequencer in the control circuit. Each individual sequencer energizes its own heating element. Electric heat controls can be wired in different ways for different operational start-up and shut-down sequence.
- While sequencers are often used to energize heating elements, they are not the only control for that purpose. Magnetic contactors and mercury contactors can also be used to energize electric heating elements.
- A baseboard heating unit is controlled by a thermostat. To de-energize such a circuit, it is safest to use a double-pole switch to disconnect both hot legs. Baseboard units often run off 240 V, rather than 120 V. Their power circuits are separate and dedicated to just the heating unit. Any electrical outlets included on a baseboard unit must be on a separate electrical circuit.
- Advantages of electric heating systems over combustion heating systems include increased efficiency, a decreased risk of toxic conditions, and a lower initial cost. Disadvantages include possible humidity problems, the high cost of electricity compared to other fuels, and the risk of working on high-voltage circuits.
- Buildings with electric heating systems must be tightly sealed and heavily insulated to reduce heat loss. However, these design elements may promote high humidity. Heat recovery ventilators (HRVs) and energy recovery ventilators (ERVs) help alleviate humidity problems while still minimizing heat loss.
- When installing heating elements, replacement elements must be the same wattage to prevent system problems, such as overheating and short cycling. Adequate spacing and clearance must be maintained when installing heating units and other appliances. Installations must follow applicable codes.
- Using a multimeter, a technician tests electric heating elements with the power turned off to check for continuity and grounded connections. Heating elements should be kept clean and have unobstructed air passages. Terminals and connections should be tightened and cleaned of any corrosion.

Review Questions

Answer the following questions using the information in this chapter.

1. Examples of convection electric heating systems include all of the following, *except* _____.
   A. baseboard heating units
   B. electric furnaces
   C. fan heaters
   D. infrared heaters
2. How much electrical power is needed to heat a home that requires 70,000 Btu/hr?
   A. 20.5 kW
   B. 58.3 kW
   C. 291 kW
   D. 2,500 kW
3. The three basic types of electric heating elements include all of the following, *except* _____.
   A. open wire
   B. open ribbon
   C. thermocouples
   D. tubular cased wire
4. Although not all electric heating systems require ductwork, _____ do require ductwork.
   A. baseboard heating units
   B. electric furnaces
   C. fan heaters
   D. infrared heaters
5. A device often added to an electric furnace that can absorb and remove heat during the cooling season is a(n) _____.
   A. accumulator
   B. baseboard unit
   C. evaporator
   D. fan heater
6. A single unit containing an array of electric heating elements installed in a run of ductwork is called a(n) _____.
   A. baseboard heating unit
   B. duct heater
   C. fan heater
   D. infrared heater
7. Although it actually contains electric heating elements and a fan to circulate heated air, a(n) _____ may only look like a wall vent.
   A. baseboard heating unit
   B. duct heater
   C. fan heater
   D. infrared heater
8. What is the current draw of a 2,000 W baseboard heating unit rated at 240 V?
   A. 8.3 mA
   B. 8.3 A
   C. 83 A
   D. 480 A
9. Natural convection is the method of air circulation used by _____.
   A. baseboard heating units
   B. electric furnaces
   C. fan heaters
   D. infrared heaters
10. Which of the following is *not* a reflection angle used by radiant heaters?
    A. 45°
    B. 60°
    C. 90°
    D. 360°
11. In _____ radiant heating systems, heating elements heat a large mass, which then radiates heat to occupants.
    A. continuous
    B. convection
    C. direct
    D. indirect
12. Fixed outdoor electric deicing and snow-melting equipment is considered by the NEC to be a continuous load. This means that maximum current is expected to continue for _____ or more.
    A. 60 minutes
    B. 3 hours
    C. 12 hours
    D. 24 hours
13. All of the following are control devices used to confirm adequate airflow before allowing a duct heater or electric furnace to energize its heating elements, *except* _____.
    A. fan interlock relays
    B. mercury contactor
    C. pressure switches
    D. sail switches
14. A sequencer's _____ produces heat that actuates the sequencer's bimetal element to close multiple sets of contacts.
    A. blower fan
    B. coil
    C. switch
    D. transformer

Copyright Goodheart-Willcox Co., Inc. 2017

15. One example of a high-temperature safety cutoff is a _____.
    A. fusible link
    B. mercury contactor
    C. sail switch
    D. sequencer coil

16. Which of the following should be placed on the same circuit as a 240 V baseboard heating unit?
    A. Appliances.
    B. Electrical outlets.
    C. Lights.
    D. None of the above.

17. Advantages of electric heating systems over combustion heating systems include the following, *except* _____.
    A. 100% energy efficient operation
    B. cost per unit of heat is lower than other fuels
    C. highest temperatures produced are below ignition temperatures (less of a fire hazard)
    D. no flue or chimney necessary for combustion gases

18. Buildings with electric heating systems often use a(n) _____ as a means of ventilation that minimizes heat loss.
    A. sequencer
    B. energy recovery ventilator
    C. insulated floor slab
    D. sail switch

19. It is safest to use a thermostat with a(n) _____ switch to control the 240 V lines to an electric baseboard heating unit.
    A. airflow
    B. double-pole
    C. low-current DIP
    D. single-pole

20. Electric heating system service includes the following tasks, *except* _____.
    A. cleaning corroded terminals
    B. cleaning grilles and ducts
    C. oiling the heating elements
    D. tightening loose terminals

- 44.5.2 Oil and Gas Heating
- 44.5.3 Heat Pumps

44.6 Converting Solar Energy to Electricity
- 44.6.1 Solar Cell Construction
- 44.6.2 Solar Cell Applications

44.7 Solar Energy Cooling Systems
- 44.7.1 Solar Absorption Air-Conditioning Systems
- 44.7.2 Solar Mechanical Air-Conditioning Systems

44.8 Thermal Energy Storage (TES) Systems
- 44.8.1 Sensible Thermal Energy Storage
- 44.8.2 Latent Thermal Energy Storage
- 44.8.3 Operation of Thermal Energy Storage Systems
- 44.8.4 Cold Thermal Energy Storage

Learning Objectives

Information in this chapter will enable you to:

- Understand the nature of solar energy.
- Compare flat-plate collectors, evacuated tube collectors, and concentrating collectors.
- Characterize passive, active, and hybrid solar energy systems.
- Describe the operation of air-based and liquid-based solar heating systems.
- Recall applications for solar heating systems.
- Explain how solar heating can be combined with various supplemental heating sources.
- Summarize strategies for using solar power for comfort cooling applications.
- Describe how solar energy is converted to electricity.
- Explain the operating principles of sensible and latent thermal energy storage (TES) systems.

Review of Key Concepts

Reviewing these concepts from earlier chapters will help you understand new concepts presented in this chapter:

- Heat that brings about a change of state with no change in temperature is called latent heat. Heat that causes a change in the temperature of a substance is called sensible heat. (Chapter 4)
- Semiconductors are substances, such as silicon and germanium, that can be made to conduct electricity under certain conditions. This is done by adding impurities (doping), which causes an excess or shortage of electrons in the semiconductor material. (Chapter 14)
- N-type material has a surplus of electrons. P-type material has holes, or positively charged spaces, that are ready to receive electrons. (Chapter 14)
- A heat pump is a compression refrigeration system that pumps refrigerant through a system in either direction to move heat back and forth between a conditioned space and an unconditioned space, depending on its mode of operation. This allows heat to be absorbed or rejected in either of its two primary heat exchangers. (Chapter 40)

Introduction

Most of the earth's energy sources can be traced back to the sun. The sun radiates energy to space as a result of nuclear fusion. The energy radiating from the sun heats the earth. Energy from the sun heats the atmosphere, creating winds. These winds can be converted to mechanical or electrical energy by wind machines.

Hydroelectric energy generated by water turbines at sites such as Niagara Falls and Hoover Dam is also indirectly related to the sun. Solar energy evaporates surface water, which eventually condenses in the atmosphere, and the resulting rain fills reservoirs. Falling water in pipes from the reservoir water is then used to drive the water turbines in hydroelectric power plants.

Even heat energy produced by burning wood in stoves and fireplaces is derived from solar energy. Solar energy was absorbed by the tree as it grew. Photochemical processes changed the solar energy to fuels. Fossil fuels (coal, oil, and natural gas) are formed by similar processes. The stored energy in the fuel is released as heat and light as the fuel is burned.

All of the above are examples of indirect uses of solar energy. This chapter describes methods of converting solar energy directly to useful heat and electrical energy that can be used for heating or as the power source for cooling systems.

44.1 The Nature of Solar Energy

Solar energy (solar radiation) is electromagnetic energy. The energy in a beam of radiation can be described as a stream of particles called *photons*. Although it is helpful in some cases to think of solar radiation as a stream of particles, it is also helpful to realize that the beam has wave characteristics. An electromagnetic wave, as shown in **Figure 44-1**, has a wavelength and amplitude. The wavelength is the distance between two peaks. The amplitude is the height of the wave. The energy of a wave at any given amplitude depends upon the wavelength. The shorter the wavelength, the greater the energy of the wave.

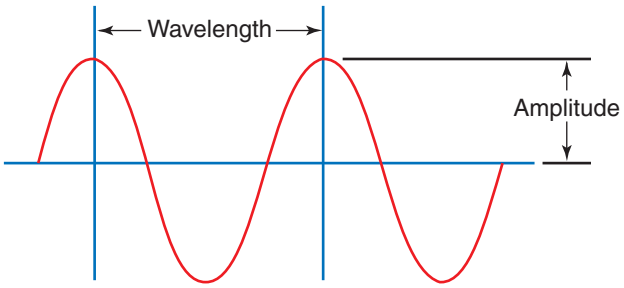
Light radiation with wavelengths that are greater than 740 nanometers (nm) is called *infrared radiation*. Radiation with wavelengths less than 380 nm is called *ultraviolet radiation*. Light radiation with wavelengths between 380 nm and 740 nm is called *visible light*. Visible light is only a small fraction of the radiant energy present. Our eyes are sensitive to about 25% of the energy in solar radiation.

Pro Tip

Measuring Wavelength

Wavelengths of light may be measured in units of meters (m), millimeters (mm), micrometers (μm) or microns, nanometers (nm), or angstroms (A). A millimeter equals 10^{-3} m. A micrometer equals 10^{-6} m. Micron is another name for micrometer, and is also equal to 10^{-6} m. A nanometer equals 10^{-9} m (one-billionth of a meter). An angstrom equals 10^{-10} m.

Solar energy flux (flow) at different wavelengths as received by the earth is shown in **Figure 44-2**. The area under the curve represents the total energy flow. Outside the atmosphere, energy flow is approximately 1.35 kW/m^2. This is known as the *solar constant*. The atmosphere absorbs and reflects much of the solar energy due to the presence of water vapor and other gases, particularly carbon dioxide and oxygen.



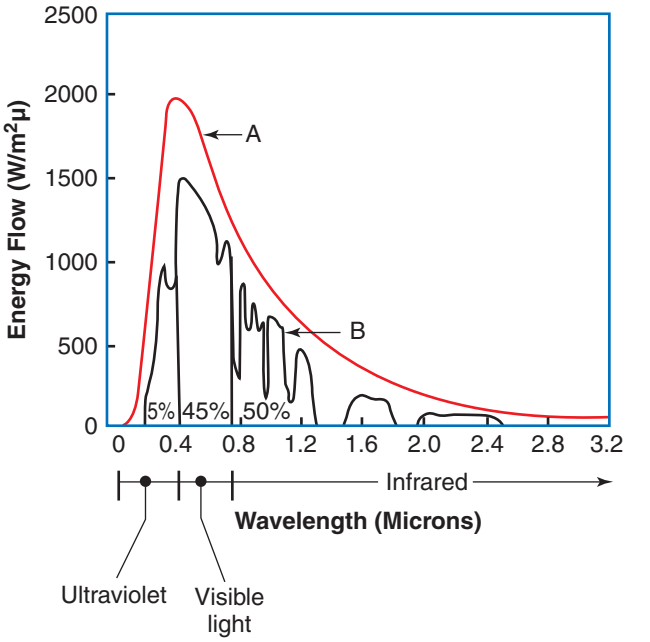
Goodheart-Willcox Publisher

Figure 44-1. Electromagnetic radiation is described as a wave with wavelength and amplitude as shown.

About 45% of the solar radiation that reaches the earth's surface is visible light. From outside the atmosphere to the earth's surface, most ultraviolet radiation is absorbed by ozone. Infrared radiation is absorbed by both water vapor and carbon dioxide.

The radiation given off by a hot object changes with its temperature. At a low temperature, an object such as a stove appears black. This indicates that most of the radiation given off is infrared radiation, outside the visible range. As the object is heated, it gives off more and more radiation in the visible range. It may first appear as a red glow. With further heating, color changes from red to yellow or white. As the object gets hotter, the wavelength at which the most radiation is given off becomes shorter and shorter.

Figure 44-3 shows how radiation given off by an object varies with temperature. At 10,000°F (5500°C), the temperature of the sun, much of the radiation is in the visible wavelength range. The peak of the solar radiation curve occurs at the wavelengths of yellow light. Thus, the sun appears to be yellow. An object at 260°F (130°C) gives off much less radiation, and most of this radiation is in the infrared range. This shift in the distribution of radiation with temperature is critical to solar collector design.



Goodheart-Willcox Publisher

Figure 44-2. Solar radiation at different wavelengths of light. Curve A illustrates the solar radiation outside the atmosphere. Curve B illustrates an approximate radiation flow at the earth's surface, indicating the atmospheric absorption of light. Approximate percentage of energy in the ultraviolet, visible, and infrared radiation regions is also shown.

Figure 44-3. Comparison of the energy of radiant rays from the sun with the heat energy of a heated object.

44.2 Solar Collectors

Solar collectors, which absorb heat from the sun's energy, form the basis of all solar energy systems. Most solar collectors in use today are flat-plate collectors. Other commonly used types of solar collectors include evacuated tube collectors and concentrating collectors.

44.2.1 Flat-Plate Collectors

A ***flat-plate collector*** uses a series of flat-plates with an insulated surface to collect solar energy. Rays from the sun are converted to heat upon striking a dark surface. This applies to visible rays, infrared rays, and ultraviolet rays. Heat from this solar radiation can be absorbed, and this is the principle behind flat-plate collectors.

Black Surfaces

The simplest flat-plate collectors use an insulated black surface as the ***absorber***. A surface looks black because it absorbs visible light. Black surfaces absorb infrared and ultraviolet radiation as well. Because black surfaces absorb more radiation from the sun than white or shiny surfaces, they also get much hotter. A black object insulated on the back and placed in the sun absorbs radiant energy and gets very hot. The temperature increases until the radiation from the object equals radiation received from the sun.

The maximum surface temperature that a black object can reach solely due to exposure to sunlight is about 253°F (123°C). At that temperature, heat is radiated away from the object at the same rate that the object is heated by the sun. However, the temperature can be increased by trapping the radiation emitted by the surface. To accomplish this, a glass cover is placed over the black surface. A sketch of a solar collector using this trapping principle is shown in **Figure 44-4**. Collector covers are described later in this chapter.

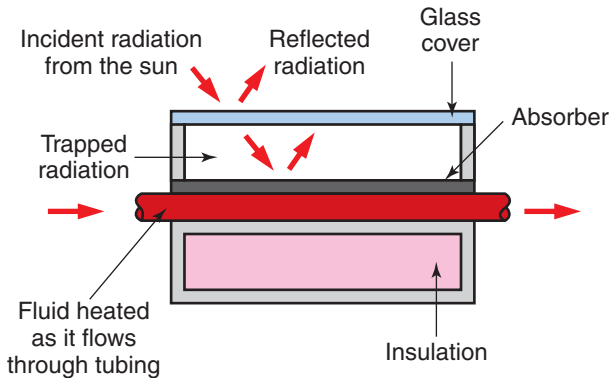
Selective Surfaces

Special absorber surfaces are sometimes used to increase the temperature of a collector. Such a design is often called a ***selective surface*** or selective absorber. This design acts much like the combined glass plate and absorber surface. It absorbs most of the radiation from the sun that has a wavelength less than a "cutoff wavelength" (around 2 microns). However, it does not absorb longer wavelength radiation.

A surface that absorbs poorly at a given wavelength also emits (gives off) radiation poorly at that wavelength. Because a selective absorber surface emits infrared radiation very poorly, its temperature increases as it is exposed to sunlight.

Many special paints and surfaces are being developed with this characteristic. They selectively absorb most of the sunlight but not infrared rays. Their performance is rated according to their absorption-to-emission ratio. This ratio is the absorptivity of sunlight with wavelength shorter than the cutoff wavelength divided by the absorptivity for longer wavelength radiation. Commercial surface materials are available with an absorption-to-emission ratio of about 20 to 1.

Selective surfaces do not absorb as much energy as black surfaces at wavelengths shorter than the cutoff wavelength. These surfaces may appear gray. However, they do not allow energy at long wavelengths to escape. Most new solar collectors use selective absorber surfaces rather than black surfaces.



Goodheart-Willcox Publisher

Figure 44-4. The glass cover and the insulation on the back of the collector allow the collector to trap radiation. Most solar radiation passes through the glass because it has a wavelength smaller than two microns. However, most radiation from the absorber is trapped because it has a wavelength greater than two microns.

Copyright Goodheart-Willcox Co., Inc. 2017

Absorber Surface Roughness

The absorber surface should be slightly roughened. This should be somewhat rougher than an eggshell finish. A rough, gray surface is a better absorber than a black, shiny surface. Smooth, shiny surfaces are not used because they would not absorb the radiant energy; they would reflect it away.

The absorber surface is usually applied using an electrodeposition process. In ***electrodeposition***, metallic particles are applied to another metal surface (conduction plate) using an electric current. This process bonds the surface material to the metal conduction plate. Paints are generally not satisfactory for coating an absorber because paint peels and cracks at the high temperature of the collector.

Insulation

If it is not properly insulated, a collector surface will both absorb solar energy and release heat energy. The solar energy coming into the collector is changed to heat. The absorber surface then radiates heat the same as any other warmed surface. To prevent excessive loss of heat, the collector surface is insulated. As described later in the chapter, a collector cover consisting of one or more layers of glass over the front surface may be used to hold in energy as it is converted from solar radiation to heat. However, the back surface of the collector must also be insulated to prevent heat from escaping through the back. About 4" of conventional insulating material provides enough insulation on the back surface.

Urethane or polyisocyanurate insulation is often used in solar collectors. It has a higher insulation (R) value per inch of thickness than any other practical insulation material and is very easy to handle. However, it must be used in solar collectors with caution. A solar collector may experience stagnation temperatures. This can cause the insulation to outgas, rapidly destroying the effectiveness of the collector. Urethane and similar products may be prohibited from use in collectors in fire hazard areas due to their toxic fume production. When such materials are used in solar collectors, they should be used underneath a blanket of other insulation material, such as binder-free fiberglass, to reduce the hazard of exposure to high temperatures. The addition of fiberglass results in a greater collector thickness than would be needed for urethane insulation alone.

Tubing and Piping

The tubes in a solar collector contain the fluid that collects the heat from the absorber. These tubes are usually made of copper, although aluminum is sometimes used. They are placed directly on top of the absorber, below the collector cover. Another variation is the use of "tube-in-strip" metal instead of tubes. In these systems, the tubes are manufactured into thin strips of copper or aluminum. The strips are placed over the absorber and help absorb and trap heat, while holding the tubes in place within the collector. Larger pipes collect the warmed fluid from the tubing and transport it to other parts of the solar heating system.

Code Alert

Building Penetrations

Section 1402.6 of the International Mechanical Code (IMC) requires roof and wall penetrations used by solar systems to be flashed and sealed to prevent entry of water, rodents, and insects. Section M2301.2.7 of the International Residential Code (IRC) requires these penetrations to be flashed and sealed in accordance with Chapter 9 (Roof Assemblies) of the IRC.

Flat-Plate Collector Covers

A transparent cover is used on most flat-plate collectors. This cover has three basic functions:

- To protect the absorber surface from the weather.
- To allow sunlight to reach the absorber surface.
- To prevent the escape of heat collected by the absorber surface.

Low-iron tempered glass is the most widely used cover material. It provides good light transmission and remains clear indefinitely. It also provides greater transmission of heat than float glass. Typical glass covers are 1/8" to 1/4" thick.

The glass allows light with wavelengths less than about 2 microns to pass through. That light is then absorbed by the black surface. At temperatures below 253°F (123°C), the black surface emits most of its energy at wavelengths greater than 2 microns. This radiation is trapped inside the collector. Temperatures of 620°F (327°C) are obtainable in collectors of this type if both mirrors and glass are used.

Glass poses problems in sealing the cover to the other parts of the collector. Glass and metal do not expand at the same rate with temperature change. A flexible sealing material or rubber gasket is necessary at the glass-to-metal joint. This prevents the glass from breaking as the materials expand and contract.

Some covers are formed in a bubble shape rather than a flat shape. The bubble shape provides more structural support and allows the collector to collect more radiation when the sun is near the horizon.

Although some covers are made of clear plastics, plastic is generally considered an inferior cover material compared to glass. Plastic cover materials usually

Copyright Goodheart-Willcox Co., Inc. 2017

soften at high temperatures. Many plastics also become brittle and opaque from absorption of ultraviolet light.

44.2.2 Angle of the Collector

Ideally, a collector surface would be perpendicular to the rays of the sun. However, in most cases, adding a device to keep the collectors properly aimed is prohibitively expensive. Therefore, the position of the collector surface usually remains fixed. The angle of the sun's rays to the horizon varies during the year. It is necessary to set the collector angle to give the best average collecting effect. The sun angle in midwinter is 66.55° minus the site's latitude angle. The sun angle in midsummer is 113.45° minus the site's latitude angle.

For solar home heating, the collector should be positioned to absorb the greatest amount of energy during the heating season. Across the midsection of the United States, the collector should be angled upward about 45° to 55° from the horizontal.

For collectors used during all seasons to provide hot water, the collector angle should be 35° to 45° to the horizontal. For year-round heating, the angle from the horizontal should be the site's latitude angle or up to 10° less. The collector should face south. However, an angle of 30° east or west of south only reduces the energy collected by about 10%.

Naturally, it is important that there be no obstructions between the sun and the collector. Buildings or trees that cast a shadow across the collector surface reduce its effectiveness. The installation site should be thoroughly checked to ensure that it will be free from shadows at all times of the day and all times of the year.

44.2.3 Evacuated Tube Collectors

The most efficient type of solar collector is the ***evacuated tube collector***. This type of collector is similar to a flat-plate collector. However, in an evacuated tube collector, the tubes that contain the fluid are contained in a slightly larger glass tube. The glass tube is sealed and the air between the two tubes is evacuated, creating a vacuum. Heat cannot travel easily through a vacuum, so almost no heat is lost in this type of system. **Figure 44-5** shows a typical evacuated tube collector.

Evacuated tube collectors work well even in very cold temperatures. However, they are more expensive than flat-plate collectors. Also, they are capable of reaching extremely high temperatures. Precautions and safeguards must be present to prevent overheating and system failure.

Sun Spot Solar and Heating, Inc.

Figure 44-5. A typical array of evacuated tube collectors for a high-temperature application. An array of flat solar modules (panels) is mounted above the evacuated tube collectors.

Code Alert

Relief Valve Requirements

Section M2301.2.3 of the International Residential Code (IRC) and Section 1402.5.1 of the International Mechanical Code (IMC) cover requirements of relief valves in thermal solar energy systems. Components containing fluid must be protected with pressure and temperature-relief valves. These relief valves must be located in the system so that a section cannot be isolated from the relief valve.

44.2.4 Concentrating Collectors

A third type of solar collector is the ***concentrating collector***, which can achieve higher temperatures than flat-plate collectors. Although there are several types of concentrating collectors, most of them use one of two technologies. Mirror-type concentrators use reflection of the light off mirrors. The mirrors are either curved or are set at specific angles to reflect the heat into a collector. Lens-type concentrators use a transparent lens to cause refraction, or bending, of light to make the light converge at a common focal point.

Concentrating collectors tend to work well only if they include a system to track the sun throughout the

Copyright Goodheart-Willcox Co., Inc. 2017

day. Also, the mirror or lens must be kept very clean. Any collection of dust or dirt seriously impairs the system's efficiency. For these reasons, concentrating collectors are not as frequently used in the United States as flat-plate collectors.

Caution

Wind Resistance

Because of the large, flat nature of most solar collectors, uplift by wind is a valid safety concern. Before installing any solar energy system, research the wind risks for the proposed location. Determine and take the appropriate steps to install the system securely to exceed the maximum anticipated wind load for the area.

44.3 Solar Heating Systems

In all solar heating systems, solar energy is used to heat a fluid. The fluid absorbs the heat and then transfers it to a specified location. The two most commonly used fluids are air (air-based systems) and water (liquid-based systems). Both air and water are relatively inexpensive to use.

Solar energy systems can be passive or active. ***Passive solar energy systems*** depend on solar radiation striking directly on the area to be heated. A good example of passive solar heating is a greenhouse. The energy flows through the glass into the area where the plants are growing. Large window areas on the south wall of a building help to warm the building during winter. This can also be considered a passive solar heating system. Passive solar energy systems require less energy input than active systems because auxiliary pumps and blowers are not as often needed to circulate heat.

In ***active solar energy systems***, the solar energy is absorbed into a collector. The energy is then transferred from the collector and used or stored. Many new residential solar applications use both passive and active systems. A combination of active and passive solar energy systems is referred to as a ***hybrid solar energy system***. See **Figure 44-6**.

44.3.1 Passive Air-Based Solar Heating Systems

Passive air-based solar heating systems warm the air to heat rooms or buildings directly. The greenhouse mentioned earlier in this chapter is an air-based heating system. Another practical application of passive air-based solar heating is a solarium. The glass walls and roof of the solarium allow thermal energy from the sun to enter. The energy is absorbed by the walls, floors, and even well-chosen furniture that has a high ***thermal mass***. Items with a high thermal mass absorb and store heat more readily than those with a low thermal mass. Wall and floor coverings should be chosen with thermal mass in mind, because this can make a large difference in the efficiency of the system.

Concrete and masonry are examples of materials that have a high thermal mass. These materials are therefore often used in another type of passive air-based system known as Trombe walls. A Trombe wall is a south-facing, 8″ to 16″ thick concrete or masonry wall. The wall is finished with black or another dark color and is separated from the outdoors by a large pane of glass. An air space of 3/4″ to 2″ is left between the wall and the glass to allow the heated air to rise. The heated air then enters the building through an opening or vent at the top of the wall. Another opening at the bottom of the wall allows cool air to enter the space, where it is heated, **Figure 44-7**.

Code Alert

Solar Ducts

Ducts used in solar space heating systems must be constructed and installed in accordance with Chapter 6 (Duct Systems) of the IMC.

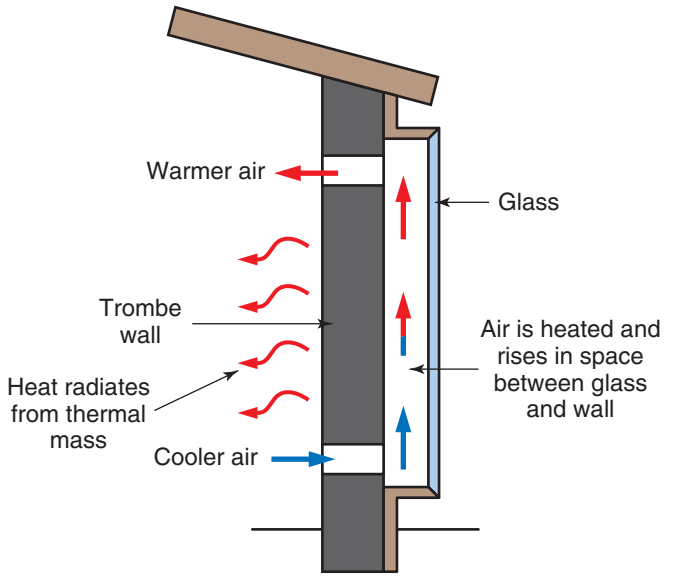
Most passive air-based heating systems are inefficient. They can be converted to more efficient active systems by adding blowers, controls, and storage methods to improve air distribution and effectiveness.

Although air-based systems are not as efficient as liquid-based systems, they do have some advantages.

Rob Bryan/Shutterstock.com

Figure 44-6. This home is equipped with a hybrid solar energy system. The large expanse of southward-facing windows provides passive solar heating. The roof overhang keeps the windows shaded during the summer months. A solar collector meets the hot water demands of the home, and a large solar array on the roof provides electricity to the home.

Copyright Goodheart-Willcox Co., Inc. 2017



Goodheart-Willcox Publisher

Figure 44-7. Two mechanisms provide heated air in a Trombe wall. The concrete or masonry wall, painted black or a dark color, absorbs heat during the day and releases it at night. In addition, the space between the wall and the glass traps the sun's heat energy. Because hot air rises, this heated air can be channeled back into the building to provide additional heat.

For example, leaks in the system do not pose any danger to the environment or building and will not cause the system to fail. Also, air-based systems are not affected by freezing temperatures. There is no danger of frozen pipes bursting.

Thinking Green

Solar Chimneys

Solar chimneys can be used to provide ventilation and passive heating and cooling. A solar chimney is essentially a chimney with a solar collector on its outer surface. When the sunlight strikes the chimney, it heats the air inside the chimney and causes it to rise. The airflow through the chimney draws in hot, stale air from inside the building, creating a low pressure inside the building. Replacement air is brought in from outside to replace the indoor air vented through the chimney. If the replacement air intake is located outside and connected to the house by a long underground duct, the earth will heat the replacement air in the winter and cool the replacement air in the summer in a manner similar to a ground-loop heat pump. Such an installation is commonly called an *earth tube*.

44.3.2 Passive Liquid-Based Solar Heating Systems

Most liquid-based solar heating systems (especially those in colder climates) use a mixture of water and glycol instead of pure water. The glycol reduces the freezing point of the water so that the water is not as likely to freeze in cold weather.

Code Alert

Freeze Protection

Section 1402.5.3 of the IMC requires that solar energy system components be protected from damage by freezing of heat transfer liquids at the lowest ambient temperatures possible during system operation. Section M2301.2.5 of the IRC echoes this and lists the approved methods of providing freeze protection.

Like air-based systems, liquid-based systems can be either passive or active. In passive systems, the sun heats the water, which then flows to a heat exchanger, where the heat in the water is transferred to the surrounding air. No pump is used in a passive system. Instead, the water flows due to temperature differences in the water itself. Like air and all other fluids, when water is heated, it becomes less dense. Water that is less dense rises above the denser cool water. This creates a natural circulation: Water rises as it heats and falls as it cools. This is known as the ***thermosiphon effect***.

Code Alert

Prohibited Heat Transfer Fluids

Section M2301.4 of the IRC and Section 1403.2 of the IMC prohibit flammable gases and liquids from being used as heat transfer fluids in thermal solar energy systems.

44.3.3 Active Liquid-Based Solar Heating Systems

In an active liquid-based solar heating system, a pump recirculates the liquid within the system. These active systems typically consist of the following components:

- One or more solar collectors.
- Piping to carry a water or antifreeze solution.
- One or more circulating pumps to move the liquid through the system.
- An insulated storage tank or heat exchanger.

Heat from the liquid may be used in one of two ways. It may give up its heat directly to the conditioned space through a radiator. Alternatively, the liquid may become a source of heat for a heat pump. The heat pump is then used to transfer the heat to the desired space.

To protect components some liquid-based heating systems use a ***drainback system***. This system uses

Copyright Goodheart-Willcox Co., Inc. 2017

gravity to drain liquid from the collectors whenever the pump is off. Drainback systems prevent freezing or overheating of the liquid in the collectors. The liquid collects in a storage tank or heat exchanger when the system is not operating.

Code Alert

Vacuum Relief

Section 1402.5.2 of the IMC and Section M2301.2.4 of the IRC require that any component of a solar energy system that may be subjected to a vacuum during operation or shutdown must be designed to withstand vacuum or be equipped with vacuum relief valves.

44.4 Applications for Solar Heating Systems

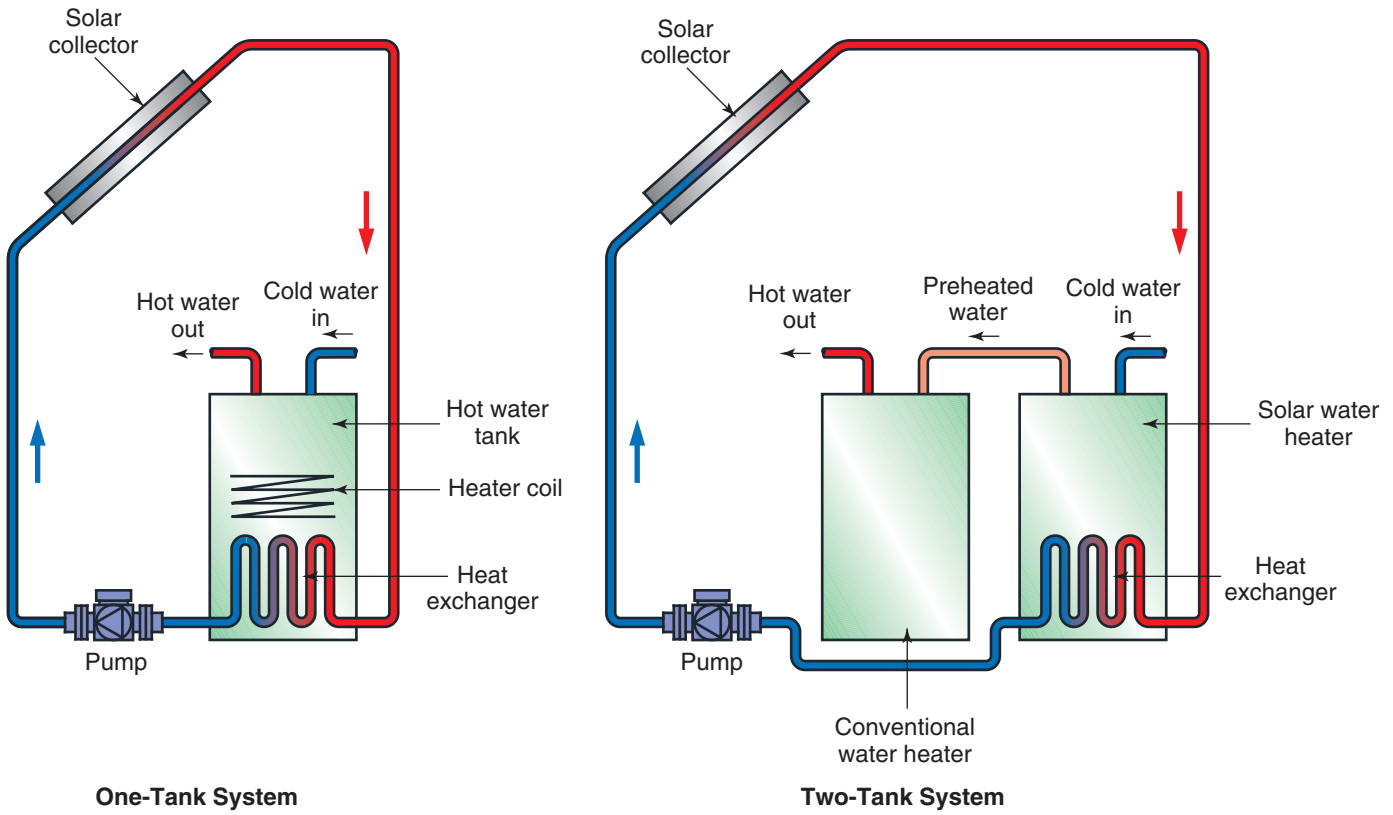
Solar space heating is less common and less cost-effective than solar water heating. This is partly because there is a demand for hot water in a home year-round. Space heating is typically used only during cold weather and only in regions with cooler climates. The two most common applications for solar heating systems are solar domestic hot water systems and heating systems for pools, hot tubs, and spas. These systems are discussed in the following sections.

44.4.1 Solar Domestic Hot Water (DHW) Systems

Perhaps the most common type of solar heating system is one that supplies hot water for domestic use. A ***solar domestic hot water (DHW) system*** harnesses solar energy to heat water for different tasks, such as dishwashing, showering, and laundry.

The temperature of water supplied from a well is fairly constant throughout the year, ranging from 40°F to 50°F (4°C to 10°C). Water supply from a large municipal water supply system is drawn either from a large reservoir or storage tanks. In some locations, the water temperature may range from 35°F (2°C) in the winter to 80°F (27°C) in the summer. The heat required to supply domestic hot water at 120°F to 140°F (49°C to 60°C) can vary considerably throughout the year, depending upon geographic location.

The two types of solar domestic hot water systems in common use are the one-tank system and the two-tank system. See **Figure 44-8**. The one-tank system consists of a single hot water tank. Liquid is heated in the



Goodheart-Willcox Publisher

Figure 44-8. One-tank and two-tank solar domestic water heating systems.

Copyright Goodheart-Willcox Co., Inc. 2017

solar collector and circulated through a heat exchanger in the bottom of the hot water tank. An auxiliary heater coil in the top of the tank provides additional heating. It brings the water to the desired temperature. In this system, the hot water tank replaces the conventional water heater.

A two-tank system uses both a solar water heater and a separate conventional water heater. The bottom of the solar water heater contains a heat exchanger. The heat exchanger preheats the water in the tank.

The solution flowing through the solar collector never comes into contact with the water in the tank of the solar water heater. Each fluid flows through completely separate and isolated circuits. This allows an antifreeze solution to be used in the solar collector without fear of contaminating the building's hot water supply. Nevertheless, a food grade glycol is generally used.

Code Alert

Solar Heat Exchangers

Section 1401.3 of the IMC covers heat exchanger requirements for use in solar space heating or water heating systems. Such equipment must be approved for use in these systems and must have adequate protection to safeguard the potability of the water supply and its system. Section 1401.2 requires the potable water supply to be protected against contamination in accordance with the International Plumbing Code (IPC).

After the water in the solar water heater has been preheated, it is circulated to the conventional water heater, where it is brought up to its final temperature. This type of system is easily added to an existing hot water system because the solar water heater is separate from the conventional water heater. A two-tank system is usually 30% to 50% more efficient than a single-tank system.

Solar DHW systems are designed to supply from 40% to 75% of the required hot water for a home. Auxiliary heating supplies the final heat to reach the temperature required, typically 120°F to 140°F (49°C to 60°C).

Pro Tip

Sizing Solar DHW Systems

Domestic hot water use is approximately 25 gallons per day for each person in a family. Solar collector sizes range from 1/2 ft^2 to 2 ft^2 per gallon of hot water required per day, depending on location. In a two-tank system, the solar water heater's storage tank is usually half as large as the storage tank of the conventional water heater.

44.4.2 Solar Heating for Pools, Hot Tubs, and Spas

Heating the water in swimming pools can be used to extend the swimming season in many areas. The solar heating system for a swimming pool can be as simple and inexpensive as a set of black plastic bags placed in the pool. The black bags absorb heat from the sun and transfer it directly to the pool.

In warm climates, solar pool heaters may be of very simple design because no storage is required and no freezing protection is necessary. Also, the collector does not need to withstand water pressure as high as that required for space or domestic water heating systems. These pool heaters require only a low-pressure pump, solar collectors, and piping. The pump circulates pool water from the pool to the solar collectors, where it is heated. The warmed pool water is then piped back to the pool.

In cold climates, a secondary loop and heat exchanger are required. The heating system uses an antifreeze solution. This antifreeze solution is circulated by a pump from the pool heat exchanger to the solar collector. The warmed solution then passes from the collector to the heat exchanger. The solution transfers its heat to the pool water running through the heat exchanger and back to the pool.

The size of a solar collector for a pool heater is approximately half of the pool surface area. This provides good spring and fall heating. The required water temperature for pools is only about 80°F (27°C). Due to this relatively low temperature, the efficiency of solar pool heaters can be as great as 70% to 80%.

Solar heating systems may also be used to heat the water in hot tubs and spas. Some newer systems also include a filter and an inline sterilizer that exposes the water to an intense ultraviolet light source. These items can be helpful in keeping harmful bacteria and mildew out of the warm, damp environment of the hot tub or spa.

Thinking Green

Pool Covers

Covering a pool or hot tub when it is not in use can reduce heat loss, which in turn reduces the amount of energy needed to maintain the proper pool temperature.

44.5 Supplementary Heat

In any location, there may be times when the sun does not supply enough heat energy to the collector. In such cases, supplementary heat must be supplied. Electric resistance heating, a gas or oil burner, or a heat

Copyright Goodheart-Willcox Co., Inc. 2017

pump may be used. As described earlier in this chapter, in two-tank DHW systems, the water is preheated by solar energy. It is then heated by a supplementary heater up to the desired temperature.

44.5.1 Electric Heating

Electric resistance heating is one form of heating used to supplement solar heat. With an air-based heating system, a direct electric resistance radiator may be installed in the air duct. A thermostat is used to control the amount of electric heat needed.

In a liquid-based space heating system, an electric heating element can be installed in an auxiliary tank. It provides supplementary heating when the heat stored in the main tank is exhausted.

In some cases, individual room resistance heating radiators may be installed. However, these tend to be expensive if they are used for more than a few hours.

44.5.2 Oil and Gas Heating

If oil or gas is used for supplementary heat, a separate furnace is installed. A thermostat turns on the burner in the furnace when heat from the solar source is not enough to heat the conditioned space to the desired temperature. In liquid-based systems that use radiators, burners may be used to heat the water in an auxiliary tank. A solar heating system with gas or oil supplementary heat is shown in **Figure 44-9**.

44.5.3 Heat Pumps

In many areas, a heat pump is one of the most efficient methods of supplementing solar heat. The heat pump is well-suited for use with solar heat. A heat pump can also function as an air-conditioning system to remove heat. A heat pump transfers heat like an air conditioner (by compressing and expanding a refrigerant in different parts of the system). It can either add heat to a space or absorb heat from a space. See Chapter 40, *Heat Pumps*, for more information on different heat pump systems.

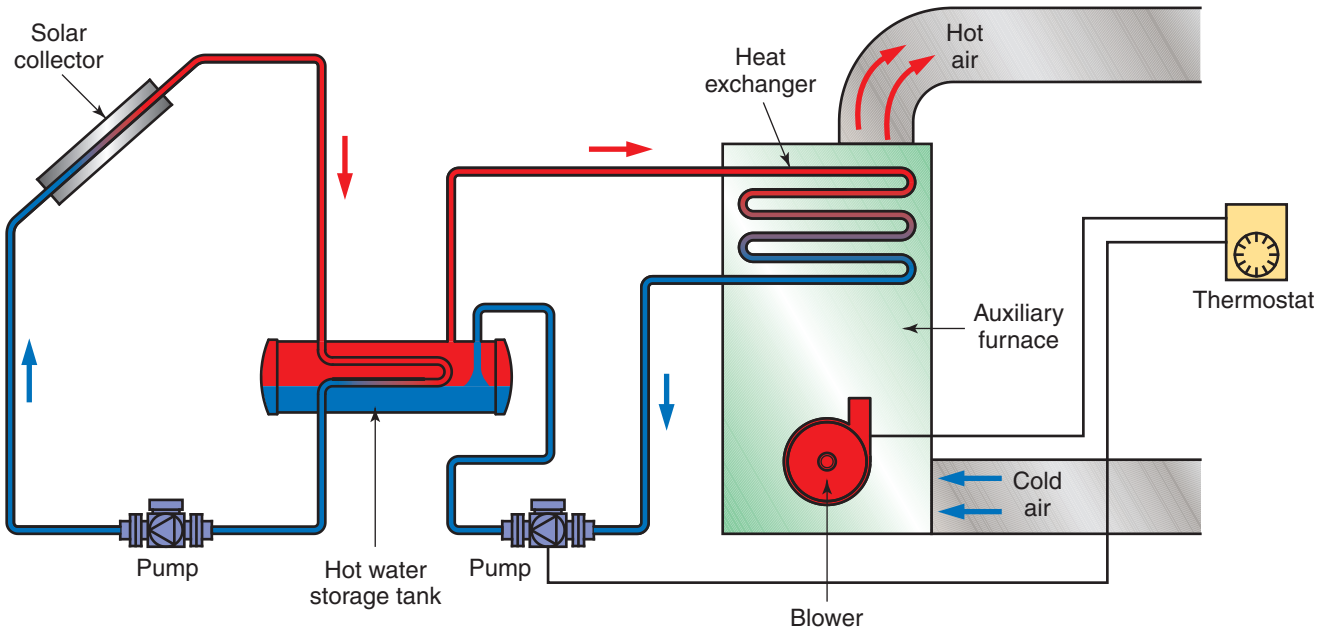
Thinking Green

Solar and Supplemental Heat Pump Systems

In mild climates with a large solar load, a heat pump with a solar energy collector may be the most efficient way to heat a building.

44.6 Converting Solar Energy to Electricity

Solar energy can be converted directly from radiant energy to electricity. The device most commonly used for this conversion is the ***solar cell*** (also called a ***photovoltaic (PV) cell***). Solar cells are often wired together with other solar cells and then enclosed, forming a ***solar module*** or *solar panel*. The solar modules are then constructed into a ***solar array***. The array can be



Goodheart-Willcox Publisher

used to power a dc electrical device or to charge a bank of batteries. If the output of the solar array is passed through an inverter (dc to ac converter), it can then be used to power an ac electrical device.

Code Alert

PV System Definitions

Section 690.2 of the National Electrical Code (NEC) covers commonly used terms and definitions used in solar photovoltaic (PV) systems. Before installing or servicing an HVACR system that incorporates a PV subsystem, become familiar with terminology and their uses in the industry.

Solar modules make good energy sources for remote locations because they are relatively maintenance-free. Small solar electric systems often provide power for remote weather stations, communication stations, and electrochemical corrosion protection systems for bridges and pipelines.

The cost of solar cells and the cost of solar electric system components have decreased due to increased worldwide manufacturing and improved technology. Solar electric systems are now being used to supply power to large commercial buildings or to provide all the power requirements of an energy-efficient home.

Code Alert

Solar Energy Occupational Hazards

Job hazards for installers of solar arrays include electric arc flash burns, thermal burns, falls, and electric shock. OSHA categorizes solar energy installers as electrical power generation, transmission, and distribution workers. Worker safety and training requirements are covered in OSHA's *Electrical Power Generation, Transmission, and Distribution Standard*, 29 CFR 1910.269.

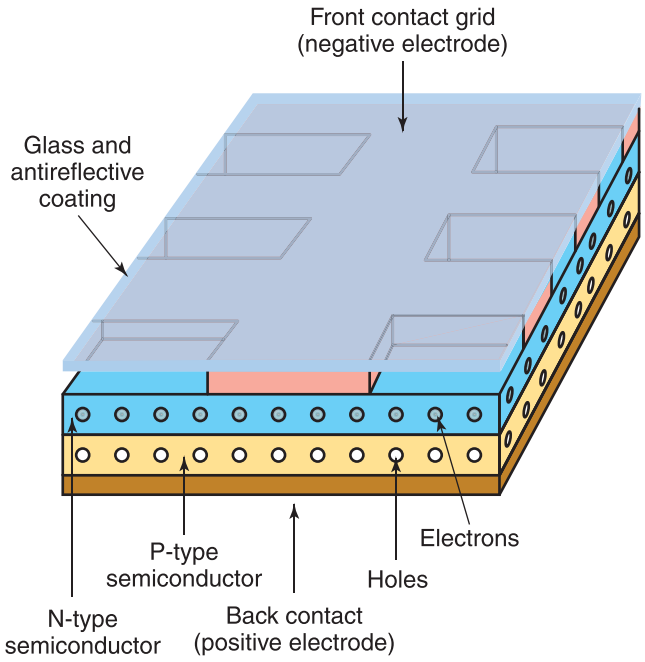
44.6.1 Solar Cell Construction

The components of a typical solar cell are shown in **Figure 44-10**. The principal elements required are N-type semiconductors and P-type semiconductors. An N-type semiconductor has an excess of electrons, or negative charges. When it is struck by photons (light), it releases some of those electrons. A P-type semiconductor has positive charges, sometimes referred to as holes. The term *hole* refers to the space remaining after an electron has been removed from an atom. The holes attract the free electrons released from the N-type semiconductor.

The P-type and N-type semiconductors in most solar cells are mainly silicon. However, pure silicon is not a good conductor of electricity, so impurities are added in a process called doping. The silicon of the N-type semiconductor contains a very small quantity of a material that, compared to silicon, has an *excess* of electrons. Commonly used doping materials, or dopants, include nitrogen, phosphorous, and arsenic. The silicon of the P-type material has a small quantity of material that, compared to silicon, has a *deficit* of electrons. Such materials include aluminum, boron, gallium, and indium.

The contact on the back is also a reflector. Therefore, any light that goes through the cell is passed back through again. In this way, more light can be absorbed. The P-type material must also be translucent. This allows the light to reach the junction between the P-type and N-type materials.

Two primary types of solar cells are manufactured today: crystalline and thin film. ***Crystalline solar cells*** are made from a thin slice of silicon known as a wafer. Typically the slices are 250 microns thick. The manufacturing process begins with a thin slice or wafer of silicon. A small amount of boron dopant is added to the molten silicon during the crystallization process. This makes the material a P-type semiconductor. A small amount of phosphorous is then diffused into the front surface of the wafer, forming a shallow N-type layer in the silicon. The combination of these two surfaces transforms the silicon wafer into a solar cell. Metallic contacts are then deposited on the front



Goodheart-Willcox Publisher

Figure 44-10. Physical components of a solar cell. Note that the diagram is not to scale. The cells are very thin compared to their length and width.

Copyright Goodheart-Willcox Co., Inc. 2017

and back of the cell to allow for external connections. These contacts also improve the flow of current out of the cell. An antireflective coating is also applied to improve the absorption of light by the cell.

Thin film solar cells are constructed by depositing layers of photovoltaic material on a ceramic, stainless steel, or glass substratum. Thin film solar cells are less efficient than crystalline cells, but they cost less to manufacture.

Solar cells may be round, square, or square with beveled corners. Most solar cells measure from 4" to 6" along an edge. See **Figure 44-11**. In most systems, they can be connected together in series and parallel to provide the desired voltage and current output. In a solar module, an assembly of interconnected cells is enclosed in weatherproof plastic and sandwiched between a sheet of tempered glass and plastic or steel. This assembly is typically framed with anodized aluminum. Multiple modules can then be connected together to form an array. A weatherproof junction box allows for external circuit connections to the array, **Figure 44-12**.

Solar modules are capable of withstanding severe weather conditions. Most solar modules have a 20-year warranty. However, estimates of actual design life exceed 30 years.

Electrically, solar cells operate similarly to batteries. Crystalline solar cells provide approximately 0.5 volt per cell. Thin film solar cells typically range from 0.5 volt to 1.5 volts per cell. For a specific solar cell material, the *voltage* remains constant under normal operating conditions. However, the *current* produced increases as the sunlight intensity increases. Therefore, the power output increases with increased sun intensity, **Figure 44-13**.

Solar cells can be connected in series, similar to batteries, to obtain higher voltages. The total voltage produced is the sum of the voltages produced by each cell connected in series. The electrical circuit may be as simple as the one shown in **Figure 44-14**. In this drawing, a solar cell is directly connected to a dc motor. The motor output varies with the intensity of the sunlight

striking the solar cell. At night, the motor would not run at all.

44.6.2 Solar Cell Applications

Solar energy systems are used in a wide variety of applications, ranging from small arrays for lighting or sensor systems to large arrays that provide the power needed for homes or large commercial buildings.

Solar arrays are produced in a wide variety of shapes and sizes for various uses. A portable 12-volt array is shown in **Figure 44-15**. This type of array is designed for battery charging or providing power at sites that are not connected to the electrical grid, such as sheds, campgrounds, and construction sites.

Portable Power Sources

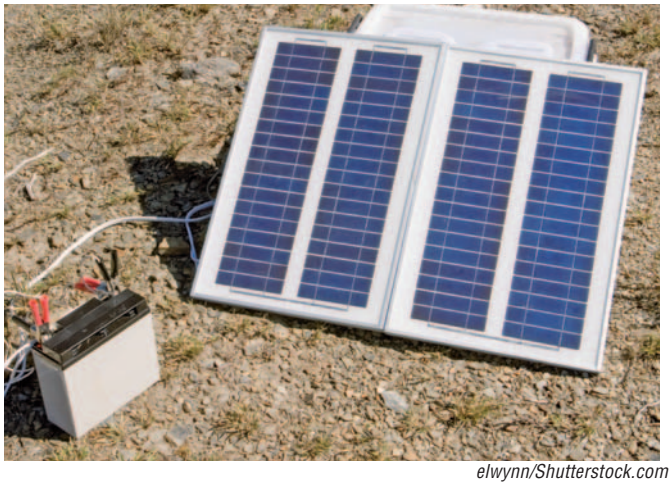
In many solar energy systems, a storage battery is installed in the circuit. In bright sunlight, the solar array delivers power directly to the load. Any excess power generated is used to recharge the battery. When there is little or no sunlight, power is drawn from the battery alone. This type of system is often used for roadside signs in remote areas. See **Figure 44-16**.

Solar arrays are used as the primary energy source for many satellites. The use of solar arrays gives the satellite a longer useful life than could be attained with onboard batteries alone. Solar cells are also used in hand calculators, allowing them to operate from interior room lighting or sunlight.

Recently, solar chargers have become available for smartphones, laptops, and other portable electronics. These chargers may be standalone products or may be incorporated into backpacks or attached to bicycles.

Net Metering

The Public Utility Regulatory Policies Act requires public utilities to allow homes with solar energy systems to connect to the public utility grid.



elwynn/Shutterstock.com

Figure 44-15. A portable solar array can be used to charge batteries, provide power to campsites, or power tools in areas where electrical service is unavailable.

Figure 44-16. A solar array constantly recharges battery packs on this portable road sign. This allows the sign to operate for extended periods of time without being connected to the power grid.

12

Copyright Goodheart-Willcox Co., Inc. 2017

In many states, homeowners can sell excess energy they generate back to the utility company. This is known as ***net metering***. These systems do not include storage batteries. Instead, the solar array is connected directly to an inverter to produce alternating current. The inverter is connected to the electrical service panel in a residence or commercial building. In sunny conditions, the solar array helps produce power to help meet the building's demand. If the array produces less power than is needed, the extra power is provided by the grid. If the array produces more power than is needed, the excess power is transmitted through the grid and sold back to the utility company.

This type of solar energy system does not provide power at night, so the building depends entirely on the power grid after the sun goes down. If the utility grid goes down, the solar array is automatically cut off from the grid, so any power produced cannot be sold back to the utility company. Despite these limitations, net metering systems are popular because they are relatively easy to install, efficient, and do not require maintenance. They also do not require the purchase of expensive storage batteries.

Building-Integrated Systems

Building-integrated solar modules appear similar to traditional building materials. In these systems, the solar modules are used as parts of the building materials, not added as a separate feature. Building-integrated solar modules can be planned into new construction or can be used to replace traditional materials in older buildings. Building-integrated systems are now being used in both large commercial buildings and residential applications, **Figure 44-17**.

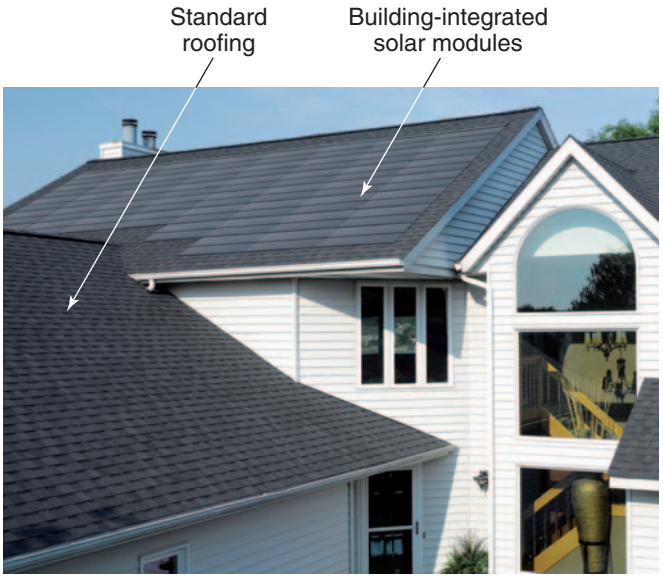
Code Alert

Roof Collector Requirements

Section M2301.2.2 of the IRC covers requirements for roof-mounted collectors used in thermal solar energy systems. A few requirements include the following: (1) The roof must be constructed to support the load of the collectors. (2) Collectors serving as roof covering (such as building-integrated solar modules) must conform to requirements found in Chapter 9 (Roof Assemblies) of the IRC. (3) Collectors and their supporting structure must be made of noncombustible material or fire-retardant-treated wood equivalent to the type used for roof construction.

44.7 Solar Energy Cooling Systems

Solar energy is primarily used for heating. The systems required to adapt solar energy for cooling can be quite expensive. There are two general ways of incorporating solar energy into a comfort cooling system. The first method is to install solar heat collectors to work in conjunction with an absorption cooling system. The second method is to use solar photovoltaic cells to supplement or entirely power a mechanical air-conditioning system.



CertainTeed Corporation

Figure 44-17. Solar shingles installed on a residential roof. Each solar module is approximately 47″ by 18″ and produces 54 watts. Each module contains 14 solar cells.

44.7.1 Solar Absorption Air-Conditioning Systems

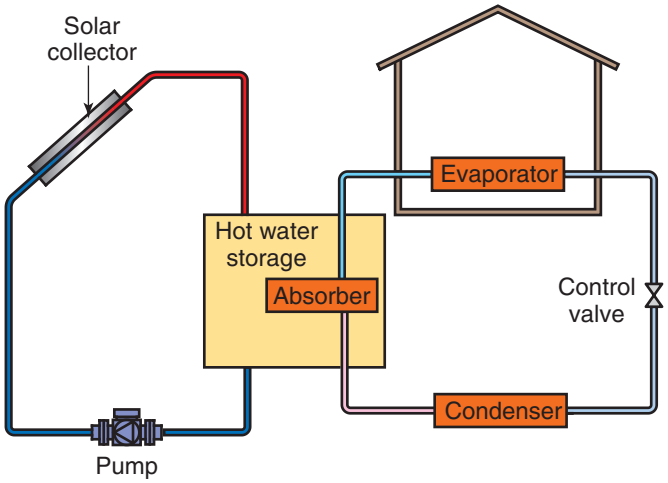
Absorption systems require a heat source. The heat is used to drive the refrigerant out of a solution. See Chapter 34, *Absorption and Evaporative Cooling Systems* for more information about absorption systems. The sun can supply the heat required to operate an absorption system.

Because the sun that heats the building also powers the cooling system, solar cooling systems have the highest energy input when the cooling demands are greatest. As a result, energy storage requirements are minimized and the energy is available when needed most.

The collectors on a solar cooling system are usually concentrating collectors. The mirrors or lenses in these collectors are used to heat the absorber to the proper temperature. The system is shown in **Figure 44-18**.

Experiments are also being made with dynamic solar cooling systems. In these systems, the solar energy is converted to electrical or mechanical energy. This energy is then used to drive a compressor.

Copyright Goodheart-Willcox Co., Inc. 2017



Goodheart-Willcox Publisher

Figure 44-18. Solar energy air conditioning that uses an absorption refrigeration system. Solar energy supplies the heat needed to operate the absorption system.

Concentrating collectors are needed for efficient operation of these systems as well.

44.7.2 Solar Mechanical Air-Conditioning Systems

Mechanical air-conditioning systems generally require a significant amount of electrical power to operate. A system's compressor often runs on 230 Vac or more and draws one of the highest electrical currents in a building. This is confirmed by Watt's law: current × voltage = electrical power. Manufacturers attuned to calls for energy efficiency are incorporating solar photovoltaic (PV) arrays into building electrical systems, **Figure 44-19**.

How a solar PV system is incorporated into the rest of a building's electrical system varies. Some systems are standalone with a bank of batteries and inverters for an off-the-grid system. Other systems connect into the grid and include an inverter but no batteries. Always refer to manufacturer literature to ensure that safe and proper procedures are followed. Refer to local authorities having jurisdiction for building code requirements.

Solar PV arrays may be used as a supplementary source of electrical power or as the sole source of electrical power for air-conditioning systems. Solar-power mechanical air-conditioning systems often require the use of special controls, components, and designs. Solar PV a/c systems for residential and commercial applications are available, **Figure 44-20**.

Code Alert

PV Systems

Section IV of Article 690 of the NEC covers the wiring methods used in solar photovoltaic (PV) systems. Section VIII covers the installation, charge controls, wiring connections, overcurrent protection, and other information regarding storage batteries used in solar photovoltaic (PV) systems. Section VI covers required markings and identifications of equipment and terminals in solar photovoltaic (PV) systems. In PV systems, wiring and devices may be alternating current, direct current, low voltage, or high voltage. Proper marking and identification makes installation and service safer and more organized.

44.8 Thermal Energy Storage (TES) Systems

Thermal energy storage (TES) refers to the temporary storage of heat energy for later use. TES systems store a medium, such as water, that has been heated or cooled during electrical off-peak hours. The medium is then used for heating or cooling during periods of peak demand. By heating or cooling the medium when electrical demand is low and then using the medium to provide heating or cooling when electrical demand is high, TES systems save the consumer money and reduce the demand on the electrical grid. Because TES systems store any excess energy produced for use at a later time, they also reduce fuel consumption and pollution.

Subcategories of TES systems have been developed for different applications, including heating and cooling systems, industrial applications, and as supplements for power generation systems. TES systems can be categorized as sensible TES or latent TES, depending on whether they rely on sensible heat or latent heat as the storage mechanism.

44.8.1 Sensible Thermal Energy Storage

Sensible TES stores energy by changing the temperature of the storage medium. The amount of energy stored in a sensible TES system depends on the initial and final temperature, mass, and specific heat of the storage medium. Sensible TES systems may use water, oil, air, bricks, clay, sand, or soil as the storage medium.

Code Alert

Air Filtration

Section 1402.7 of the IMC provides filtration requirements for forced air coming from a heat storage system that has traveled through rock or dust-producing materials.

Since the specific heat of water is nearly double that of soil, it is capable of storing twice the energy that could be stored in soil at the same temperature. Because of its higher energy storage density, water is typically used for building heating and cooling applications.

Sensible TES systems require a storage medium, an insulated container, and one or more heat exchangers. The medium for TES should be inexpensive and have a relatively high specific heat to maximize its ability to store heat. The storage container holds the medium and must be insulated to prevent the loss of thermal energy. The heat exchanger allows heat to be put into the system from a heat source, such as a solar collector. It also allows heat to be transferred out of the system to the conditioned space as needed.

In a sensible TES system, the storage medium does not change its form (physical phase) during the course of the heat storage/withdrawal cycle. The process simply raises and lowers the temperature of the storage medium. It only deals with sensible heat, no latent heat.

Copyright Goodheart-Willcox Co., Inc. 2017

A domestic solar water heater is an example of a basic sensible TES application. The water is heated during the day while the sun is shining, and then the heat is stored in a tank until needed. A more complex example is a large commercial TES system that stores hot water while the sun is shining, then uses the water to provide space heating in the winter and indirectly for cooling during the summer, **Figure 44-21**.

44.8.2 Latent Thermal Energy Storage

Latent heat is the heat that is either absorbed or released when a substance changes from one phase (solid, liquid, or gas) to another. An example of latent heat is the heat added to liquid water at 212°F (100°C) to turn it into steam at 212°F (100°C). During the phase change, the temperature of the substance does not change. However, the substance is capable of absorbing or releasing large amounts of heat energy during the phase change.

Latent TES systems consist of a storage medium, a storage container, and one or more heat exchangers. The storage medium used in a latent TES system must be able to change phase states from solid to liquid or from liquid to solid within the range of operating temperatures and pressures. Such media are known as ***phase change materials (PCMs)***. Both organic and inorganic materials are suitable for latent TES systems. Of the organic options, paraffin waxes are the most commonly used media. Paraffin is popular because it remains stable, even after numerous storage and withdrawal cycles. It is also chemically inert, nontoxic, and available at low cost. Inorganic options include various salt solutions and metals.

Latent TES systems have a higher storage density (are capable of storing more energy in the same volume) than sensible TES systems. They also release heat at a constant temperature, something that is not possible with sensible TES systems.

Caleffi North America, Inc.

Figure 44-21. Solar collectors for a commercial hot water system.

44.8.3 Operation of Thermal Energy Storage Systems

The basic principles of operation are the same for both sensible and latent TES systems. Heat from a source, such as a solar collector, is transferred to the storage medium through a heat exchanger. This causes the medium to change temperature. In a sensible TES system, the temperature increase of the medium is the sole means of energy storage. In a latent system, the temperature increase ends when the medium reaches its melting point. Any additional heat helps to melt the storage medium, but it will not increase the storage medium's temperature until all of it has melted.

When needed, the heat in the storage medium is extracted through a heat exchanger. In a sensible TES system, this causes an immediate drop in the temperature of the storage medium. In a latent TES system, the storage medium begins to solidify as heat is extracted, but the temperature of the medium remains the same. The temperature of the medium in a latent TES will drop only after all of the latent heat stored has been extracted.

The size and type of TES installed depends on the application. TES systems can be designed to store heat for moment-to-moment demand, daily demand cycles, or even seasonal demand cycles.

44.8.4 Cold Thermal Energy Storage

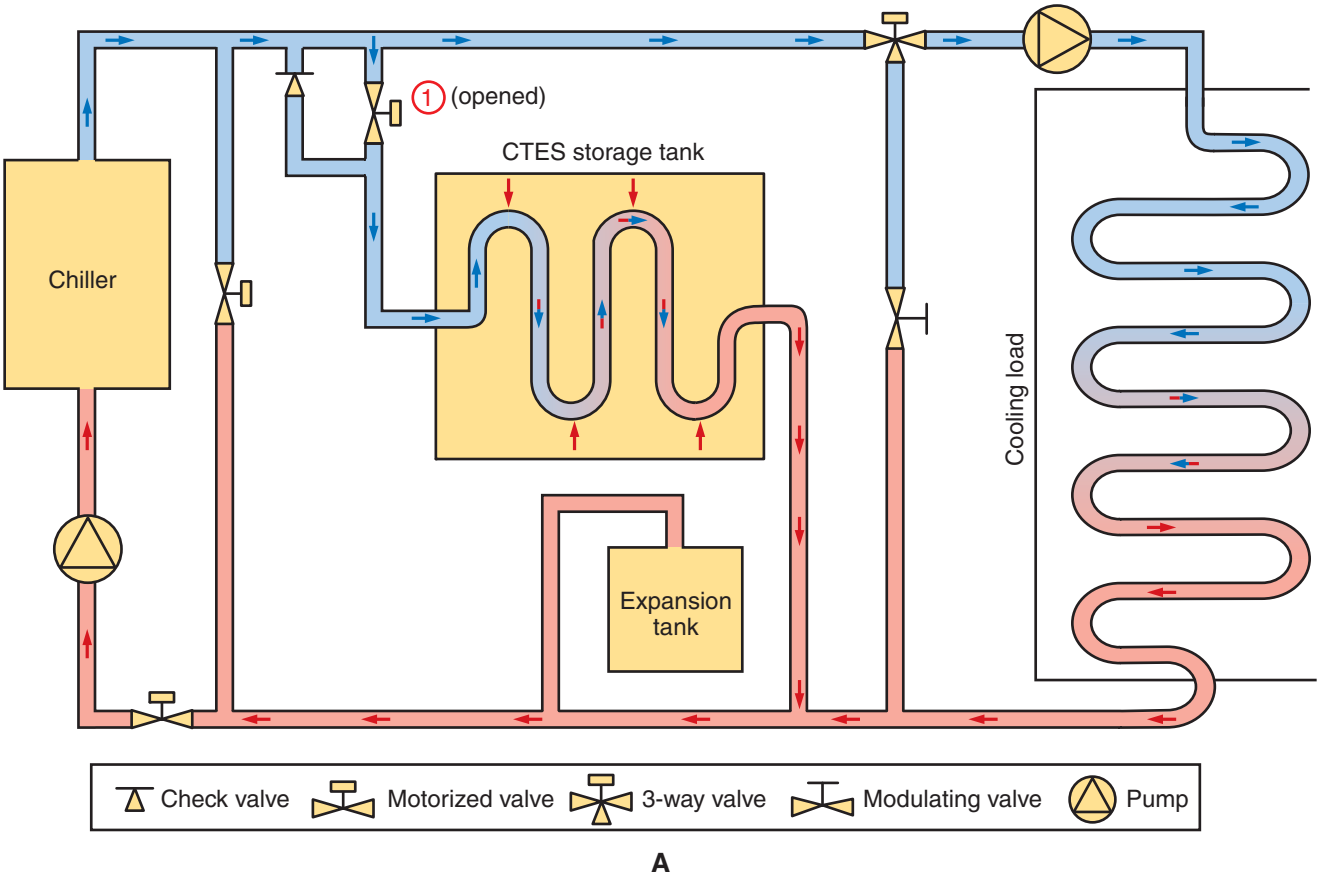
TES can also be used for cooling by removing heat from the storage medium rather than adding heat. Then, when additional cooling is needed, the precooled storage medium in the tank can absorb heat through the heat exchanger. ***Cold thermal energy storage (CTES)*** systems, sometimes referred to as cool storage, cool a storage medium at night, when energy demands are low. The precooled medium is then used to provide cooling during times of peak electrical demand, such as midday. Because electricity is typically more expensive during periods of peak demand, precooling the medium at night and using it during the day helps to lower energy costs. A CTES system incorporated into a chiller system is shown in **Figure 44-22**.

Pro Tip

Terminology

A CTES system may also be referred to as an STL system. STL is short for *stockage latent*, which means "latent heat storage."

Copyright Goodheart-Willcox Co., Inc. 2017



Goodheart-Willcox Publisher

Figure 44-22. A typical CTES system. A—During periods of low cooling demand, Valve 1 is opened, diverting some of the chilled water into the CTES storage tank. The chilled water flowing through the CTES storage tank heat exchanger absorbs heat from the CTES storage medium, cooling it. B—During periods of high cooling demand, Valve 1 is closed. Some of the warmed return water from the cooling load heat exchanger is diverted through the CTES storage tank heat exchanger. The precooled medium in the storage tank absorbs heat from the return water, chilling it. The chilled water is then sent back to cooling load heat exchanger. (*Continued*)

CTES systems may be cost-effective in a variety of situations. For example, a CTES system may be a good option in cases where the maximum cooling load is far greater than the normal cooling load. The CTES system can provide the extra cooling capacity needed during periods of peak cooling demand. CTES systems may also be cost-effective in regions where the utility companies offer demand response programs or charge a higher time of use rate for electricity during peak demand periods. Many utilities levy a demand charge that works like a speedometer on a car, charging customers based on the month's maximum energy use. In certain areas, the demand charge is ratcheted for a year so that customers are charged at the highest annual energy use for a period of one year.

CTES systems are also an environmentally friendly solution. First, a CTES system utilizes energy that is more efficiently produced at nighttime. During low-demand, off-peak periods, 10% to 30% less energy is needed to deliver power, because off-peak power plants (known as baseload plants) are that much more efficient. Secondly, it is more efficient to create cooling in the cool of the night than in the heat of the day. Transmission line losses are highest when power demand is highest. Losses of 5% to 7% are normal and can go as high as 14% on hot days.

Lastly, CTES systems help thrust renewables into the mainstream. Most energy used today consists of fossil fuels, which are a form of stored energy. Renewables are rapidly replacing fossil fuels, but they lack the element of storage. In order to continue to add renewables to the grid, storage must be added. For these reasons, CTES systems may be a good solution for green buildings, such as zero energy and LEED-certified projects in either new construction or retrofits. CTES is commonly considered when planning building expansions, when replacing a chiller or chiller plant, and when auxiliary cooling or backup cooling is needed.

Figure 44-22. Continued.

Full-Storage CTES

Full-storage CTES systems generate all of the cooling capacity for a building during off-peak hours. The system operates at full capacity during all off-peak hours. This includes both charging the system and generating all of the cooling capacity that will be needed during the peak demand periods. In other words, the chiller precools the CTES storage medium during periods of the day when energy rates are less expensive, and it shuts off when energy rates are more expensive. During those peak times, all of the cooling is provided by the precooled storage medium, **Figure 44-23**.

Partial-Storage CTES

In partial-storage CTES systems, the chiller precools the CTES storage media when cooling demands are low. However, unlike with a full-storage CTES system, the chiller continues to operate during periods of peak demand. If the chiller does not provide adequate cooling to meet demand during these peak periods, the precooled storage medium in the CTES makes up the difference. Alternatively, the chiller and energy storage can work together at the same time to cool building occupants.

Because the CTES system can provide reserve cooling capacity when needed, the size of the chiller can be smaller than would be possible if the cooling were provided by the chiller alone. Because a smaller chiller can be installed, the initial costs of a partial-storage CTES system are lower than the initial costs of a full-storage CTES system. For this reason, most CTES systems are partial-storage systems.

CTES Media

CTES storage media usually consist of chilled water, ice, or eutectic salts. The exact type of storage medium used depends on the type of application and the operating temperature of the system. Ice and eutectic salts are phase change materials.

Chilled Water

CTES systems that use water as the storage medium require larger tanks than are used with other storage media. However, these systems use less energy at the building site because less energy is needed to cool water than to freeze water. CTES systems that use

CALMAC Manufacturing Corporation

Figure 44-23. A full-storage CTES for a large cooling system could use a large tank farm as shown for cold thermal storage.

water as the storage medium typically operate at temperatures of 39.2°F (4°C). Chilled water may be mixed with glycol or another substance for a solution for a given application, **Figure 44-24**.

Water is best used in combination with a chiller system with a 2000-ton or greater capacity. Water is a popular storage medium because it is readily available and nontoxic. It is suitable for use in heating and

CALMAC Manufacturing Corporation

cooling applications that have operating temperature ranges between 41°F (5°C) and 113°F (45°C). Because it can be used in both heating and cooling applications, it can be used economically year-round.

Ice

Ice CTES systems have a number of advantages over water CTES systems. First, the tanks used in ice CTES systems are modular and can be smaller than those in a comparable water CTES system. Ice CTES systems can also provide increased cooling capacity. Ice systems can be used in lower-temperature applications.

Since an ice CTES has greater cooling capacity, smaller fans and ducts can be used to provide cool air to the conditioned space. Also, the cooler temperatures condense more moisture from the air, resulting in less humid air.

Because energy is being stored below the freezing point of water, the equipment used to precool the ice must operate at temperatures below the normal operating temperature range of air-conditioning equipment.

Special equipment is available that has been designed specifically for precooling the storage media in an ice CTES. As an alternative, a standard chiller can be modified to produce the low temperatures required.

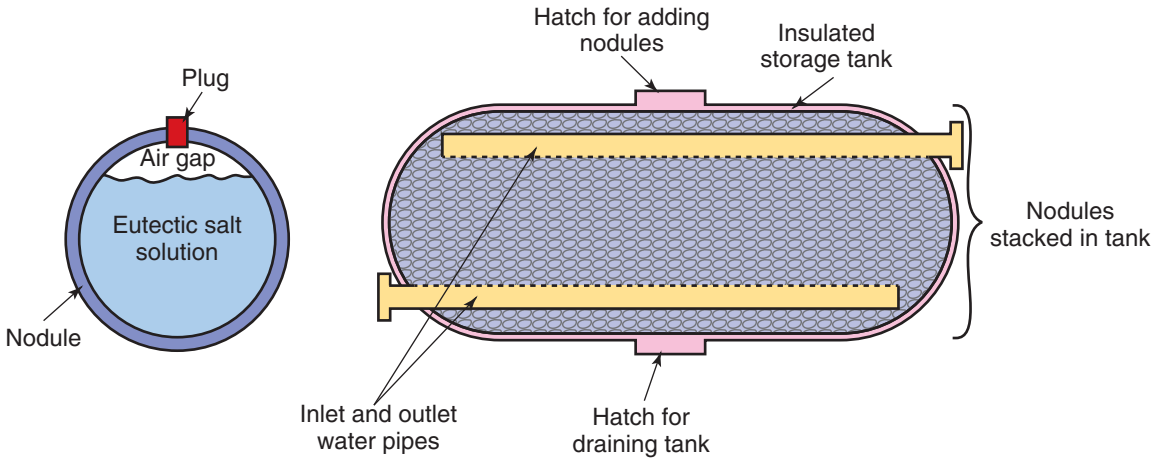
Eutectic Salts

Eutectic salts consist of a combination of inorganic salts, water, and various elements formulated to freeze at a desired temperature. In a eutectic salt CTES system, a round plastic or stainless steel shell, called a nodule, is filled with a eutectic salt solution. See **Figure 44-25**. A small air gap is left to allow for expansion of the material. The nodule is then plugged and sealed. An insulated tank is filled with the nodules. The tank also contains two water pipes with openings that allow water to flow into the tank. The water passes through the small gaps around the nodules, transferring heat to or from the nodules. The spherical shape of the nodules provides a large surface area for heat transfer.

The eutectic salt solution most frequently used in such nodules freezes at 47°F (8.3°C). This setup provides both the benefit of latent heat storage (eutectic salt nodules) and the benefit of a liquid heat transfer medium (water). Eutectic salt systems are no longer as widely used as they once were.

Mechanical HVAC CTES Systems

Chiller systems are not the only HVAC systems to utilize CTES. Some mechanical HVAC systems also incorporate ice storage for energy savings. A commercial mechanical air-conditioning system can include an add-on CTES system. The CTES system operates in freeze mode during the cool of the night to freeze an ice bank that can later be accessed during peak hours of daytime use. It uses its own evaporator, compressor, and condenser to absorb and reject heat for freezing the ice bank. During peak hours,



Goodheart-Willcox Publisher

the CTES ice storage system only runs a low-power pump to circulate refrigerant through the ice bank and then through a cooling coil installed adjacent to the RTU HVAC system's evaporator, **Figure 44-26**.

Adding a separate cooling coil to a rooftop unit (RTU) allows the refrigerant circuits of the HVAC system and the ice storage system to remain separate and isolated. This simplifies the installation process considerably, as the RTU's refrigerant circuit does not need to be recovered, evacuated, and recharged, **Figure 44-27**.

The ice storage system's cooling coil provides peak-hour cooling, allowing the HVAC system's compressor and evaporator to sit idle during this time. Low-cost cooling is provided by the RTU's blower circulating air across the cold storage coil for cooling. Since only a low-power pump is being used to circulate the refrigerant, much less electrical power is used for this cooling mode.

CTES systems used with mechanical HVAC systems are generally partial-storage systems for use during peak hours. Regular air-conditioning operation resumes once the ice bank melts and temperature controls signal to the system, **Figure 44-28**.

Chapter Review

Summary

- Solar radiation is electromagnetic energy that can be described as a stream of photons or as electromagnetic waves of various wavelengths. As a wavelength gets smaller, the energy level of the radiation increases.
- The three primary types of solar collectors are flat-plate collectors, evacuated tube collectors, and concentrating collectors. Of these, flat-plate collectors are the most common.
- Passive solar energy systems use solar radiation directly to provide heat. Active solar energy systems absorb heat energy into a collector, then redistribute or store it. Hybrid solar energy systems are a combination of passive and active solar energy systems.
- Solar heating systems use solar energy to heat a fluid (usually air, water, or an antifreeze solution) and then use the fluid to transfer the heat to a different location. Both air-based systems and liquid-based systems can be either passive or active.
- The most common application for a solar heating system is a domestic hot water system. Other common applications include heating pools and hot tubs.
- Solar heating can be supplemented with electric resistance heating, gas-fired or oil-fired heating, or a heat pump.
- Solar energy can be converted directly from radiant energy to electricity using solar photovoltaic (PV) cells. Solar cells can be combined to create solar modules, and solar modules are combined to create solar arrays. The direct current produced by solar modules can be stored in a bank of batteries, or it can be fed through an inverter to produce an ac voltage for use in a building or on the electrical grid.
- Solar energy can be adapted to cooling applications in two ways. The heat of solar radiation can be used as a heat source for an absorption cooling system. The electricity produced by photovoltaic (PV) modules can be used to power a mechanical air-conditioning system.
- Sensible TES systems store energy solely by changing the temperature of the storage medium. Latent TES systems store energy both by changing the temperature of the storage medium and by changing its phase.
- Cold thermal energy storage systems can reduce cooling costs by storing a cold thermal mass for use during peak hours. This can be incorporated into both chiller systems and traditional direct-expansion air-conditioning systems.

Review Questions

Answer the following questions using the information in this chapter.

1. Which of the following surfaces would be most effective for the absorber in a solar collector?
   A. Rough black surface.
   B. Rough white surface.
   C. Shiny black surface.
   D. Shiny white surface.
2. Which of the following is *not* a basic function of a flat-plate collector cover?
   A. To prevent the escape of heat collected by the absorber surface.
   B. To protect the absorber surface from the weather.
   C. To allow sunlight to reach the absorber surface.
   D. To position the absorber perpendicular to the sun.
3. The tubes in an evacuated tube collector lose almost no heat because heat cannot travel easily through _____.
   A. air
   B. compressed air
   C. a vacuum
   D. a water/glycol mixture
4. Which of the following is an example of a passive solar energy system?
   A. A closed liquid-based system supplemented by a heat pump.
   B. A forced-air solar heating system.
   C. A greenhouse addition on a home.
   D. A pumped water-based solar heating system.
5. A(n) _____ solar heating system may use a thick concrete wall to store thermal energy for heating at a later time.
   A. active liquid-based
   B. passive air-based
   C. passive liquid-based
   D. None of the above.

Copyright Goodheart-Willcox Co., Inc. 2017

6. Liquid-based systems in cold climates often use a mixture of water and _____ instead of pure water to reduce the freezing point of the liquid.
   A. butane
   B. glycol
   C. R-12
   D. paraffin

7. An example of the thermosiphon effect is _____.
   A. a concrete wall becoming warmer when exposed to energy from the sun
   B. evacuated tube collectors losing less heat than flat-plate collectors
   C. using gravity to drain solar collectors when the temperature is below freezing
   D. water rising as it heats and falling as it cools in a passive heating system

8. Which of the following statements regarding solar domestic hot water (DHW) systems is *not* true?
   A. A one-tank solar DHW system replaces a conventional water heater but still uses an auxiliary heating coil.
   B. A two-tank solar DHW system preheats water but still relies on a conventional water heater.
   C. Solar DHW systems are more widely used and more cost-effective than solar space heating systems.
   D. Solar DHW systems pump potable domestic water through solar collectors for direct heating.

9. Which of the following would *not* be used to provide supplementary heat for a liquid-based solar heating system?
   A. A gas-fired burner.
   B. A heat pump.
   C. An in-tank electric resistance heating element.
   D. An object with high thermal mass.

10. In a solar cell, the P-type semiconductor has an excess of positive charges, called _____.
    A. electrons
    B. holes
    C. neutrons
    D. positrons

11. Which of the following statements about net metering solar energy systems is *not* true?
    A. Excess power generated by the net metering system may be sold to the utility company.
    B. An inverter is used to produce alternating current.
    C. Net metering systems do not provide power at night.
    D. Net metering systems must include storage batteries.

12. An advantage of building-integrated solar modules is that they _____.
    A. are more energy efficient than other types of solar materials
    B. blend in with the appearance of traditional building materials
    C. can only be used to power various portable devices
    D. do not need a solar collector

13. Which of the following statements regarding solar energy cooling systems is *not* true?
    A. A drawback of solar-powered absorption cooling is that energy output is lowest when cooling demand is the highest.
    B. Solar power can be adapted to provide the heat source for an absorption cooling system.
    C. Solar power can be used to power a mechanical air-conditioning system.
    D. Solar power is typically used for heating rather than for cooling.

14. Which of the following can be used as a storage medium in sensible thermal energy storage (TES) systems?
    A. Paraffin.
    B. R-123.
    C. Sand.
    D. Wood.

15. Which of the following statements regarding sensible TES systems is true?
    A. Paraffin wax is the commonly used storage medium.
    B. The amount of energy stored depends partly on the initial and final temperatures of the storage medium.
    C. The temperature of the storage medium remains more constant than in a latent TES system.
    D. They have a higher storage density than latent TES systems.

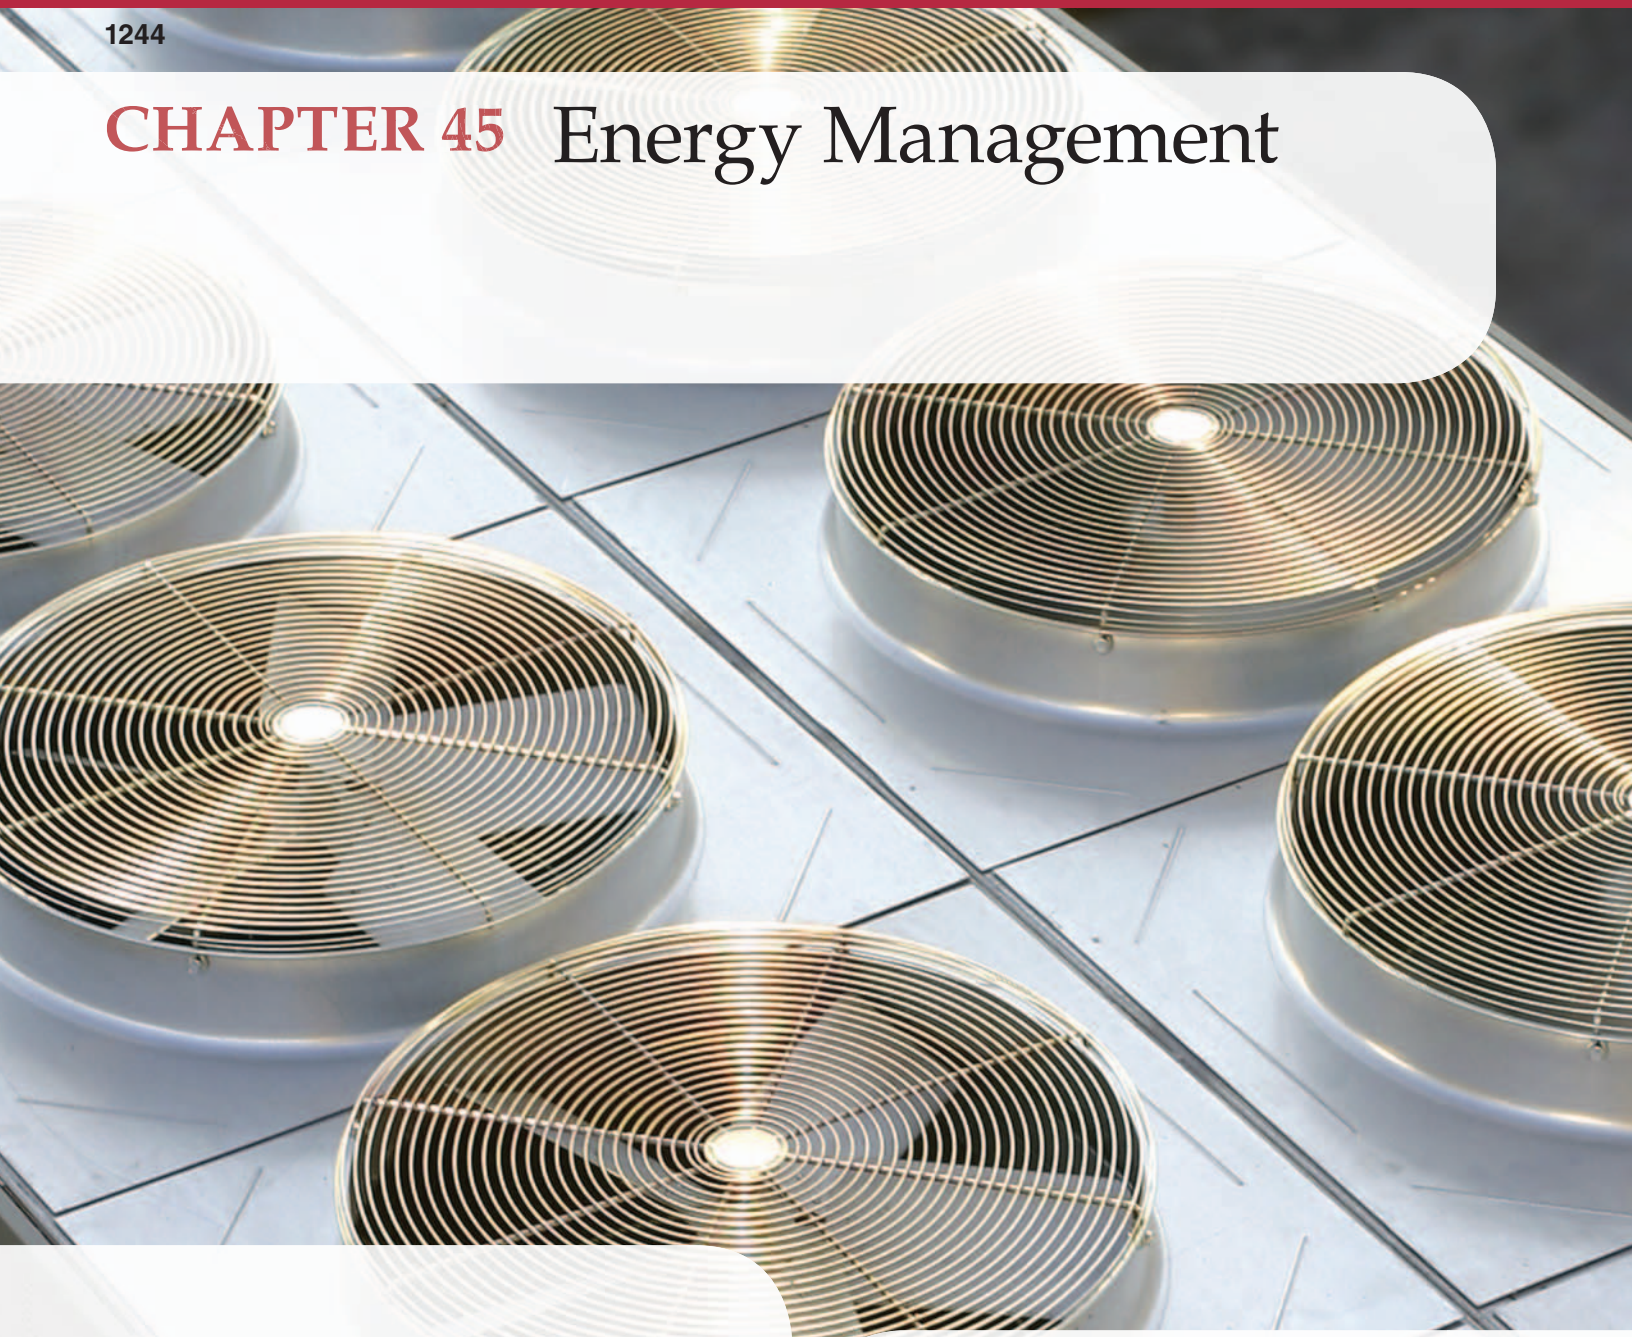
CHAPTER 45 Energy Management



Chapter Outline

45.1 Energy Consumption
45.2 Energy Audits
- 45.2.1 Residential Energy Audits
- 45.2.2 Commercial and Industrial Energy Audits

45.3 Building Control Systems
- 45.3.1 Functions of a Building Control System
- 45.3.2 System Selection and Usage

45.4 Controllers for Building Control Systems
- 45.4.1 Localized Controllers
- 45.4.2 Remote Controllers
- 45.4.3 Centralized Computer Control

45.5 Building Control Protocols
- 45.5.1 BACnet
- 45.5.2 Other Building Control Protocols

45.6 Building Control System Diagnostics and Repair

Learning Objectives

Information in this chapter will enable you to:

- Identify factors affecting heat gain, heat loss, and building energy consumption.
- Explain the purpose of a building control system.
- Understand the energy audit process.
- Describe the three general types of building system controllers.
- Explain the purpose of building control protocols, such as BACnet.
- Summarize principles of control system diagnostics and repair.

remote controller
router
server
total energy management (TEM)
workstation

Review of Key Concepts

Reviewing these concepts from earlier chapters will help you understand new concepts presented in this chapter:

- Heat can be transferred through radiation, conduction, convection, or a combination of any of these three methods. Heat always flows from hot to cold. (Chapter 4)
- A control system is a collection of interacting components that work together to achieve a purpose. HVACR control systems regulate conditions such as temperature, pressure, and humidity within specified areas. Components used in control systems include sensors, controllers, and controlled devices. (Chapter 16)
- A controller is a circuit that responds to changes in the signals from sensors and issues signals to controlled devices. (Chapter 16)
- Direct digital control (DDC) is a type of control system that utilizes multiple digital and analog inputs and outputs in the form of low-voltage and/or low-current signals connected to a microprocessor that operates an HVAC or automated building system. (Chapter 16)
- Infiltration is the natural and unintentional or accidental leakage of outside air into a building through doors, cracks around windows, and other construction joints. (Chapter 28)

Introduction

Many buildings in the United States were built when energy was relatively cheap and few people understood the need to conserve and the benefits of conserving. Energy types, sources, and costs have changed dramatically since then. Older buildings are now being modified for better efficiency, and new buildings are designed to operate using less energy. Computer-controlled systems that condition different building areas independently are now used not only for precise comfort control but also for energy efficiency.

12

Copyright Goodheart-Willcox Co., Inc. 2017

45.1 Energy Consumption

Energy use in a building is determined by several factors, especially concerning energy loss. As related to HVAC, these primarily include the settings of the conditioned environment, the type of HVAC equipment in the building, regional climate, building type and materials (such as floors, walls, roof, and windows), and site-specific variables, such as heat produced by machinery, an industrial process, and the number and activity of occupants.

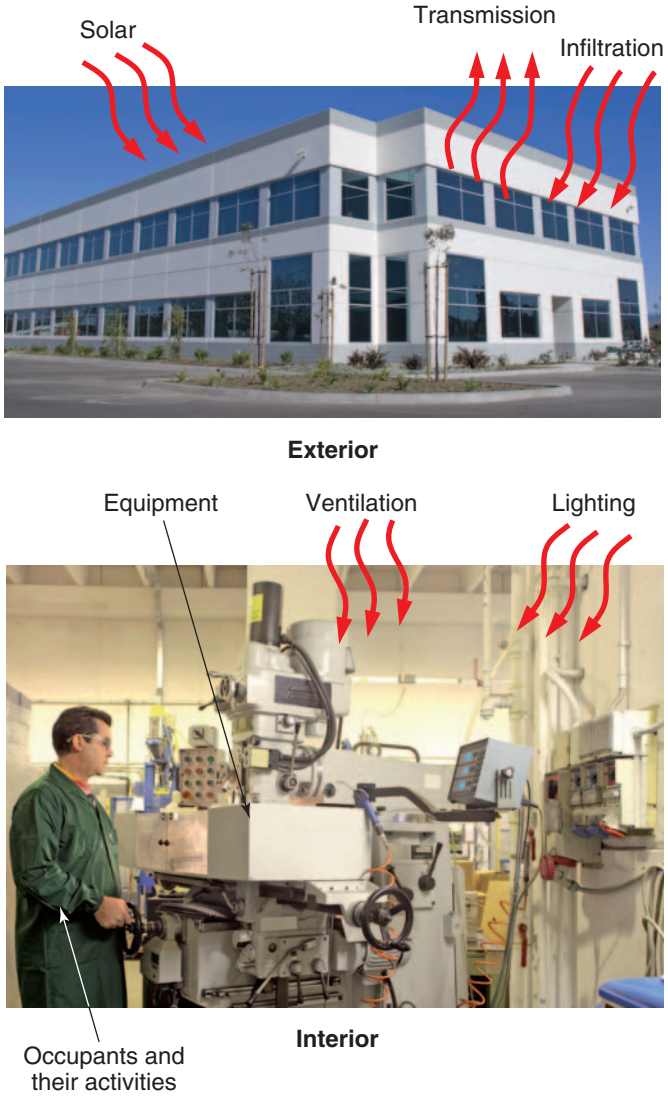
Many of these factors can be modified to reduce energy consumption, which would achieve significant energy savings. Devices that consume energy are the easiest to define in terms of direct energy usage. Therefore, the tendency is to concentrate conservation efforts in this area.

However, it is often more cost-effective to control heat loss and heat gain in an existing building prior to replacing outdated, inefficient HVAC equipment. The first step to reducing energy consumption is to minimize energy waste by improvements to the building's envelope. This is often accomplished through improved wall and ceiling insulation, caulking or replacing windows with more energy-efficient models, and updating lighting systems with energy-efficient controls, fixtures, and bulbs.

Heating and cooling should not be viewed as adding heat to or removing heat from room air to achieve a given temperature. Rather, heating and cooling are the processes of providing controlled heat loss or heat gain in a building. Heat loss and heat gain occur at the same time. One is usually greater than the other, depending on the outside temperature.

As shown in **Figure 45-1**, factors that influence heat loss or gain include:

- Infiltration—the passing of outside air into a building through doors, cracks around windows, and other openings.
- Exfiltration—heat loss or gain from conditioned air escaping a building through ceilings, walls, floors, windows, and other building components.
- Ventilation—forced airflow that takes place, by design, between the inside and outside of a building.
- Solar—heat generated as a result of the intensity and direction of the sun's rays.
- Lighting—heat generated in direct proportion to the wattage of the lights.
- Equipment—heat generated during operation.
- Occupants—sensible heat and latent heat (moisture) generated by people and their activities.



ollyy/Shutterstock.com; Arthur Eugene Preston/ Shutterstock.com

Figure 45-1. Factors that influence heat loss and heat gain in a building.

As a result of these and other factors influencing heat loss or heat gain, heating and cooling can be complex problems in a large commercial or industrial setting. Complexity increases dramatically with the number of systems to be integrated. Chapter 37, *Heating and Cooling Loads* covers these items in greater depth.

45.2 Energy Audits

An ***energy audit*** is the process of evaluating a building's energy consumption and identifying methods of reducing energy cost and usage. The energy auditing process generally involves the following steps:

1. Analysis of current energy usage.
2. Inspection of existing structure and equipment.

Copyright Goodheart-Willcox Co., Inc. 2017

3. Additional testing.
4. Final analysis and recommendations.

For an energy audit of a single-family residence, these steps may be relatively simple. The entire audit could be completed by a single auditor in a relatively short time. For an energy audit of a large industrial facility, the audit process could involve a significant amount of testing and analysis performed by a team of auditors over a period of weeks or months.

45.2.1 Residential Energy Audits

The number of activities conducted as part of a residential energy audit can vary based on the preference of the homeowner. In many cases, a basic analysis and inspection by an energy auditor will identify recommendations for reducing energy usage. Often, the future cost savings enjoyed by the homeowner by implementing some recommendation exceeds the cost of the audit.

The analysis of current energy usage for a residence may be as simple as reviewing utility bills from the previous year. Comparing the energy usage to that of similar houses in the same locality provides a rough estimate of the overall energy efficiency.

The inspection portion of a residential energy audit can lead to many recommendations. The following provide an example of items included in a residential inspection:

- Windows. Windows have a large impact on infiltration, which in turn has a large impact on the amount of energy needed for heating and cooling. An energy auditor will note the type of window construction and inspect the "tightness" of the wall opening around the window.
- Doors. A door's material and the construction of its wall opening can have a large impact on the amount of air infiltration.
- Heating and cooling system. Older furnaces and air-conditioning units may consume more energy than newer units would. Improper maintenance or improper installation of components (such as ductwork, registers, and dampers) may result in excessive energy consumption. Thermostat type (for example, programmable vs. nonprogrammable) and settings are noted.
- Lighting. Lighting fixtures, type of lightbulbs in use, and use of timers and dimmers is noted in the inspection.
- Insulation/air barriers. The type and condition of insulation in walls, roofs, attics, and basements is inspected. Air infiltration and construction methods at wall corners, wall openings, wall-to-roof intersections, and other locations are evaluated.

A residential energy audit may incorporate additional safety inspections. An electrical safety inspection can involve a check of the service entrance, meter, service panel, wiring methods, and GFCI and AFCI usage. A combustion appliance inspection can test combustion appliances such as furnace, oven, and water heater to ensure a safe fuel supply and proper combustion.

A more thorough residential energy audit will incorporate additional testing. A blower door test can be performed to measure the overall amount of air infiltration and to identify specific locations of high infiltration. How to perform a blower door test is described in Chapter 30, *Ventilation System Service*. Thermal imaging may be used to identify areas of relatively high levels of heat transfer. Meters can measure the amount of electricity used by specific appliances.

A residential energy audit report provides the homeowner with a summary of the current level of energy usage, the energy-related findings of the inspection and testing, and specific suggestions of ways to reduce energy usage. Often, each suggestion will include an estimate of the cost to implement and an estimate of the reduction in energy usage and corresponding savings in energy cost. These estimates help the homeowner determine which suggestions to implement.

Pro Tip

Energy Auditing Resources

The US Department of Energy and many local utility companies provide energy auditing resources, such as evaluation forms and checklists. Utility companies may offer rebate programs for conducting an energy audit or implementing building improvements identified in an audit.

45.2.2 Commercial and Industrial Energy Audits

Energy audits of commercial and industrial facilities are far more complicated than residential energy audits. Commercial and industrial energy audits are normally conducted by a team of energy auditors or, in large corporations, by a specific group within the company.

Commercial and industrial energy audits follow the same basic procedure as residential energy audits, but each step in the process is much more involved. The analysis of current energy usage could include a detailed analysis of all equipment in the facility.

Copyright Goodheart-Willcox Co., Inc. 2017

In addition, the method of energy transmission throughout the building or complex is evaluated. A large amount of historical data may be available from company records and from the utility company.

Rate plans for commercial and industrial energy usage can be complicated. Energy cost can vary throughout the day. The cost may be based on a variety of factors, such as the time of day, the day of week, and the total amount of energy being used at a given time.

Commercial and industry energy audits may include extensive testing and measuring of equipment. This testing may be performed over a period of weeks to allow for a range of conditions.

The analysis phase is critical when performing a commercial or industrial energy audit. Due to the complexity of energy usage in these environments, a single change, such as replacing a blower in an air handler, can impact the entire energy system. Evaluating these impacts, estimating implementation costs, and estimating future cost savings is often completed by engineers or highly skilled energy auditors.

45.3 Building Control Systems

Energy management or control systems have been used for many years to manage individual systems within buildings. Each system within the building is optimized or calibrated to get maximum efficiency. However, although each system can be optimized for efficient performance, multiple systems require multiple management protocols. This often causes inefficiency, because the systems cannot communicate and coordinate with each other.

The green movement has produced a number of new ideas and ways of thinking about energy management. One such idea is ***total energy management (TEM)***. TEM is a conservation concept in which a building is viewed in terms of its total energy usage, rather than by analyzing the requirements of separate systems, **Figure 45-2**.

TEM is accomplished using a ***building control system***, which acts as a master system that controls all of the individual energy management systems, or subsystems. You may encounter other names for building control systems, such as *building automation systems (BAS)*, *building automation and control networks*, *facility management systems*, *building management systems*, and *energy management systems (EMS)*. All of these terms mean basically the same thing, although some of them focus more on one aspect of building control than others. For example, energy management systems tend to focus on reducing energy use and costs.

Code Alert

NEC EMS Definitions

Section 750.2 of the National Electrical Code (NEC) provides definitions for several useful terms. As related to this topic, *control* is defined as "the predetermined process of connecting, disconnecting, increasing, or reducing electric power." The term *monitor* is defined as "an electrical or electronic means to observe, record, or detect the operation or condition of the electric power system or apparatus." *Energy management system* is defined as "a system consisting of any of the following: a monitor(s), communications equipment, a controller(s), a timer(s), or other device(s) that monitors and/or controls an electrical load or a power production or storage source." When conversing with colleagues and customers, confirm terminology so everyone can communicate effectively.

A building control system increases building efficiency by causing each subsystem to operate at peak efficiency without compromising functionality of any of the other subsystems. Unlike system-specific energy management systems, a building control system allows monitoring of multiple types of energy usage in real time and responds quickly to changing conditions and energy needs. See **Figure 45-3**. This ability provides the flexibility needed to run the entire building at peak efficiency at all times. This, in turn, allows facilities and building managers to conserve energy and cut costs. At the same time, it meets the needs of the building's users.

For example, the security system in a building may indicate that an area is vacant for the night. This information is obtained from motion detectors in the building and passed on to the building control system. The building control system then instructs the HVAC controller to lower blower speed and adjust the set point of the area thermostat to allow the temperature to rise or fall beyond the normal set point temperature. At the same time, the building control system issues a command to the lighting controller to dim or turn off lights in the area. By integrating the security, HVAC, and lighting systems, the building control system manages energy use more efficiently than any of the systems could if they were managed independently.

Code Alert

Load Management Restrictions

Section 750.30 of the NEC places restrictions on electrical load management. For example, an energy management system cannot override load shedding controls that ensure the minimum electrical capacity is available for fire pumps, emergency systems, legally required standby systems, and critical operations power systems. Other restrictions prevent an energy management system from disconnecting power to certain circuits and from overloading a branch, feeder, or service circuit.

45.3.1 Functions of a Building Control System

At a minimum, building control systems integrate a building's mechanical, electrical, and plumbing systems. Control of HVAC equipment (including air handling units, rooftop units, heat pumps, chillers, and boilers) constitutes a major part of a building control system. See **Figure 45-4**. Security, fire alarm and prevention, lighting, and plumbing systems are also usually integrated into the systems. Even elevators, escalators, and other people-moving devices can be incorporated.

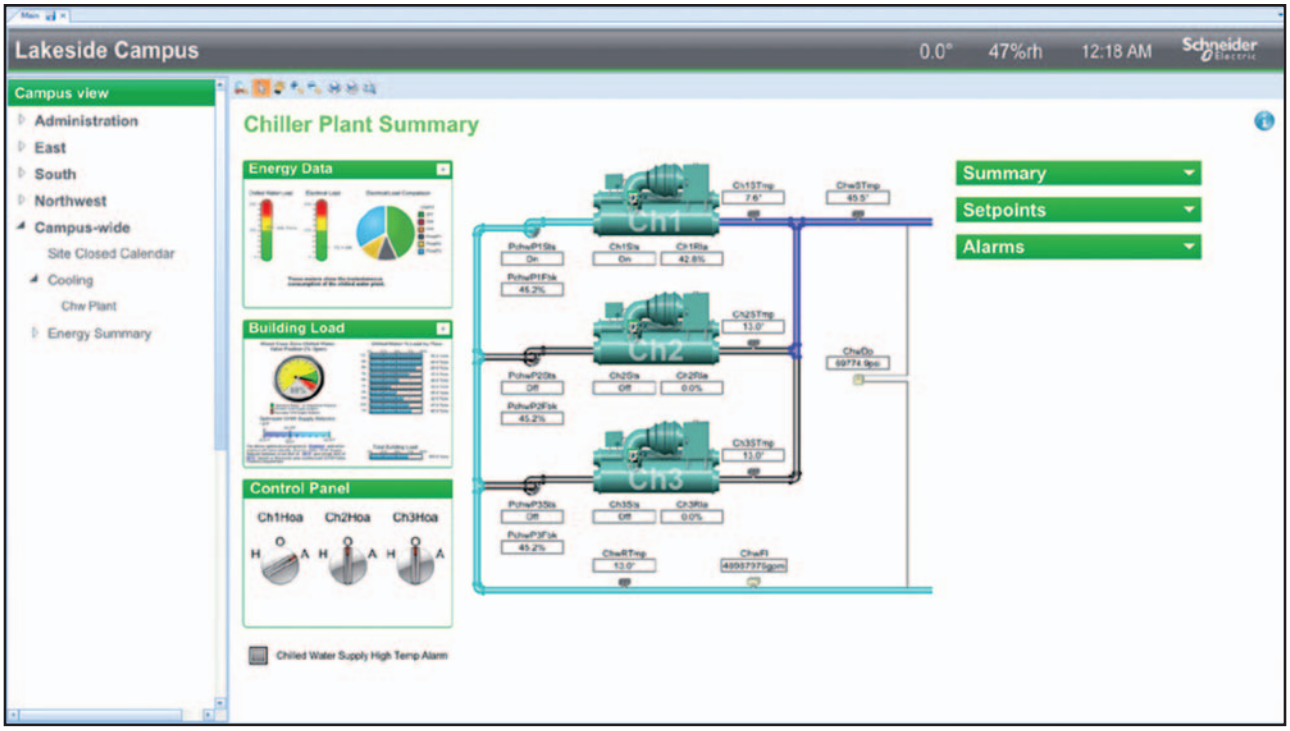
45.3.2 System Selection and Usage

The first step in selecting a building control system is to determine the energy needs of the building. This is done through the use of an energy audit. An energy audit is the recording and calculating of energy consumption in a building. Initially, an auditor walks through the structure noting all areas where waste and inefficiency are obvious. This walk-through is followed by an accurate recording of all energy consumed during the audit. The recording is usually performed over a period of a month or two. An example of the audit form used in this process is shown in **Figure 45-5**.

Information gathered as part of the total energy audit includes the following:

- Previous year's energy use data.
- Weather data (for accurate comparisons).

Copyright Goodheart-Willcox Co., Inc. 2017



Schneider Electric

Figure 45-4. Building control system monitoring the status of a chiller plant housing three chillers. A single building control system can manage the systems in a campus consisting of several buildings.

- Building data, such as plans or accurate floor layouts.
- Equipment operation logs.
- Other information on any aspect of energy consumption within the structure.

The energy audit is needed to compare against energy use intensity. The ***energy use intensity (EUI)*** acts as a reference showing the annual energy use per square foot for a commercial building. This can vary by the type of building and by different climate zones. EUI is calculated by dividing energy consumption in Btu by the square footage of conditioned space. This calculation is shown in the lower-right corner of the energy audit form in **Figure 45-5**.

The sum of all this information is then processed using computer programs specifically designed for this purpose. The overall status of energy management for the structure is determined. Then, based on the cost, time, and efficiency, a building control system is chosen.

45.4 Controllers for Building Control Systems

There are three general types of energy management system controllers: localized controllers, remote controllers, and centralized computer control. Each type of system controller uses direct digital control. *Direct digital control (DDC)* is a type of control system that utilizes multiple digital and analog inputs and outputs in the form of low-voltage and/or low-current signals connected to a microprocessor that operates an HVAC or automated building system.

Code Alert

Class 2 Circuits

Many of the circuits used in DDC are Class 2 circuits. These are power-limited circuits that often run on 24 Vac for building control. Article 725 of the NEC covers Class 1, Class 2, and Class 3 remote-control, signaling, and power-limited circuits. Review the requirements of such circuits before servicing or installing any building control system.

DDC processes input and output information according to the user's preset instructions and sends out control signals to various controlled devices to condition the necessary areas of the building. Direct digital control is an extremely versatile and powerful form of control. It can be used to manipulate valves, damper position, fan speed, and compressor operation for multiple areas of a building. It eliminates the need for conventional thermostats, humidistats, and timers.

45.4.1 Localized Controllers

A ***localized controller*** is a building system controller used to provide independent control for a specific system or piece of equipment. This type of controller is available at a relatively low cost. Each localized controller is *independent*. It controls its specific system and has no interaction with any other controlling device. Typical localized controllers include time clocks, alarms, and local optimization devices, such as controllers that operate dampers based on zone temperatures.

Localized controllers are used for relatively simple HVAC system control. They are used when individual system efficiencies are more important than total system management or when minimum cost is desirable.

45.4.2 Remote Controllers

A ***remote controller*** is a building system controller that can control the operation of one or more energy-consuming devices from a remote location. Newer remote controllers have wireless capabilities and contain microprocessors that allow programmable options and settings. Remote controllers are the most common type of total energy management system controller in use today.

Functions typically found in a remote controller include the following:

- Remote start/stop—turns systems and devices on and off at certain times.
- Optimized start/stop—turns devices on and off based on a preprogrammed schedule to minimize energy use.
- Status monitoring—indicates whether the system is operating.
- Alarms—indicate if a system is operating incorrectly.
- Demand control—monitors overall demand for electrical power and modifies for minimum energy consumption. This may include shutting down lights, lowering blower speeds, or changing room temperatures based on occupancy in different sections of a building. For example, demand-controlled ventilation systems use carbon dioxide sensors or other means to determine when an area is occupied and condition the area only when people are present. This helps avoid wasting energy on conditioning unoccupied spaces.
- Duty cycling—establishes the most efficient run times and then cycles systems on and off accordingly to maintain minimum energy consumption.

Code Alert

Field Markings

When an energy management system is used to control electrical power through remote means, Section 750.50 of the NEC requires that a directory identifying the controlled devices and circuits be posted on the enclosure of the controller, disconnect, or branch-circuit overcurrent device.

45.4.3 Centralized Computer Control

A ***centralized computer control*** is a building system controller that consists of one or more centralized computers that make control decisions based on operating data, programmed information, and data already stored in computer memory. This is the most elaborate and the most costly of the three types of systems. However, it offers the widest range of control functions. In large, complex structures, this centralized system results in the best overall energy consumption control.

Centralized computer control is used in most newly constructed large building complexes. Wiring is relatively easy to install during the construction stage. However, wireless systems now allow many older structures that use large amounts of energy to be retrofitted with these controllers. In fact, wireless technology is now beginning to replace the older wired technology even in new construction, because it allows more flexibility over the lifetime of the building.

Functions of a centralized computer system include all of the tasks performed by remote and localized controllers. However, computer controllers may also have other features. Some systems available today monitor utility usage and verify billing. They may also schedule and notify personnel of all needed maintenance functions.

The centralized computer control system is classified into two general categories, based on system construction:

- A packaged centralized computer control is a complete system furnished by a single manufacturer. The manufacturer also usually provides some level of service and follow-up after installation. In some cases, the manufacturer performs ongoing monitoring services for the system.
- A hybrid centralized computer control is a system composed of components from several manufacturers. These systems may be designed by personnel within the company or through

Copyright Goodheart-Willcox Co., Inc. 2017

an outside firm. The same personnel may then assume total system responsibility.

45.5 Building Control Protocols

Early building control systems used pneumatic controls that were connected to a central controller or relay control module. These systems were expensive to install, requiring the use of hoses for pneumatic actuators and controls. Most pneumatic systems were also designed to operate only with the specific manufacturer's equipment. If a pneumatic control failed, it had to be replaced by one from the same manufacturer.

With the introduction of computers, electrically actuated controls became feasible. However, most systems were proprietary designs. This required that service technicians be trained in the operation of that particular company's system. In addition, most buildings used one type of system for their HVAC control and different systems for fire, safety, and security controls. These systems could be confusing to operate and did not "talk" to each other. Because these systems were not interconnected, duplicate wiring and controls for different applications within the same building resulted. Also, significant training was needed for building operators of each specific control system.

45.5.1 BACnet

To reduce the amount of wiring and training needed and to allow for the use of products from different manufacturers within a single system, a common method of building control was needed. ***BACnet*** (short for "building automation control network") is a common protocol or set of rules for software and hardware communication that allows controllers from one company to work with those from another company. Unlike many other network protocols, BACnet was designed specifically for building automation and control. Its purpose is to provide a standard format for communication between components of building automation used for networking, printing, operating system software, and hardware integration.

BACnet was originally an ANSI (American National Standards Institute) and ASHRAE (American Society of Heating, Refrigeration and Air-Conditioning Engineers) standard for common communication between HVAC and building automation devices. It was developed primarily for use in the United States. In 2003, BACnet became an ISO (International Organization for Standardization) standard; it is now recognized throughout the world as the standard format for control language.

In addition to allowing devices from different manufacturers to communicate, BACnet includes a "network layer" that allows communication among different types of networks. The following common network protocols are recognized:

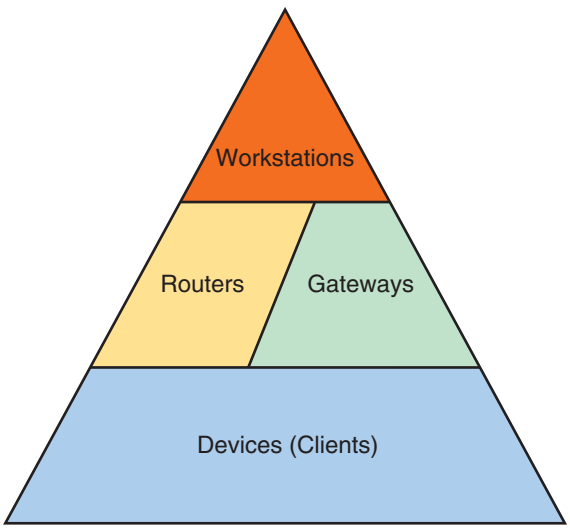
- Ethernet.
- ARCNET.
- LonTalk.

For other types of network communications, BACnet includes rules for master-slave/token passing (MS/TP), point-to-point (PTP), and BACnet/IP (Internet Protocol). These rules are designed not only to allow use by networks of today, but also by other network types that may be developed in the future.

BACnet-controlled systems may include the following components:

- Workstations.
- Routers.
- Gateways.
- Native BACnet controllers and devices.
- Nonnative controllers and devices.

These components are structured similar to a pyramid, **Figure 45-6**. One or more ***workstations*** are used to control all of the building systems. BACnet/IP



Goodheart-Willcox Publisher

Figure 45-6. BACnet system configuration. The workstations from which the building control system is managed are at the top of the pyramid. Routers and gateways connect other networks and nonnative devices to the BACnet network so that all of the systems can be run from a single user interface.

Copyright Goodheart-Willcox Co., Inc. 2017

protocol allows the viewing and operation of systems from workstations remotely via the Internet, so the controlling workstations do not necessarily need to be within the building, **Figure 45-7**.

Information from the BACnet routers and gateways are supplied to the workstation. Technicians use the workstations to monitor, control, and coordinate system functions. Troubleshooting is also performed at the workstation.

Routers and gateways perform interpreting tasks among the controllers and devices at the pyramid's base. ***Routers*** are used to connect different types of networks within the building, as shown in **Figure 45-8**. One router is required for each type of network other than the base network to which the controlling workstation is connected, **Figure 45-9**.

Even within a single network, some existing devices may not recognize the BACnet protocol. ***Gateways*** are similar to routers but are more complex. In addition to connecting different types of networks within a system, they connect nonnative controllers and devices (those that do not "understand" the BACnet protocol) to the system. The gateway translates BACnet instructions into the nonnative or proprietary device format (protocol). The gateway then interprets the information from the devices back to BACnet so that it can be understood by the workstations. See **Figure 45-10**. BACnet-compatible devices (native and

Figure 45-10. Gateways allow controllers, sensors, timers, and other equipment that do not recognize the BACnet protocol to be connected and controlled by the BACnet network.

nonnative) include temperature sensors, airflow measurement devices, humidity measurement devices, and most HVAC-controlled devices.

BACnet uses a client/server model. The controllers and controlled devices in a building control system that uses BACnet may be referred to as ***servers***. Examples of servers are HVAC controllers that operate individual HVAC units, **Figure 45-11**.

Workstations act as ***clients***, which send instructions to and receive information from the servers. To ensure that devices may both receive commands from workstations and send feedback on operational status, all the devices on the network (clients and servers) need to be able to "talk" to each other. This is the job of the routers and gateways, **Figure 45-12**.

Conversion of an existing building to BACnet-automated operation may involve changing out many control devices and sensors. Most new systems today are wireless, but even in wired systems, wireless

transmitters are used to avoid hard wiring in difficult to reach locations. Wireless transmitters operate on RF (radio frequency) waves that relay data to a BACnet controller. The sensors send a data signal to the radio frequency receiver that is connected to a BACnet server.

45.5.2 Other Building Control Protocols

Although BACnet is considered the industry standard, other protocols are also in use. For example, ***LonTalk*** is a proprietary communications protocol developed by Echelon that permits integration of components from different manufacturers. It provides a common assignment of data input and output parameters to allow communication between controllers and controlled devices.

Although LonTalk was originally manufactured only by the Echelon Corporation, it is now licensed to other electrical controls manufacturers. As a result, LonTalk is based on a different communication protocol and does not communicate directly with BACnet devices. However, BACnet systems can recognize and incorporate some LonTalk devices.

Another communication protocol used in building control and automation is ***Modbus***. This protocol was originally developed in the 1970s for use with programmable logic controllers (PLCs). Modbus was initially developed by Schneider Electric. It is now updated and developed as an open protocol by the Modbus Organization.

45.6 Building Control System Diagnostics and Repair

Diagnosis and repair of control system problems is the key to efficient system operation. Simple control systems are often more difficult to diagnose and repair than more complex electronic control systems. Simple systems, such as controls for basic gas or oil furnaces, usually involve mechanical and individual electrical components. The more advanced building control systems use electronic circuit boards and offer computer diagnostic advantages.

Manufacturers of controls typically provide a troubleshooting guide. Also refer to the control system manufacturer's troubleshooting guide. Building control system problems can be divided into three primary areas:

- Building Ethernet/IP communication failure.
- Controller and cable loss of signal.
- Component failure.

Figure 45-13 shows part of a troubleshooting guide for a building management system. Note that

Troubleshooting Guide

Problem	Possible Cause	Remedy
No LED display on display panel.	1. On-off power switch is in the off position.	1. Slide switch to the on position.
	2. Loss of input supply voltage.	2. Take a voltage reading across input voltage terminals on the terminal strip of the interface PC board. There should be a reading of input voltage. If not present, check for a tripped circuit breaker. Verify primary input (120 V) at the electrical outlet and secondary output voltage at the secondary of the transformer.
	3. Blown fuse on interface board.	3. Check for improper wiring or shorts to ground and replace fuse if necessary.
	4. Loose ribbon cable connection.	4. Check the ribbon cable connection on the processor and interface PC boards to see that it is properly inserted.
	5. Faulty microprocessor PC board.	5. Take a voltage reading across the quick disconnects on the microprocessor PC board. There should be a reading of input voltage. If there is no voltage, replace the ribbon cable. If there is voltage, replace the microprocessor PC board.
LED display frozen. Clock will not advance and program modes cannot be accessed.	1. Defective microprocessor PC board.	1. Replace microprocessor PC board.

Goodheart-Willcox Publisher

Figure 45-13. An excerpt from a typical control system troubleshooting guide. Notice that complete replacement of a circuit board is sometimes recommended.

Copyright Goodheart-Willcox Co., Inc. 2017

repair may include replacement of a given circuit board within the control device.

It is best to start troubleshooting building control issues from the macro view down to the component or actuator level. Determine if the problem is widespread (an entire system outage) or localized (one section of a building). If large portions or an entire system is down, there is most likely an Ethernet problem. The following are basic troubleshooting procedures for various issues:

Troubleshooting a Building Ethernet/IP Communication Fault

1. Use the main controller troubleshooting software to run a diagnostic of the system.
2. Check the network connectivity alarms.
3. Look for Ethernet port communication errors by checking the LEDs.
4. Reboot any routers that have indicator alarms.

Troubleshooting a Controller and Cable Loss of Signal

1. Once the failure has been isolated to a specific area of a building or specific function, check the controller. Controller alarm and failure LEDs may be set.
2. Check the cable of twisted pair wires by using a cable analyzer.
3. Check between the controller and controlled device for shorts and grounds.

Troubleshooting to Component Level

1. Measure the current between the sensor or actuator and the controller.
2. Based on the measurement, verify whether the communication between the controller and the controlled device is the correct signal for the operation being commanded.
3. After identifying the source of the failure to a specific controlled device, such as a sensor or actuator, that device can be quickly analyzed and replaced if necessary.

Troubleshooting an Electrical Failure

The following are some general steps to pursue in the event of an electrical failure. Always refer to the control system manufacturer's troubleshooting guide.

1. Check fuses or circuit breakers and the power-in with a suitable test light or voltmeter.
2. Check the main switch and thermostat switch to make sure they are in the closed position.
3. Check the thermostat. It must be on a setting that will close the thermostat switch.
4. Check the contactor or motor starter. It must be pulled in. If it is not, the contactor circuit is open. Review the following points:
   - Contactor is not buzzing and its circuit is open. Contactor coil is not powered. Check the control circuit using a voltmeter and ohmmeter.
   - Contactor is buzzing and its circuit is open. Contactor coil is operating, but the armature is not pulled in. Either the armature is stuck or the control coil voltage is too low.
   - Contactor circuit is closed and the motor hums. Motor is powered but will not start. Check the capacitors, if used, for low voltage. Check for excessive pressures in the system.
   - Contactor circuit is closed and the motor does not hum. Motor is not powered. Check motor voltage for safety. If not powered, then check for an open circuit by continuity test after removing any chance of a live circuit or capacitor discharging.

Chapter Review

Summary

- HVAC energy usage in buildings depends on the desired conditioned space settings, regional climate, HVAC equipment, building type and materials, and site-specific variables. Heat loss and gain are greatly influenced by infiltration, exfiltration, ventilation, lighting, solar conditions, equipment, and occupants.
- An energy audit is the process of evaluating a building's energy consumption and identifying methods of reducing energy cost and usage.
- A building control system is a master system in a building that controls all of the building's subsystems, including HVAC, electrical, plumbing, security, fire prevention, and other systems.
- The three general types of energy management system controllers are localized controllers, remote controllers, and centralized computer control.
- Several standards and protocols have been developed so the components used in building control systems can communicate and operate together even when produced by different manufacturers. Some of the industry protocols in use today are BACnet, LonTalk, and Modbus.
- Older building controls using individual and independent mechanical and electrical control may be difficult to diagnose and repair. Newer building controls that use electronics and networked computer controls, although more complex, often have system-wide monitoring for easier diagnosing of problems.

Review Questions

Answer the following questions using the information in this chapter.

1. The passing of outside air into a building through doors, cracks around windows, and other openings is _____.
   A. air conditioning
   B. exfiltration
   C. infiltration
   D. ventilation
2. Heat loss or gain from conditioned air escaping a building through ceilings, walls, floors, windows, and other building components is _____.
   A. air conditioning
   B. exfiltration
   C. infiltration
   D. ventilation
3. The acronym *TEM* stands for _____.
   A. thermal efficiency management
   B. ton of energy magnitude
   C. total energy management
   D. totally efficient machine
4. Which of the following systems is *not* typically managed by a building control system?
   A. Fire prevention system.
   B. Grievance management system.
   C. HVAC system.
   D. Security system.
5. Recording and calculating the consumption of a building's individual types of energy is one step of performing a(n) _____.
   A. building control protocol
   B. energy audit
   C. energy management strategy
   D. energy use intensity
6. Dividing energy consumption in Btu by the square footage of a conditioned space shows the relationship of Btu consumed per year for a given area, which is called the _____.
   A. efficiency usage indication
   B. electric utility indication
   C. electricity usage index
   D. energy use intensity
7. The use of a control system that utilizes multiple digital and analog inputs and outputs in the form of low-voltage and/or low-current signals connected to a microprocessor that operates an HVAC or automated building system is called _____.
   A. direct digital control
   B. local control
   D. pneumatic control
   D. remote control
8. In energy management systems, a building system controller that provides independent control for specific systems or equipment is called a _____.
   A. centralized computer control
   B. localized controller
   C. pneumatic controller
   D. remote controller

Copyright Goodheart-Willcox Co., Inc. 2017

9. Energy management system controllers that can control the operation of energy-consuming devices from a distant location are called _____.
   A. centralized computer controls
   B. localized controllers
   C. pneumatic controls
   D. remote controllers

10. Early building control systems used _____.
   A. centralized computer control
   B. localized controllers
   C. pneumatic controls
   D. remote controllers

11. The network protocol that is now recognized as a worldwide standard for building automation and control systems is _____.
   A. BACnet
   B. BackTalk
   C. LonTalk
   D. Modbus

12. All of the following are sets of rules within BACnet that allow communication with other types of networks, *except* _____.
   A. BACnet/IP
   B. direct digital control (DDC)
   C. master-slave/token passing (MS/TP)
   D. point-to-point (PTP)

13. Which of the following elements is at the top (peak) of the BACnet "pyramid", issuing orders to and requesting information from the other elements?
   A. Controllers.
   B. Workstations.
   C. Routers.
   D. Gateways.

14. In a BACnet-driven building control system, the individual devices (such as controllers that operate individual HVAC units) may be called _____.
   A. clients
   B. networks
   C. servers
   D. workstations

15. Building control systems are often easier to troubleshoot than the less complex controls for individual systems because building control systems typically offer _____ that are often missing in the simpler systems.
   A. built-in computer diagnostics
   B. more mechanical components
   C. troubleshooting guides
   D. instruction manuals

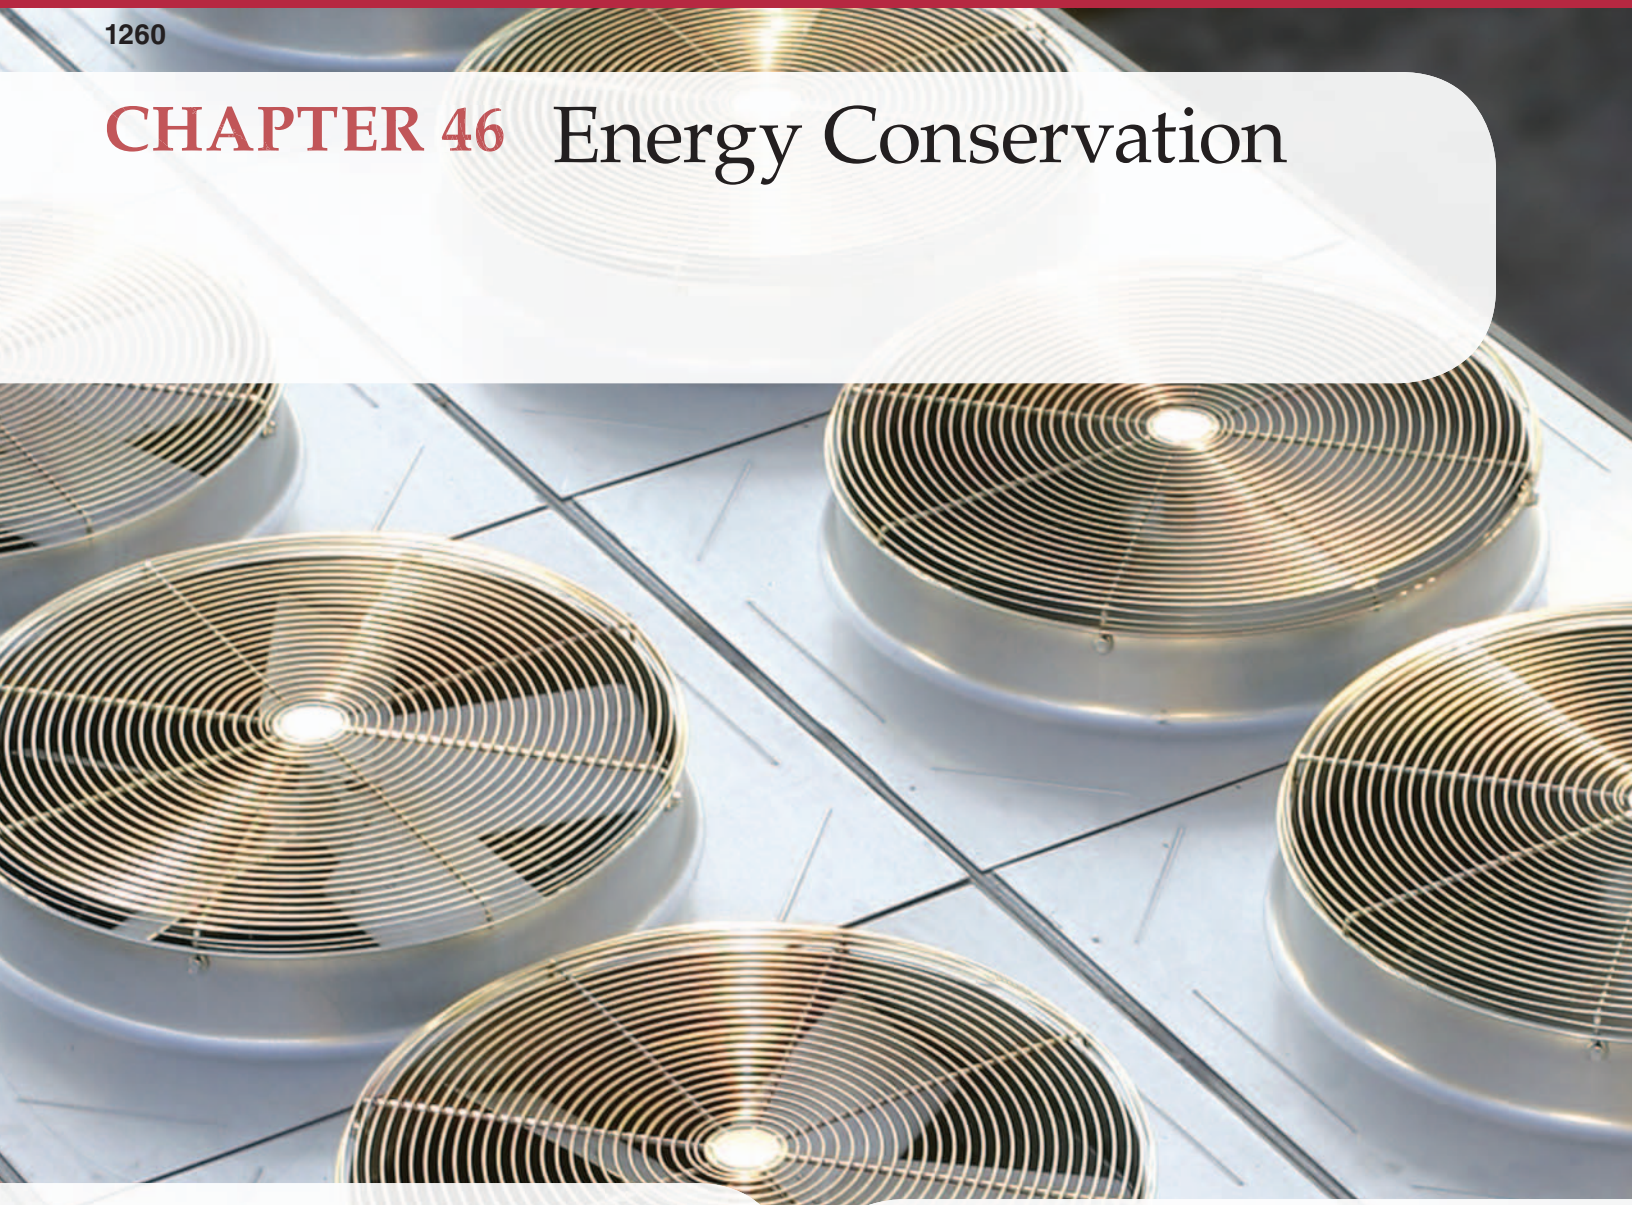
CHAPTER 46 Energy Conservation



Chapter Outline

46.1 Building Efficiency
- 46.1.1 Insulation and Vapor Barriers
- 46.1.2 Roof Construction
- 46.1.3 Commercial Construction
- 46.1.4 Energy-Efficient Construction
- 46.1.5 Determining Heating and Cooling Costs

46.2 HVAC Equipment Efficiency
- 46.2.1 Furnaces and Boilers
- 46.2.2 Air Conditioners
- 46.2.3 Heat Pumps

46.3 HVAC Alternatives for Energy Conservation
- 46.3.1 Energy-Saving Components
- 46.3.2 Total Energy Systems
- 46.3.3 Evaporative Cooling Designs

46.4 The Role of the HVACR Technician
- 46.4.1 Know and Explain the Options
- 46.4.2 Perform Proper Installation and Maintenance

Learning Objectives

Information in this chapter will enable you to:

- Explain how the construction of a building relates to its heating and cooling efficiency.
- Describe how the degree-day method can be used to estimate heating and cooling costs.
- Differentiate among the various efficiency ratings used to evaluate furnaces, air conditioners, and heat pumps.
- List individual components that can be changed or added to an existing HVAC system to increase energy efficiency.
- Describe alternative systems and solutions that may be used to increase energy conservation.
- Explain the role of the HVACR technician in energy conservation.

total energy system

Review of Key Concepts

Reviewing these concepts from earlier chapters will help you understand new concepts presented in this chapter:

- A building envelope consists of the components of the structure (such as walls or floors) separating conditioned space from unconditioned space. A "tight" building envelope minimizes the amount of air passing through the envelope between conditioned and unconditioned space. (Chapter 30)
- The thermal resistance, also known as the R-value, of a material or building component is a measure of its resistance to heat transfer. The higher a material or component's R-value, the slower the rate at which heat will transfer through that material or component. (Chapter 37)
- Degree-days are a measure of the heating or cooling needed for a given region. Daily average temperatures below 65°F are considered heating degree-days. Those above 65°F are classified as cooling degree-days. (Chapter 27)
- The measurement of furnace efficiency is the annual fuel utilization efficiency (AFUE) rating. The higher the AFUE rating, the more efficient the furnace. (Chapter 41)
- A heat recovery ventilator (HRV) is a heat exchanger that allows heat to pass between incoming fresh air and outgoing stale air. This pretreatment of the incoming air improves system efficiency. An energy recovery ventilator (ERV) does the same as an HRV, but it also transfers humidity. (Chapter 28)
- An evaporative cooling system achieves cooling by passing warm, dry air over water, resulting in evaporation. (Chapter 34)

Introduction

There is a growing movement in the HVACR industry toward "going green". This includes offering cost-effective, environmentally friendly energy conservation options to both business and residential customers. In the context of HVACR, ***energy conservation*** is a reduction in the amount of energy needed for HVACR-related processes and equipment operation. However, energy conservation consists of more than just installing newer, more efficient systems. It also includes installing the new systems correctly and servicing or upgrading existing systems to improve their efficiency.

A building's energy efficiency depends both on the physical characteristics of a building and on its existing HVAC system. An efficient building design and efficient HVAC equipment can save a building owner a significant amount of money and reduce the building's impact on the environment.

12

Copyright Goodheart-Willcox Co., Inc. 2017

46.1 Building Efficiency

A building's construction and materials contribute greatly to its level of energy efficiency. Heating and cooling systems create some of the most energy-intensive loads in any building, whether residential or commercial. See **Figure 46-1**.

Existing buildings can be examined for heat loss using a thermal imaging camera that shows different temperature ranges in contrasting colors. Thermal imaging is used to check both the interior and the exterior of the structure. The entire building envelope is examined, and areas of air infiltration are identified. Each of these areas can then be evaluated and repaired. **Figure 46-2** shows a thermal image being made of a typical home.

The location of a building determines how much solar load the interior will receive, and the locations of windows, doors, and other openings help determine how much infiltration of air will occur. For example, window and door openings on the side of a building that receives the prevailing winds allow the potential for higher air infiltration.

Ductwork throughout a building can be another source of energy waste. Heated air traveling through ducts to a conditioned space can leak out through air gaps in the ductwork. Heat in the warmed air can also be transferred to the air surrounding the duct. Similarly, cooled air absorbs heat as it flows through ductwork. Insulated ducts significantly reduce these energy losses. Insulation can be glued to the inside or the outside of the duct, **Figure 46-3**.

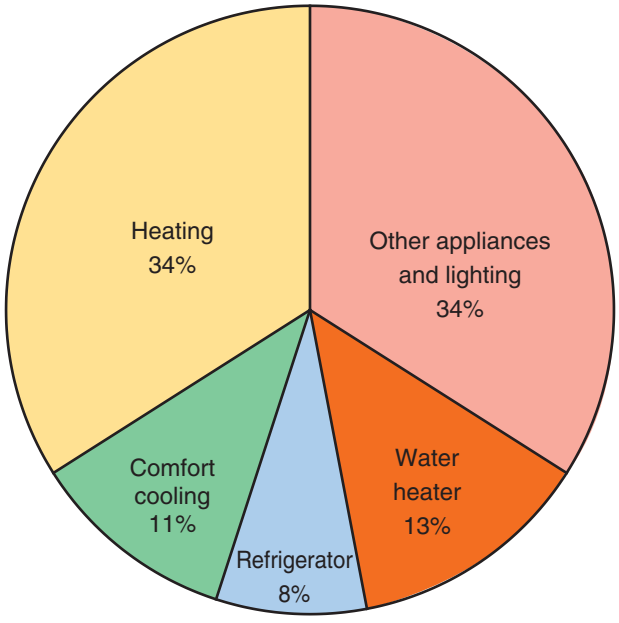
Figure 46-2. Thermal imaging of this home reveals heat leaks (red and orange areas) around windows and doors.

Code Alert

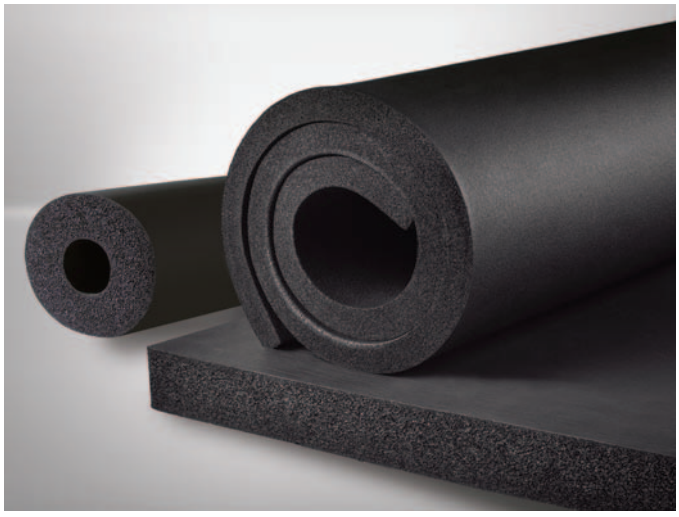
Duct Insulation

Articles M1601.3 and M1601.4.5 of the International Residential Code (IRC) cover duct insulation material and installation in one- and two-family dwellings. Local building codes specify how ductwork and system piping is to be insulated. Codes may call for all ductwork in unconditioned spaces to be insulated.



Adapted from the US Department of Energy—DOE

Figure 46-1. Pie diagram showing energy usage in a typical home. Heating and comfort cooling account for 45% (nearly half) of the total energy used.



Armacell LLC

Figure 46-3. Insulation is available in different shapes and sizes to be cut and formed around any place needed.

Copyright Goodheart-Willcox Co., Inc. 2017

An HVAC technician should have a basic understanding of common construction practices. Typical house styles include single-floor type (ranch style), two-floor type (colonial style), and a combination of both (split-level style). Each style may be built over a basement, a crawl space, or a cement slab. Each type of structure requires careful consideration when installing or servicing an HVAC system. The materials used in construction must also be taken into consideration because they have significant effects on the heating and cooling of the structure.

46.1.1 Insulation and Vapor Barriers

A large number of different insulating materials have been developed for buildings. Insulation's primary purpose is to reduce heat loss. The insulation selected should have sufficient strength to support itself and not shrink or settle. It must not deteriorate in the presence of moisture, nor should it have any unpleasant odor. The insulation should be vermin-proof and fire-resistant.

Hygroscopic (moisture-absorbent) insulation must be properly sealed. This is particularly important in cooling applications. The insulation will lose much of its insulating value if it fills up with moisture. Aluminum sheet, plastic sheet, and tar paper are popular sealing materials. Even insulation not affected by moisture should be vapor sealed.

Vapor barriers should be installed in walls. These barriers reduce the transmission of water vapor through the walls, which helps prevent the formation of condensation in the insulation. Where vapor barriers are used, they should also be sealed as tightly as possible. The barriers may be made of tarred paper, aluminum foil, or plastic film. See **Figure 46-4**.

Aluminum foil has a reflection value as well as being a vapor-tight seal. Ideally, a hermetically sealed (airtight) insulation, such as extruded polystyrene, should be used in areas where dew point temperatures occur during the heating or cooling season or where moisture intrusion is a concern. See **Figure 46-5**.

Safety Note

Working with Insulation

Always wear long sleeves, safety glasses, and gloves when working with fiberglass or cellulose insulation. A dust mask is also required when working with loose fiberglass or cellulose insulation.

The type of insulation used depends, to some extent, on the method of application. Easy-flowing bulk insulation can be blown into the space between the studs of an existing building, as shown in **Figure 46-6**.

Sue Smith/Shutterstock.com

Figure 46-6. Easy-flowing bulk insulation being blown into an attic area.

12

Copyright Goodheart-Willcox Co., Inc. 2017

Insulating foam board sheathing is commonly used on the exteriors of new construction. Batt fiberglass insulation is easy to install in new construction or in existing attic spaces. It comes in rolls and easily conforms to any irregularities in the construction. See **Figure 46-7**.

Insulating a new or existing building is one of the least expensive and easiest methods of conserving energy. Insulation is usually fiberglass or cellulose that is available in mat rolls, foam board, or loose fill. The ability of insulation to resist heat transfer is known as its R-value. A higher R-value indicates a greater resistance to heat transfer.

Photo used with permission of Owens Corning. Copyright © Owens Corning Intellectual Capital. LLC.

Figure 46-7. Flexible fiberglass roll, or batt, insulation being installed in an attic.

The amount of insulation required for a building depends on where the building is located. The US Department of Energy has developed guidelines for insulation based on climate zones. ***Climate zones*** are areas of land that are typically classified together based on common temperature ranges and yearly precipitation levels. **Figure 46-8** shows the various climate zones in the United States.

Different R-value insulation is used for specific areas of a building. These R-values are also based on climate zone. **Figure 46-9** lists the recommended R-value insulation to be used in each part of a building for each climate zone.

Modern wall construction techniques limit heat leakage and moisture passage through the wall structure. The foundation or basement walls should be protected with exterior foam board insulation and exterior sealing to prevent water intrusion. Exterior walls should be constructed of 2 × 6 framing to provide more room for insulation. Prefabricated walls that include ***structural insulated panels (SIPs)*** have a foam core between two layers of oriented strand

board or plywood. The tightness of the structure can be increased by covering the exterior walls with foam board insulation and/or an exterior housewrap, as shown in **Figure 46-10**.

To create the tightest possible envelop, any breaks in the seal should be taped or tarred. Various methods and products are available to seal breaks in an envelope, **Figure 46-11**.

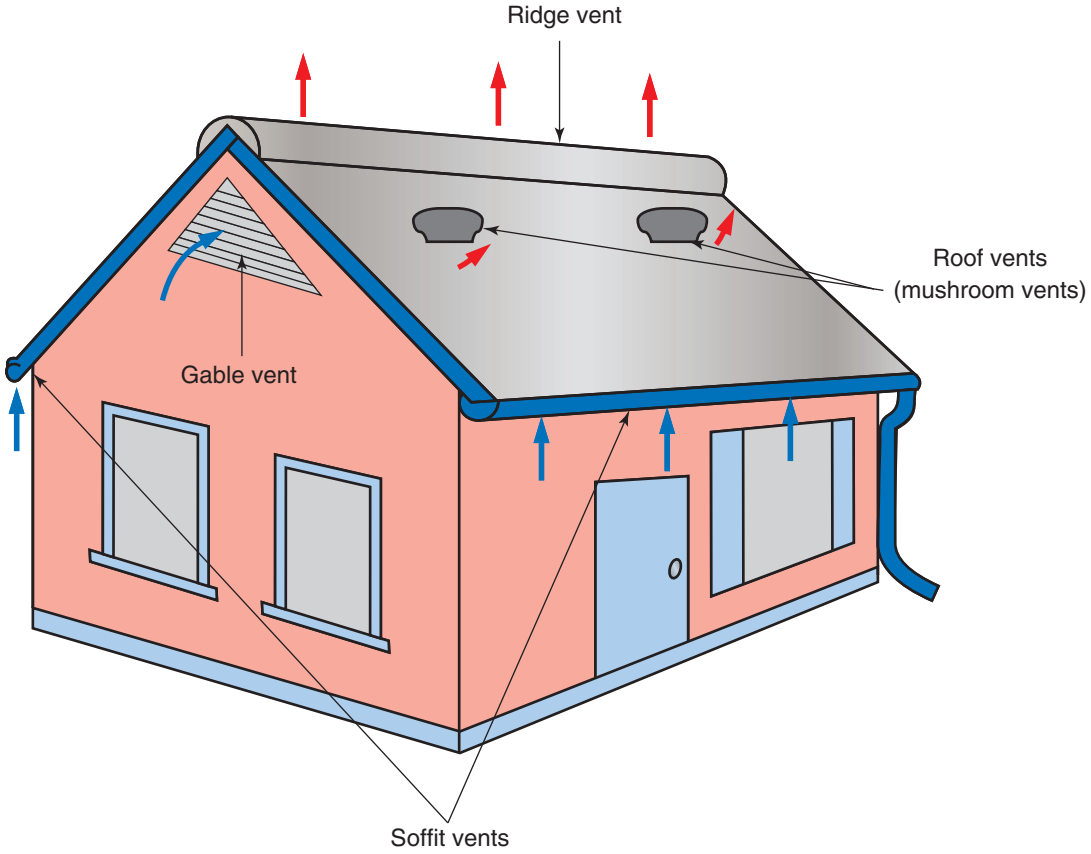
46.1.2 Roof Construction

Heat loss through the roof of a building is influenced by several factors, including the type of roof construction, ventilation, and insulation capability (R-value). Proper ventilation is important in the attic. Most attic areas are vented so that, in summer, cool air can come in through soffit vents. This air picks up heat and is exhausted through roof vents or ridge vents. Gable vents on each end of the building provide cross ventilation through the attic. See **Figure 46-12**. For more information on attic ventilation, see Chapter 29, *Air Distribution*.

The R-value of the roof also contributes to the energy efficiency of the building. The total R-value of a roof is the sum of the R-values of its individual components. For example, roof coverings (such as shingles or tiles) for pitched roofs are installed over sheathing, with insulation beneath the sheathing. The R-values of all of these items are added to find the total R-value for the roof.



Goodheart-Willcox Publisher

Figure 46-12. Attic ventilation helps to keep the attic cool in summer, which means less cooling will be needed for the conditioned areas of the building. A second use of ventilation is to help keep snow from melting on top of the roof, running down, and freezing at the overhang. An ice dam at an overhang can force water under the shingles.

46.1.3 Commercial Construction

Small commercial buildings use many of the same construction practices and materials as the residential buildings discussed in this chapter. Foundations, wall and window construction, and roof design may be similar. Small offices or retail shops are examples of these types of buildings. Buildings for small industrial firms are typically constructed in the same way as other commercial buildings.

In many instances, low-rise shopping centers have replaced individually constructed shops. These buildings are now one of the largest consumers of air conditioning and refrigeration products. Most are made of concrete block on a concrete slab. Common walls between businesses may be made of concrete block (each with its own footing) or of wood-stud construction. Both allow for floor plan changes to suit the tenants.

Concrete block construction takes much longer to heat up or cool down than wood construction. A concrete wall acts as a thermal mass, which retains heat for a long period of time. Thermal mass is discussed more fully in Chapter 44, *Solar Power and Thermal Storage*.

In the summer, it is often more efficient to begin cooling a commercial concrete block building early in the morning, prior to tenant arrival. If the building is allowed to warm up, the HVAC system will need to cool the large concrete mass and the conditioned space, which may require more energy. In winter months, the concrete block holds in the heat for longer periods of time than wood construction does. The heating system may be shut down sooner during the day, as the concrete block will release its heat to the interior of the building for a longer time.

High-rise buildings and large industrial buildings are much more complex in their construction. In these cases, you should become familiar with the general building design. Study the blueprints prior to doing any major HVAC work involving the building's structure.

46.1.4 Energy-Efficient Construction

Building homes to be energy-efficient has become a priority in recent years. The US Department of Energy (DOE) has developed guidelines for building construction to increase energy efficiency. Buildings, appliances, and HVAC equipment that meet the requirements are labeled with the US Department of Energy's ***Energy Star*** label. Energy Star–rated buildings include the following features:

- Tight construction. Buildings should have minimal air gaps to minimize infiltration and transmission of conditioned air. Unnecessary heat leakage around doors and windows should be prevented by good sealing techniques.
- High-performance windows and doors. Windows should be designed to limit heat transfer and infiltration and transmission. Energy-efficient windows usually have multiple panes of glass with an inert gas between the panes. The inert gas, such as argon, minimizes heat transfer between the glass panes. See **Figure 46-13**. Windows may also have a low emissivity (low-e) coating to block ultraviolet light.
- Metal, foam-insulated doors should be used.
- Tight ducts. Ductwork should have minimal air gaps to prevent leakage.
- Improved insulation. Increased insulation should be used where possible, especially between roof and ceiling surfaces. The resulting increase in R-value is directly proportional to energy savings from reduced heat loss.
- Energy-efficient HVAC equipment. The building's heating and cooling systems should adequately heat and cool the building with minimum energy input.

46.1.5 Determining Heating and Cooling Costs

Before suggesting changes to or replacement of an HVACR system in an existing building, it is wise to know the current cost to heat and cool the building. The degree-day method is a way of estimating fuel consumption and heating costs during the heating season and energy costs during the cooling season. This method uses previous weather records and readings during the current season to determine the average temperature of each day during the season.

The degree-day method uses 65°F (18°C) indoor and outdoor temperatures as benchmarks. A degree-day is the difference in the actual average (mean) temperature from the benchmarks. For example, suppose the average temperature outside is 15°F (–9°C). The temperature difference between the benchmark and actual temperature is 65°F – 15°F = 50°F. Therefore, that day would have 50 heating degree-days in Fahrenheit units.

Each heating degree-day requires a certain heat load to keep the inside temperature at 65°F (18°C). A certain heat load requires a certain amount of fuel to be used to produce that heat. The estimated fuel consumption per degree-day can be calculated by dividing the total fuel consumed by the number of degree-days. Knowing the number of degree-days since a fuel oil or LP tank was filled makes it possible to accurately calculate the amount of fuel left in the tank. Also, if the average number of degree-days for a heating season is known, the estimated heating cost for that season can be calculated.

The method of calculating cooling degree-days is similar. If the average (mean) outdoor temperature for a day is 85°F (29°C), the temperature difference between the day's average and the 65°F (18°C) benchmark is 20°F (11°C). Therefore, the day would have 20 cooling degree-days in Fahrenheit units. To estimate the energy used per cooling degree-day, simply divide the energy used during the season by the number of degree-days in the season.

As with any statistical average, the more data samples used to calculate the average, the more accurate it will be. In other words, using the degree-days and fuel or energy consumption for an entire season will yield a more accurate estimate than using data from a single week or even a month.

Pro Tip

Converting between Fahrenheit and Celsius Degree-Days

Occasionally, as when purchasing foreign-built equipment, it may be necessary to compare Fahrenheit and Celsius degree-days. Multiply Celsius degree-days by 1.8 to convert them to Fahrenheit degree-days. Multiply Fahrenheit degree days by 0.56 to convert them to Celsius degree-days.

46.2 HVAC Equipment Efficiency

The other factor that affects energy use is the efficiency of the existing HVAC equipment. In order to compare the efficiencies of different models of furnaces, boilers, heat pumps, and air conditioners, it is necessary to have a standardized method of calculating and expressing efficiency. Since each category of equipment relies on different operating principles and energy sources, different efficiency measurements have been developed for each category.

Code Alert

Equipment and System Sizing

Local building codes will often specify how heating and cooling systems are to be sized based on calculated heating and cooling loads. Typically, systems should have the minimum capacity required to meet the design load.

46.2.1 Furnaces and Boilers

Furnace and boiler efficiency is measured by the amount of fuel used to provide heat. The Department of Energy rating system for furnaces is the annual fuel utilization efficiency (AFUE) rating. This rating reflects the efficiency of the equipment (how efficiently it burns fuel) over an entire season. Older furnaces may have AFUE ratings as low as 55%. Energy Star–rated gas-fired furnaces must have an AFUE rating of 90% or higher for use in southern regions and 95% or higher in northern regions. Oil-fired furnaces must have an AFUE rating of 78% or higher, and oil-fired boilers must have an efficiency of at least 80%.

46.2.2 Air Conditioners

Air conditioners are rated in Btu or ton capacity. The efficiency of an air conditioner depends on how much electrical energy is required to provide the rated capacity of cooling.

Energy Efficiency Ratio

An air conditioner's ***energy efficiency ratio (EER)*** is a performance ratio that expresses a unit's cooling capacity in Btu/hr for each watt of power consumed.

Copyright Goodheart-Willcox Co., Inc. 2017

This ratio is used to evaluate an air conditioner much the same as a miles per gallon (mpg) rating is used to evaluate the fuel efficiency of an automobile. The higher the value, the more efficient the machine.

The EER is calculated by dividing the cooling output in Btu/hr by the power input in watts. These numbers are generally listed on a system's condensing unit. EER is expressed in Btu/W-hr. The formula is:

$$EER = \frac{P_o}{P_i}$$

where

P_o = cooling output under test conditions (Btu/hr)

P_i = power input under test conditions (watts)

An EER rating is calculated under a specific set of operating conditions: an outdoor air temperature of 85°F (29.4°C), an indoor air temperature of 80°F (26.7°C), and an indoor relative humidity of 50%. However, an air conditioner's cooling capability varies with outdoor temperature. As the outdoor temperature increases, the air conditioner must run for a longer time to achieve the same cooling effect. As a result, the EER rating is accurate only for the specific operating conditions under which it was measured.

Seasonal Energy Efficiency Ratio

The ***seasonal energy efficiency ratio (SEER)*** rating is similar to the EER rating, but SEER estimates the average efficiency of an air conditioner throughout the entire cooling season. It is used to describe the efficiency of refrigeration and air conditioning units sold for household use in the United States. The SEER rating is the total estimated cooling accomplished by a unit during its normal annual usage, divided by the total estimated electric energy input in watt-hours during this time.

When a unit starts, it draws locked rotor amps. Therefore, more power is consumed when the unit starts than when it is fully operational. The more frequent the cycles, the more power is used. The SEER wattage is adjusted to include the average number of starting and running cycles.

Improved energy efficiency has been mandated by the governments of the US and European Union. All new air conditioners must achieve a SEER rating of 13. Older units may have a SEER rating as low as 6. To qualify for an Energy Star rating, air conditioners must have a SEER of 15 or higher. The use of variable speed compressors, variable speed blower motors, newer refrigerant blends, and the increased use of automatic control systems have allowed systems to achieve SEER ratings higher than 20. **Figure 46-14** illustrates the data for a model with a SEER of 16.

The formula for calculating a SEER is:

$$\text{SEER} = \frac{Q_c}{P}$$

where

Q_c = Sum of all cooling outputs under all test conditions (Btu/hr)

P = Sum of all power inputs under all test conditions (W)

Pro Tip

SEER System Ratings

It is important to remember that all parts of a system contribute to a given SEER rating. If you replace a customer's condensing unit, the system may not be able to perform at the SEER rating given to that condensing unit. The condensing unit was given its SEER rating based on use with an evaporator of a certain size. If an evaporator is not replaced with the one specifically designed for the new condensing unit, the system probably will not be able to perform at its SEER rating. Connecting parts of a system based only on their nominal rating will not guarantee SEER rating performance.

Coefficient of Performance

A ***coefficient of performance (COP)*** is similar to an EER in that it is used to express the heating or cooling effect per energy input under specific operating conditions. However, in calculating a COP, the heating or cooling output and the power input are both converted to the same units before the calculation is made. As a result, the units cancel out. Therefore, a COP rating has no units associated with it.

$$\text{COP} = \frac{E_o}{E_i}$$

where

E_o = Energy output under test conditions (Btu)

E_i = Energy input under test conditions (Btu)

A COP is typically a snapshot of the system's efficiency, like an EER. However, a COP can also be used to describe the average efficiency of the system throughout a heating or cooling season. This is commonly referred to as a ***seasonal average COP***.

$$\text{Seasonal Average COP} = \frac{E_{so}}{E_{si}}$$

where

E_{so} = Total energy output for season under all conditions (Btu)

E_{si} = Total energy input for season under all conditions (Btu)

46.2.3 Heat Pumps

The efficiency of a heat pump's cooling cycle can be measured using the same efficiency ratings used for an air conditioner (COP, EER, or SEER). However, the efficiency of a heat pump's heating cycle must be measured using a coefficient of performance (COP) or a heating seasonal performance factor (HSPF). A ***heating seasonal performance factor (HSPF)*** is a measurement of how efficiently a heat pump works throughout the heating season. Whereas a heat pump's COP is a snapshot of how efficient the heat pump is under a specific set of operating conditions, the HSPF gives the consumer a better idea of how efficient the heat pump is under varying operating conditions. The relationship between a COP and an HSPF is very similar to the relationship between an EER and a SEER. An HSPF is calculated as follows:

$$\text{HSPF} = \frac{Q_h}{P}$$

where

Q_h = Sum of all cooling outputs under all test conditions (Btu/hr)

P = Sum of all power inputs under all test conditions (W)

46.3 HVAC Alternatives for Energy Conservation

Because HVAC systems account for such a large portion of energy use and utility costs, various methods of improving their efficiency have emerged. Through the use of new refrigerants, energy-efficient motors, and system balancing, the HVAC industry is continually improving the efficiency of systems and buildings.

New, energy-efficient systems are a good alternative for new construction, but facility managers in existing buildings have to consider whether installing an entirely new system is more cost-effective than revamping the existing system. Even if the new system is considerably more efficient to run, they calculate how long it would take to recoup the initial expense of a new system.

The first step toward saving energy should therefore be to take a close look at the existing system. A formal energy audit should be performed, as described in Chapter 45, *Energy Management*. The audit may identify several low-cost opportunities for saving energy, such as improving duct insulation in certain areas and fixing detected air leaks. Resolving these performance

Copyright Goodheart-Willcox Co., Inc. 2017

issues may result in a surprising increase in energy efficiency.

Code Alert

Equipment Performance Requirements

Local building codes may specify a minimum efficiency requirement for new and replacement equipment. If the components of a system are designed to work together, the efficiency rating for the system is typically available from the manufacturer. If separate components from different manufacturers are assembled on site, the system designer may need to provide calculations proving their combined efficiency.

46.3.1 Energy-Saving Components

After all of the obvious performance issues have been addressed, the next step may be to determine whether updating specific parts of the system (rather than replacing the entire system) would result in a significant reduction of energy use. Some components require only minimal installation cost, while others are more labor-intensive.

Programmable Thermostats

Possibly the easiest component to change in an existing system is the thermostat. Both residential and business customers can benefit immediately by replacing older thermostats with programmable thermostats. Programmable thermostats are discussed in greater detail in Chapter 36, *Thermostats*.

Variable Speed Motors and Variable Frequency Drives

Replacing older compressors with compressors that can operate at variable speeds can result in greater equipment efficiency and lower electrical costs. A variable speed motor is one in which the output speed can be changed based on need or other external factors.

Variable frequency drives can also be installed in certain applications to help save energy. A variable frequency drive varies the frequency and voltage of a motor to control motor speed and torque. For example, variable frequency drives can be added to pumps to intelligently adjust their motor speeds. Some larger fan motors on older HVAC units can be fitted with variable frequency drives to adjust airflow. Smaller fan motors might be replaced with an ECM (electronically commutated motor).

Heat Exchangers

In traditional HVAC systems, a large amount of energy is wasted when conditioned air is simply exhausted to the outside of the building. This energy can be recaptured and conserved with the proper equipment. Heat recovery ventilators (HRVs) and energy recovery ventilators (ERVs) are air-to-air heat exchangers. The heat of outgoing conditioned air is passed to incoming unconditioned air. This brings unconditioned air closer to indoor temperature, meaning that it will require less conditioning and less energy expended by the HVAC system.

Heat recovery ventilators (HRVs) and energy recovery ventilators (ERVs) improve system efficiency by adjusting the temperature of incoming air and conserving the energy already used in conditioning the air. These air-to-air heat exchangers are discussed in Chapter 29, *Air Quality*.

Thinking Green

Outdoor Ventilation and Heat Reclamation

Although outdoor air can be brought in to improve indoor air quality, this approach can result in considerable energy waste. The use of heat recovery ventilators (HRVs) and energy recovery ventilators (ERVs) can reduce the waste by 60%–80%.

Another type of heat exchanger is the refrigerant-to-water heat exchanger. This type can be used in domestic hot water systems in residential settings to heat the water using waste heat from an air conditioning system or heat pump. If a heat pump is used, this system can provide hot water year-round. If an air conditioner is used, the water is heated only when the air conditioner is running.

Solar Products

In residential applications, the addition of a solar water heater or solar pool or spa heater can result in significant energy savings. Also, some air-conditioning equipment is designed to be powered by the energy produced by solar photovoltaic (PV) systems. These different systems are described in more detail in Chapter 44, *Solar Power and Thermal Storage*.

Building Control Systems

As described in Chapter 45, *Energy Management*, an existing HVAC system can be integrated into an automated building control system. The building control system reduces energy costs by integrating the HVAC system with other building systems so that all of the systems run at top efficiency.

Methods of Subcooling

One method of increasing a mechanical HVAC system's capacity and energy efficiency is to increase its subcooling. This is especially beneficial when outdoor ambient temperature is high. Higher ambient

Copyright Goodheart-Willcox Co., Inc. 2017

temperature requires a mechanical HVAC system to work harder to displace heat outdoors. The harder a system must work, the more energy it must expend in operation.

An air-cooled condenser must raise head pressure to a level that corresponds with a high-side refrigerant temperature that is a certain number of degrees hotter than ambient air. Remember that a temperature difference is necessary for heat displacement. Therefore, high-side refrigerant must be hotter than ambient temperature to displace heat into outdoor air. The hotter ambient temperature is, the higher the corresponding head pressure must be. The higher the head pressure, the more amps the compressor must pull to create the high pressure. The more amps, the more the electrical power consumed during operation. The change of one variable can create a chain reaction affecting other variables, **Figure 46-15**.

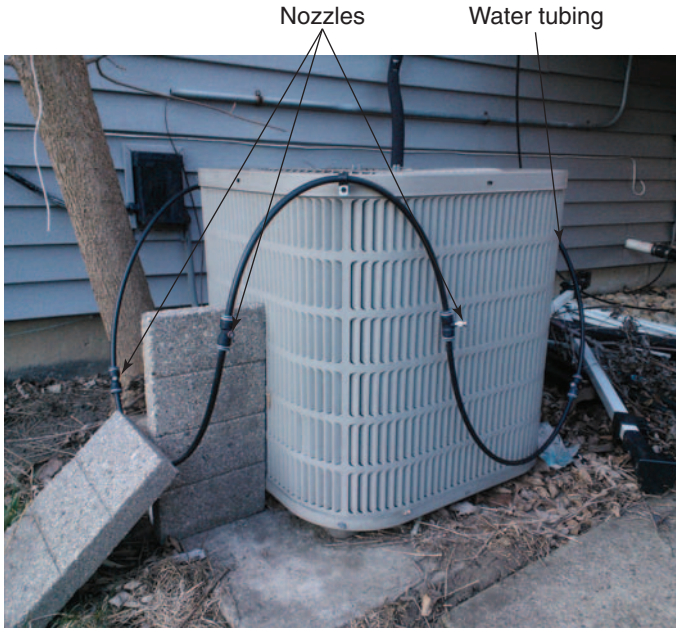
There are two primary factors to change when trying to increase subcooling. These are as follows:

- Increasing the amount of heat displaced from the refrigerant on the high side.
- Decreasing the amount of electrical power used to operate the HVAC system.

Often, these two factors can go hand in hand. There are several different methods of increasing subcooling in a mechanical HVAC system. A simple preventive method of doing this is to block the condenser from the rays of the sun. The sun transmits a tremendous amount of heat energy, and sunlight on a condensing unit is adding to the heat load. A source of shade, such as a sun barrier or a tree can help reduce the initial heat load of a system. This can help keep subcooling lower and save energy; however, adequate airflow must still be ensured for proper system operation.

Another method of increasing subcooling is to use a suction line-liquid line heat exchanger. There are different builds available for these devices. A common example is a tube-within-a-tube construction. These allow the cool suction gas of the low side and the warm liquid of the high side to exchange heat. The cooler the liquid going to the evaporator, the greater its cooling effect.

Evaporative or water cooling is another effective method of increasing subcooling. Remember that water can absorb more heat than air. In such a system, water vapor is sprayed into the condenser airways, where it evaporates and increases the amount of heat removed from the high-side refrigerant. Home kits are available using flexible tubing, nozzles, and a water pump, **Figure 46-16**.



Malcolm Prather

Figure 46-16. When this residential condensing unit cycles on, a water pump pressurizes the water line to create an envelope of mist that is drawn in through the sides of the unit. The water droplets increase the amount of heat absorbed from the refrigerant and decrease its temperature, increasing subcooling and system performance.

Chain Reaction of Factors Affecting Efficiency

Factors	Ambient Temperature Rise	Ambient Temperature Drop
High-Side Temperature	Increases	Decreases
High-Side Pressure	Increases	Decreases
Compressor Current Draw	Increases	Decreases
Electrical Power Usage	Increases	Decreases

46.3.2 Total Energy Systems

Recently, many large buildings have been constructed using "total energy" or "single energy" systems. In a ***total energy system***, all of the energy-using devices are designed to capture and use all or most of the so-called "waste" energy and by-products of combustion. Heat energy that was formerly considered waste is used to generate power. In other words, the system generates both heat and electricity in the building. Systems that produce both heat and electricity are also known as *combined heat and power (CHP)* or *cogeneration* systems. These concepts were first introduced in Chapter 34, *Absorption and Evaporative Cooling Systems*.

For example, instead of depending on the electric utility to provide both electricity and gas to a building, the building is supplied with natural gas only. The combined heat and power unit burns this fuel to produce both heat for the building and to run an electric generator to produce electricity on site.

Advantages of a total energy system include the following:

- Increased energy efficiency.
- Reduced air pollution.
- Lower utility costs.
- Reduced demand on the utility grid.

Electricity is generated using a reciprocating gas engine, gas turbine, or steam turbine. The engines drive electric generators in the building. While running, these engines produce heat that must be displaced. Water is often used to cool the engine and capture this heat, which would otherwise be wasted. Once captured, the heat can be put to another use.

Engine exhaust gas is another major heat source. A gas engine or turbine uses about 33% of its fuel energy to generate electricity. Another 30% produces heat that ends up in the water-cooling jacket. About 30% produces heat that is released in the exhaust gases. The remaining 7% produces heat that warms the lubricating oil or is lost by radiation.

Heat from the cooling jacket water, exhaust gases, and hot lubricating oil can be converted to useful purposes:

- Absorption systems often use the exhaust heat to operate air conditioning (comfort cooling).
- Exhaust heat from turbines may be used to raise the temperature of water in a hydronic heating system during the heating season.
- Heat from the water jacket can be used to furnish nonpotable hot water or with a heat exchanger to heat potable water.

A total energy system may include other aspects as well. For example, heat from the return air ducts of the heating system can be released through channels in lighting fixtures. As the cool return air passes across the lighted fixtures, the air is heated. The needed heat for that room is then supplied through a duct. The surplus heat from the lights is passed back to the primary duct system, where it can be directed for use wherever it is needed in the building.

Total energy systems are gaining in acceptance as companies and utilities strive to lessen their impact on the environment and to reduce cost. The principle has also been applied to more than just wasted heat energy. For example, large industrial plants may perform operations that generate large amounts of waste products, such as waste heat from manufacturing processes or wood chips from paper mills. In the past, these were considered necessary wastes and were disposed of. Total energy systems improve energy efficiency by using these wastes to generate useful energy, such as electricity, comfort heating, or process heating.

46.3.3 Evaporative Cooling Designs

If warm, dry air is moved rapidly over water at the same temperature, some of the water evaporates. When the water molecules evaporate, they absorb heat energy from the surrounding molecules, causing the temperature of the remaining liquid water to drop. When this natural cooling process is used to cool a space or objects, it is referred to as evaporative cooling. This cooling method is used primarily in climates with high ambient air temperatures and low relative humidity. In dry climates, evaporative cooling is both effective and practical. Evaporative cooling and roof mist cooling systems are discussed in greater detail in Chapter 34, *Absorption and Evaporative Cooling Systems*.

Ponded Roofs

In some parts of the world, buildings are provided with some summer comfort cooling by ponded roofs. A ***ponded roof*** is a flat roof that maintains 2" to 3" (5 cm to 8 cm) of standing water, which absorbs heat from the sun and dissipates that heat through evaporation. This type of cooling is well suited to commercial one-story factory and market buildings that are constructed to be able to handle the additional weight of a ponded roof. To be effective, the roof area should be as large as the floor area.

The cooling effect comes from the evaporation of water from the roof. Naturally, ponded systems are most effective in areas that have a high temperature, low relative humidity, and bright sunshine. By ponding, roof temperature may be kept below that of the surrounding atmosphere.

Ponded roofs require a means of maintaining a constant level of water on the roof. This is accomplished

Copyright Goodheart-Willcox Co., Inc. 2017

by placing the roof gutter drains at the correct height to maintain an adequate water depth on the roof. Once the water reaches this height, excess water drains from the roof. Drains are needed to take away excess water due to rain. If the roof is large, wave breakers are installed to prevent waves from forming under high winds. The waves could cause a large quantity of water to be blown off the roof edge.

A ponded roof may reduce the required air conditioning capacity by as much as 30%. However, the added weight on the roof results in higher construction costs. A ponded roof should never be added to an existing building unless the roof structure can support the additional weight of the water.

Code Alert

Evaporative Cooling

Local building codes regulate the installation of ponded roof, roof misting, and other evaporative cooling systems. The codes specify details such as acceptable roof grade, proper flashing techniques and material, proper drainage, and acceptable methods of potable water backflow prevention.

46.4 The Role of the HVACR Technician

The majority of this chapter discusses building and HVAC efficiency and provides ideas for energy conservation in general. Many of the decisions regarding building construction and HVAC specifications are not within the scope of the HVACR technician. However, there are several things technicians can do to help customers achieve better energy efficiency.

46.4.1 Know and Explain the Options

As fuel costs continue to rise and as people become more concerned about the effect of fossil-burning fuels on the environment, opportunities to educate customers increase. During routine maintenance and service calls, it is not uncommon for a building owner, manager, or resident to ask questions about the current HVAC system and to ask for suggestions for improvements in energy efficiency. A technician who keeps up with current technologies and best practices can discuss options for improvement based on the customer's specific system.

Many people believe that the cost of switching to a more energy-efficient HVAC system is beyond their financial means. The technician can help in these cases by explaining current financial incentives from the government and other sources. In addition, the technician may be able to suggest small alterations in the customer's current system that will make the system more energy-efficient, as described earlier in the chapter.

46.4.2 Perform Proper Installation and Maintenance

Even the most efficient system will not conserve energy if it is improperly installed. Be sure to follow the manufacturer's recommended installation procedure for each system carefully.

For customers who cannot afford or do not want to purchase an entirely new system, one of the most effective methods for conserving energy is to perform proper preventive maintenance. Tips for careful system maintenance include:

- Check for leaks at every service call.
- Check for acid and water in the refrigerant at every service call.
- Explain EPA Clean Air Act requirements to equipment owners as necessary to help them comply.
- Clean heat exchanger coils (evaporator and condenser).
- Maintain clean, unobstructed airways (at the air handler and the condenser).

By checking a system routinely, the technician can often find and fix problems before they become major. Not only does this help prevent potential pollution, it may also prevent expensive equipment (or refrigerant) replacement.

Chapter Review

Summary

- The energy efficiency of a building is directly impacted by its construction and materials, including insulation as well as roof and wall construction.
- A building's fuel or energy consumption per degree-day can be estimated by dividing the fuel or energy consumption by the number of degree-days. This estimated fuel consumption rate can then be used to determine fuel remaining in a tank or to project the heating or cooling cost for the season.
- Annual fuel utilization efficiency (AFUE) rating is the ratio of fuel burned to heat provided. Various ratings are used to evaluate the efficiency of HVAC equipment. AFUE is used to measure the efficiency of furnaces and boilers. EER, SEER, and COP are used to evaluate air conditioners and the cooling cycles of heat pumps. HSPF measures the efficiency of a heat pump's heating cycle.
- Energy-saving components such as programmable thermostats, variable speed motors and variable frequency drives, heat exchangers, various solar products, and subcoolers can be added to existing systems to increase their efficiency. Integrating an HVAC system into a building control system to manage operation can also increase efficiency.
- Total energy systems can be designed for use as combined heat and power (CHP) or cogeneration systems, making use of all the energy created in its different forms. This can increase energy efficiency, reduce air pollution, reduce utility costs, and reduce demand on the electrical grid.
- Although the HVAC technician usually has no direct control over system specification, the technician can contribute to energy conservation by explaining alternatives to customers when asked, installing and maintaining systems properly, and conserving refrigerant as best as possible.

Review Questions

Answer the following questions using the information in this chapter.

1. The US Department of Energy's _____ label may be used to identify buildings, appliances, or HVAC equipment that meets certain efficiency requirements.
   A. Big E
   B. Earth Saver
   C. Energy Star
   D. Tree Hugger
2. The degree-days method of determining heating and cooling costs is based on _____ as a temperature benchmark.
   A. 45°F
   B. 65°F
   C. 85°F
   D. 95°F
3. Which energy efficiency rating is used to measure the efficiency of boilers?
   A. AFUE.
   B. COP.
   C. HSPF.
   D. SEER.
4. Which of the following efficiency ratios may be used to describe the efficiency of an air conditioner?
   A. AFUE, COP, EER.
   B. AFUE, HSPF, SEER.
   C. COP, EER, SEER.
   D. COP, HSPF, SEER.
5. Under what conditions is an EER rating calculated?
   A. 65°F outdoor temperature and 70°F indoor temperature at 80% relative humidity.
   B. 75°F outdoor temperature and 75°F indoor temperature at 40% relative humidity.
   C. 85°F outdoor temperature and 80°F indoor temperature at 50% relative humidity.
   D. 90°F outdoor temperature and 75°F indoor temperature at 60% relative humidity.
6. The difference between the EER and the SEER is that _____.
   A. SEER can be used to rate furnaces and boilers
   B. SEER estimates average efficiency throughout the entire season
   C. SEER is less accurate than EER
   D. SEER units are all converted to Btu before the calculation is made

Copyright Goodheart-Willcox Co., Inc. 2017

7. Which of the following statements is true about the coefficient of performance ratio?
   A. It can be used to rate the heating efficiency of a heat pump.
   B. It has no units associated with it because the units cancel out.
   C. It is calculated by dividing output in Btu/hr by input in watts.
   D. It reflects how efficiently a furnace operates over an entire season.
8. The first step toward changing a building's HVAC system to increase energy efficiency is to _____.
   A. add random energy-efficient components if they are already in the truck
   B. evaluate the existing system
   C. install a building control system
   D. install a completely new energy-efficient system
9. The key feature of total energy systems is the _____.
   A. generating of all of its own power without any energy input
   B. use of a chemical process to generate electricity
   C. use of nuclear fusion to produce heat
   D. use of waste heat to perform a useful function
10. One of the most effective ways a technician can help a customer reduce energy costs is to _____.
   A. encourage the customer to replace the entire system
   B. perform proper preventive maintenance
   C. report the customer's energy needs to a supervisor
   D. talk trash about their old system

CHAPTER 47 Overview of Commercial Refrigeration Systems

Chapter Outline

47.1 Applications
- 47.1.1 Bakeries
- 47.1.2 Supermarkets
- 47.1.3 Other Applications

47.2 Commercial Refrigeration Systems
- 47.2.1 Commercial Cabinet Construction
- 47.2.2 Walk-In Cabinets
- 47.2.3 Florist Cabinets
- 47.2.4 Hot and Cold Merchandisers
- 47.2.5 Display Cases
- 47.2.6 Quick Chillers and Blast Chillers/Freezers
- 47.2.7 Refrigerated Dispensers
- 47.2.8 Milk Coolers
- 47.2.9 Ice Machines

47.3 Industrial Applications
- 47.3.1 Industrial Processes
- 47.3.2 Industrial Freezing of Foods

Learning Objectives

Information in this chapter will enable you to:

- Recognize the various types of commercial refrigeration systems and their applications.
- Explain how and why ice banks are used in certain refrigeration systems.
- Explain how and why air curtains are used in commercial refrigeration systems.
- Explain how quick chillers and blast chillers differ from other commercial refrigeration systems.
- Describe the two types of water coolers.
- Describe the different types of evaporators found in commercial ice machines.
- List some of the industrial applications of refrigeration systems.

Copyright Goodheart-Willcox Co., Inc. 2017

Technical Terms

blast chiller
blast freezer
cryogenic food freezing
dispensing freezer
distributed system
hot and cold merchandiser
ice bank
ice machine
locker plant
milk cooler
parallel compressor rack
passively chilled beverage dispenser
pressure dew point
processing plant
quick chiller
self-contained water cooler
tap water cooler
ultraviolet lamp
walk-in cabinet
water cooler

Review of Key Concepts

Reviewing these concepts from earlier chapters will help you understand new concepts presented in this chapter:

- Refrigerating or freezing food helps preserve freshness and product integrity. (Chapter 23)
- Refrigerating systems for food preservation use not only compressors, condensers, metering devices, and evaporators but also different heat exchangers, dampers, and defrost and condensation controls. (Chapter 24)
- Gay-Lussac's law states that at constant volume, the absolute pressure of a given quantity of a gas varies directly with its absolute temperature. In other words, when a gas is held at a constant volume, its pressure and temperature will rise together or will fall together. (Chapter 5)
- Many large food processing plants use cryogenic fluids, such as liquid nitrogen or carbon dioxide, to rapidly freeze foods. These liquid refrigerants range in temperature from –250°F (–157°C) to nearly absolute zero (–460°F or –273°C), which is the cryogenic range. Common cryogenic fluids are R-702 (hydrogen), R-704 (helium), R-720 (neon), R-728 (nitrogen), R-729 (air), R-732 (oxygen), and R-740 (argon). (Chapter 9)

Introduction

Commercial refrigeration systems vary greatly to meet their different applications. Many are high-capacity systems with aluminum and stainless steel cabinets for greater durability and ease of maintenance. Commercial refrigeration systems may also use multiple compressors, condensing units with multiple fans and flow controls, and specialized evaporators. Examples of commercial systems include supermarket refrigeration units, food display cases, refrigerated beverage and ice cream dispensers, and ice machines.

Copyright Goodheart-Willcox Co., Inc. 2017

47.1 Applications

Commercial refrigeration systems can be found in many types of businesses. Since refrigeration systems can be designed to achieve and maintain a variety of temperature ranges at different rates and efficiencies, they have been incorporated into the day-to-day work of numerous commercial operations.

47.1.1 Bakeries

Many raw products used by bakeries must be refrigerated to preserve or improve quality. Bakeries must refrigerate perishable raw materials, perishables during interrupted processing, and finished products, **Figure 47-1**.

Frozen ingredients must be stored. Even water and flour used for bread making require cooling during certain periods of the year. Health codes require these practices. Creams and custards can last longer when at a cool temperature.

Both medium-temperature and low-temperature refrigeration is used. Normal refrigeration is suitable for butter, eggs, coconut, cream, fat, meat, margarine, nuts, and yeast and also for dough retardation (controlling length and strength of fermentation). Low-temperature systems are needed to freeze baked goods that are sold frozen. For example, bread that is fast-frozen to –1°F (–18°C) will remain fresh for almost a month.

Controlled temperature and humidity are important in many baking processes. Therefore, air-conditioning equipment is also used in bakeries.

Traulsen Refrigeration

Figure 47-1. This type of refrigerated cabinet can easily be used in bakery applications. It has a top-mounted condensing unit.

47.1.2 Supermarkets

In the United States, the FDA Food Code and its supplements set requirements for food storage equipment, whether in bars, restaurants, grocery stores, or wholesale distribution warehouses. It is important that the food temperature be at or below 41°F (5°C) at all times. As equipment has become more efficient, operating temperatures for discharge and return air have risen. For example, for reach-in merchandisers manufactured in 2010, the evaporator air temperature was 27°F (–2.8°C), and the discharge air temperature was 32°F (0°C). By comparison, for reach-in merchandisers manufactured in 1990, the evaporator air temperature was 23°F (–5°C), and the discharge air temperature was 30°F (–1.1°C).

A supermarket will have a mix of reach-in displays with different arrangements and multiple decks. These units will refrigerate dairy, produce, fresh meat, salads, and delicatessen meats and cheeses. A supermarket reach-in case may have multiple doors. Doors and door frames are chosen separately from the case. A door is typically 30″ × 67″ for standard height or 30″ × 75″ for tall cases, **Figure 47-2**.

The location of the coolers, freezers, reach-ins, and other types of refrigeration units will vary with each supermarket installation. The layout of the store factors into what type of unit may be used. The condensing unit may be split from the cooling cabinet and located remotely, or the condensing unit may be packaged with the rest of the refrigeration system. When packaged as a single unit, the condensing portion of a system is usually located in the top or the base of the cabinet. A forced-draft evaporator installed inside the cabinet connects to a forced-draft condenser outside the cabinet. Larger installations may use multiple condensing units. These condensing units may be located on top or in the back of the unit, in a separate area of the building, or outside the supermarket on a pad or on top of the roof, **Figure 47-3**.

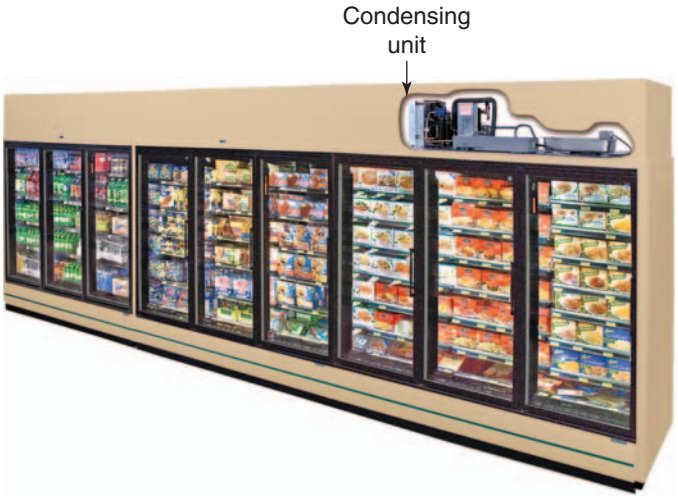
Figure 47-2. Supermarkets frequently connect several display cases in a row to form aisles.



A

B

Zero Zone, Inc.

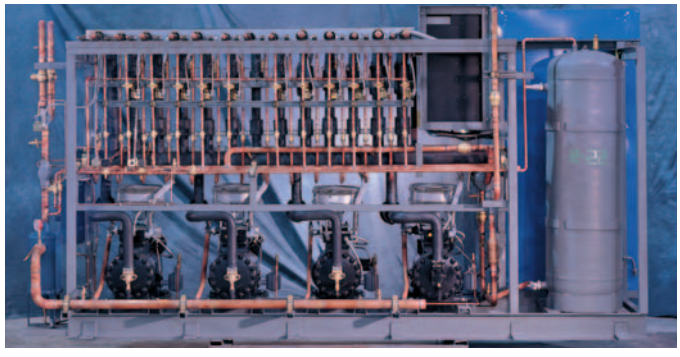
Figure 47-3. A—Large display case with a condensing unit mounted on top and out of sight of customers. B—Top-mounted condensing unit.

A ***parallel compressor rack*** is an arrangement of compressors piped in parallel with a common suction line, a common liquid line, and a common liquid receiver. It is the central part of a multiple-compressor refrigeration system. **Figure 47-4** shows a parallel compressor rack with four compressors piped in parallel.

Each display case connected to a parallel compressor rack has its own evaporator and refrigerant metering device. The unit shown uses a microprocessor control system to operate the units for maximum efficiency. The compressors may all run at the same time for high-load conditions or be cycled to provide refrigeration during low-load conditions.

Parallel compressor racks are often located away from the display cases and refrigerated spaces to which they connect. Often these compressors and equipment are located in a machine room in the back of the store or on the roof. The machine room may include multiple condensing units that were provided prewired and piped. Machine rooms are designed with their own ventilation, lighting, energy management, and electrical systems. The compressors and condensers are piped and wired to the various food display cases and walk-in coolers located inside the supermarket, **Figure 47-5**.

Another option is to install equipment as close as practical to the refrigerated cabinets. The compressors can be placed near the conditioned spaces, such as at the end of an aisle of display cases in a supermarket. A ***distributed system*** is a unit containing multiple compressors that circulate refrigerant through the evaporators in a nearby conditioned space, such as reach-in coolers or display cases. A distributed system typically contains only compressors and their controls. A distributed system is usually connected to a remote condenser located elsewhere. This remote condenser is often an air-cooled unit directly above on the rooftop. In some cases, a distributed system may contain a water-cooled condenser.



Hill Phoenix, Inc.

Figure 47-4. Note the use of a liquid line receiver on this commercial mechanical rack of four compressors in parallel.

13

Copyright Goodheart-Willcox Co., Inc. 2017

A distributed system's compressors operate in a multiplexed manner (common discharge line and common suction line) to refrigerate a row of coolers containing products, such as produce, dairy, or frozen food, **Figure 47-6**. As the temperature of one or more of the products is satisfactory, the compressor or compressors are cycled off to match the capacity of the refrigeration system to the coolers. The primary benefit of distributed systems is a 65% to 75% reduction in refrigerant charge. This reduced refrigerant charge is cost-effective. Additional benefits include flexibility in installation and controls.

47.1.3 Other Applications

Heating, cooling, preserving, and freezing food, drinks, and other products are a major part of numerous businesses. Many of the refrigeration systems used in bakeries and supermarkets can be found performing in similar situations in restaurants, pharmacies, convenience marts, and other businesses. Refrigeration systems with special temperature and humidity controls are also used in florist shops, laboratories, hospitals, and funeral homes. Refrigeration systems used in different applications for different purposes vary in their controls, operating components, and capacity, **Figure 47-7**.

Hill Phoenix, Inc.

Zero Zone, Inc.

Figure 47-6. Opening the front panels reveals several multiplexed compressors and their controls. Distributed systems may be used to operate multiple produce, dairy, meat, or frozen food merchandisers.

47.2 Commercial Refrigeration Systems

The type of refrigeration system installed depends on the conditions that must be maintained. Owners and installers must consider the amount of product that must be refrigerated, the space required to fit the unit, the temperature and humidity set points, the amount of heat that will be introduced throughout the day, and related factors. Some commercial refrigeration systems are prebuilt for specific applications. Others must be custom-made.

Figure 47-7. A—A refrigerated preparation table keeps pizza and sandwich ingredients cool, fresh, and readily available for restaurant orders. B—Refrigerated mortuary body boxes are used to prevent deterioration of the deceased.

47.2.1 Commercial Cabinet Construction

Commercial cabinet surfaces are either metal or plastic. Finishes are designed for easy cleaning. Structural members are steel, capable of supporting the evaporator and condensing unit. Insulation is usually polystyrene or urethane in slabs or foamed in place.

The capacity of the evaporator and condensing unit must be adequate for the required application. Refrigeration should be possible under the most severe service conditions. In some cases, heat leakage may cool the cabinet surfaces enough to cause moisture to condense on them. To avoid this condition, some cabinets have a resistance heating strip. The strips are located around certain outer surfaces to warm them and prevent condensation from forming.

Many commercial refrigeration cabinets are designed to be used with a remote condensing unit. These condensing units may be simultaneously connected to several refrigeration cabinets of different temperatures. Most commercial refrigeration condensing units are air-cooled, but some are water-cooled.

Temperature Alarm Systems

In some installations, such as food freezers, an electrical alarm system will sound if the temperature in the cabinet rises above an upper safe limit. These systems sometimes operate from the electrical circuit powering the compressor. Others are provided with a battery arrangement. If the batteries are in good condition, the alarm will work even during a power failure.

Ice Banks

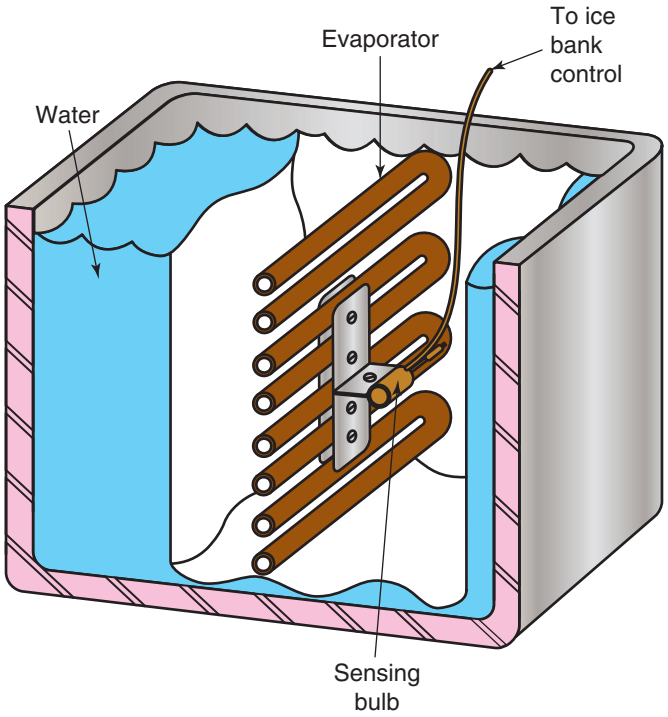
Many types of coolers, vending machines, and other medium-temperature commercial refrigeration systems use ice banks to provide reserve cooling capacity. During periods when the system cooling demand is low, an ***ice bank*** (solid block of ice) forms around the evaporator. When demand increases, the ice bank is able to absorb much of the heat and prevent the refrigeration system from being overloaded, **Figure 47-8**.

A typical system of this type is found in some drink dispensers. Ice builds up during periods of low activity. This ice is then used to cool beverages during periods of high activity. Another use for this type of refrigeration is in an air-conditioning system used on a periodic basis (such as a church building).

A control is needed to limit the amount of ice that is formed. A conventional temperature control cannot distinguish between ice and water, since either can exist at 32°F (0°C). An ice bank control must be used.

Older ice bank controls use a sensing bulb with two compartments divided by a membrane. One side contains water. When frozen, the water expands and flexes the membrane. The other side contains a liquid that transmits

Copyright Goodheart-Willcox Co., Inc. 2017



Invensys Climate Controls Americas

Figure 47-8. In this ice bank, a sensing bulb monitors temperature and pressure. If the temperature is below 32°F, the ice bank control turns the compressor off. If the temperature is at 32°F, the bulb senses a pressure increase due to ice crystals forming in part of the bulb. Then the control also turns the compressor off.

the membrane movement up to the head of the sensing bulb. This movement operates a control switch that turns off the compressor. With the system off, some of the ice is allowed to melt. The cycle for making and detecting ice can then begin again. These bulb-type ice bank controls are still sold and in use to some extent.

A modern ice bank control senses the electrical conductivity between a set of stainless steel electrodes and modifies its output accordingly. The electrodes are used to measure the thickness of the ice and control the level of liquids. Ice bank controls are used in a small refrigeration system to provide a greater than normal refrigeration capacity for set periods of time during peak demand. Ice bank controls are typically used in vending machines, milk coolers, beer coolers, and similar systems.

47.2.2 Walk-In Cabinets

Many restaurants and supermarkets store perishable items in ***walk-in cabinets***, which provide a large commercially refrigerated space for various products. These cabinets have large doors and sometimes windows. Walk-in cabinets may be referred to as *butcher boxes*, **Figure 47-9**.

Sizes of walk-in cabinets vary. However, two heights are usually considered standard: 7′-6″and 9′-10″ (2.3 m and 3 m) outside dimensions. The dimensions of other walk-in cabinet sizes are listed in **Figure 47-10**.

Many cabinets are made with metal linings and exteriors. The usual metal is galvanized steel or aluminum. Vinyl, porcelain, and stainless steel are also used extensively. Cabinet doors are usually of the same construction as the box. They are lined with gaskets to make the box airtight. Door latches must be accessible from inside a cabinet for safety, **Figure 47-11**. The doors may also be provided with heating wires along the edge. These wires eliminate sweating and freezing. Often these heating wires are called mullion heaters.

Some walk-in cabinets are dual-temperature units. They have a compartment to keep food cold (about 40°F) and a compartment to keep food frozen (below 0°F).

Cabinets may have additional reach-in doors, usually with two, three, or four panes of glass. Instead

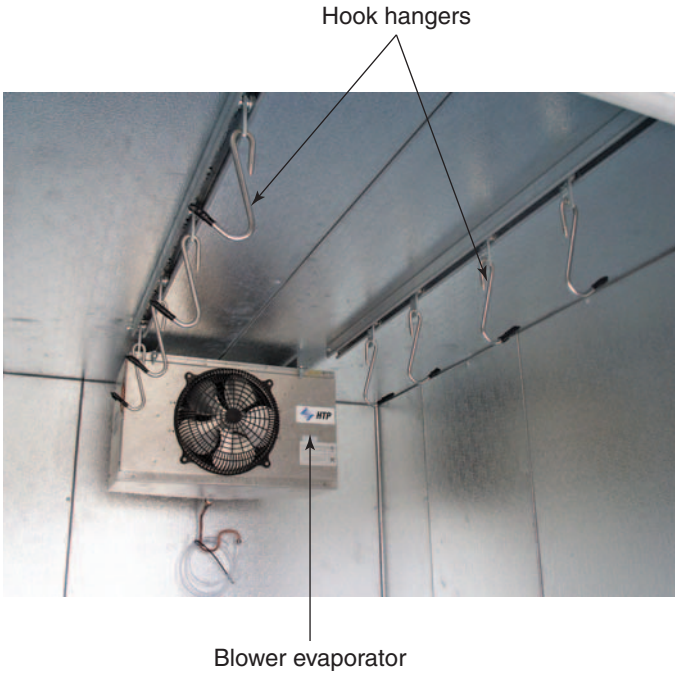
of insulation, these doors have two or three dead-air spaces arranged in such a way that they are airtight. Plate glass is usually used. Special chemicals, such as calcium chloride, keep the spaces between the panes free from moisture.

Most walk-in cabinets now use foamed-in-place insulation of rigid polyurethane. Foamed between the inner and outer walls, such insulation produces a strong wall. The insulation eliminates the need for metal framing. Insulation is usually 4″ (10 cm) thick. Floors are also insulated to prevent heaving from underlying frost.

Walk-in cabinets usually have a lighting system. Some have a wall-mounted evaporator that is separated from the main part of the cabinet interior by a vertical baffle. Forced-draft evaporators are popular, **Figure 47-12**.

The temperature of a walk-in cabinet depends on its use. For meat or fresh produce storage, a temperature between 35°F (2°C) and 40°F (4°C) is needed. Relative humidity should be about 80%. Air movement is necessary. ***Ultraviolet lamps*** may also be used to help control bacteria and mold growth, **Figure 47-13**.



U.S. Cooler Company

Steril-Aire

Figure 47-13. The blue glow from ultraviolet lamps floods these evaporators with protection from undesirable biological growth.

Caution

Ultraviolet Light

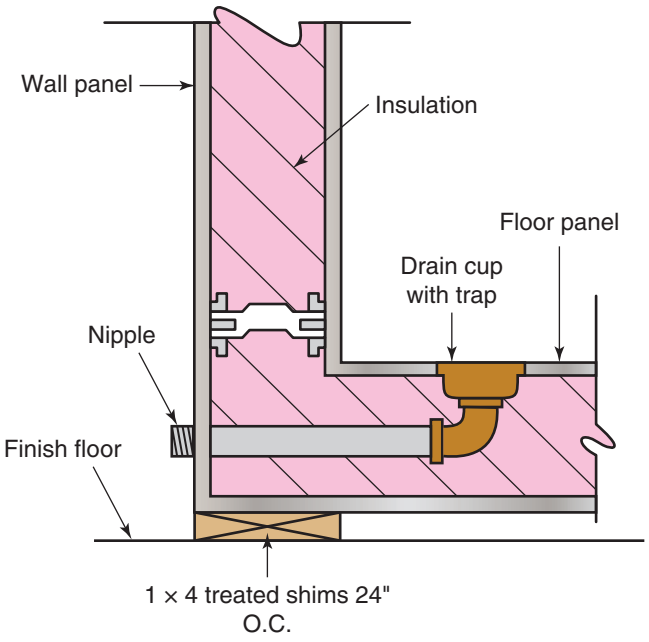
Overexposure to ultraviolet rays is dangerous. Therefore, people working near these lamps must be protected from the rays. Otherwise, the lamps must be turned off when anyone is in the cabinet.

13

Copyright Goodheart-Willcox Co., Inc. 2017

Some type of drain is recommended for walk-in cabinets. **Figure 47-14** shows a common drain installation method for a prefabricated walk-in that is located on a permanent floor.

In systems where dehydration of foods is not important, colder temperatures may be used. Less attention may be paid to relative humidity. Examples of this are milk storage and beverage cooling. Forced-draft evaporators are commonly used in these installations. Walk-in cabinets (walk-in freezers) are also used for storing frozen foods.



Goodheart-Willcox Publisher

Figure 47-14. Note that the connection of this walk-in cabinet drain is part of the prefabricated bottom section.

47.2.3 Florist Cabinets

Florist cabinets form a unique market in the refrigeration industry. Display cabinets are often the focal point of the entire retail operation, both in cabinet design and product presentation. See **Figure 47-15**.

Florist cabinets differ from food service cabinets in the following ways:

- Humidity is important in maintaining a long life for the floral items.
- Because many floral items are fragile, only low-velocity air evaporator coil designs are used. Proper equipment sizing allows for warm air defrost.
- Floral cabinets use large amounts of glass in their doors and windows. The additional heat loads from these components must be taken into account when sizing the equipment.
- The lighter product load of floral equipment should be a factor when determining a final Btu/hr load requirement.

The Society of American Florists (SAF) recommends a storage temperature range between 34°F and 38°F (1°C and 3°C) with 80%–90% humidity. Due to the delicate nature of flowers, the upper ranges of this temperature range are recommended to avoid product loss. Humidity levels above 90% can cause condensation, which may create a mold infestation.

Cabinet walls and ceiling panels should be well insulated with a minimum of R-22 value insulation. A vapor barrier between the cabinet and outside wall must be designed to prevent condensation on outside walls. Insulated floors, while not required on grade level applications, do provide energy savings. They are required if any cavities exist under the floor on which the cabinet rests. Glass doors should be rated for operation in a refrigerated application. Glass panels should be of thermal-pane construction, and glass heat will be required if ambient store conditions will not be properly maintained. Due to the high humidity present, all internal shelving should be constructed of nonabsorbent, corrosion-proof material. All drain lines must be trapped to allow for free flow of condensate water to an approved drain, and to eliminate negative pressurization of the evaporator coil.

Figure 47-15. A florist's refrigerated display cabinet with pass-through glass doors, lighting, and low-velocity evaporator coils.

Ethylene gas is a naturally occurring hormone produced by all plant tissue. It is an odorless gas that accelerates the aging process in flowers and plants. This causes up to 30% of loss, due to shrinkage, in the floral industry. Improper temperature and humidity accelerate the production of ethylene gas. Signs of ethylene damage include discoloration, wilting, spotting, and the dropping of petals and leaves. Ethylene gas filters (EGF) are formulated with a natural mineral compound. These filters trap and neutralize the gases. Replace EGFs every 120 days, **Figure 47-16**.

Figure 47-16. Ethylene gas filters (EGF) decrease damage due to ethylene in floral cabinets.

Alto-Shaam, Inc.

Figure 47-17. Unit designed to warm items in the upper section while cooling the items in the lower section.

47.2.4 Hot and Cold Merchandisers

The combination of both hot food holding and cold food refrigeration in one unit is called a ***hot and cold merchandiser***. The heated upper section uses a gentle, uniform heat source, providing better moisture retention, appearance, and a longer holding life of food. The upper canopy includes a sneeze guard for an extra measure of safety, while overhead heating and lighting illuminates the product display. The lower refrigerated display base may be used for packaged side dishes, soft drinks, and precooked entrees, **Figure 47-17**.

47.2.5 Display Cases

Refrigerated display cases are used by merchants to provide ease of shopping and to promote their products. These cases have a top or side opening through which customers can see and access the items. At the same time, the food is kept safely refrigerated behind glass doors or air curtains. Display cases are often used for fresh produce, frozen foods, fresh meats, and dairy products, **Figure 47-18**.

Courtesy of Sporlan Division - Parker Hannifin Corporation

Figure 47-18. An assortment of refrigerated display cases.

13

Copyright Goodheart-Willcox Co., Inc. 2017

The location of display case evaporators may be overhead, on an end, or at the base. These evaporators must be narrow to allow for maximum conditioned cabinet space. The evaporators are made with fins as small as 1 1/4″ (32 mm) wide. Some of the shelf evaporators are plain tubing. Display case evaporators are usually connected in series.

Many display cases are now using forced-draft evaporators for cooling, since these require little space. Because of the circulating air, they provide even refrigeration temperatures throughout the display case. Higher temperature cases are used for fresh meats and dairy products. In order for frozen food display cases to maintain temperatures near 0°F (–18°C), the evaporators must operate at –10°F to –15°F (–23°C to –26°C). Temperature settings are based on the contents in a display case. **Figure 47-19** shows the recommended temperature for some common applications.

The need to maintain a low temperature presents an evaporator defrosting problem. The evaporator must be defrosted at least once a day. This must be done quickly to prevent the case from getting too warm. The defrosting is often done automatically with a timer signaling the system to perform hot-gas defrosting or to energize an electric heat defrosting device. See Chapter 21, *Heat Exchangers*, for details concerning defrosting methods and controls.

Display cases vary in design, length, and height. They can be designed as upright cabinets or as chests. Both of these designs can be made as one of the two general types:

- Glass-enclosed display case.
- Open display case.

Glass-Enclosed Display Cases

Glass-enclosed display cases may be designed as a chest or an upright cabinet, **Figure 47-20**. Some cases have additional refrigerated storage space beneath the display section of the counter. Such cases usually serve as a temporary container for food or produce. Those contents are then transferred to a walk-in cabinet overnight. Therefore, temperatures may be kept at 40°F (4°C) to 45°F (7°C) in both compartments.

The low temperatures used in storing and displaying frozen foods in glass-enclosed cabinets may cause moisture to condense on the glass and obstruct the view. In order to stop condensation, heater wires are installed along those parts of display cases where condensation from the air might collect.

Open Display Cases

Chest-style open display cases have an opening on top that provides access to the refrigerated products

Display Case Temperatures

Type of Fixture	Temperatures	
	Minimum[a]	Maximum[b]
Dairy		
Multideck	36°F	38°F
Produce, Packaged		
Single-Deck	35°F	38°F
Multideck	35°F	38°F

Multideck	[c]	–10°F[d]
Glass Door Reach-in	[c]	–5°F[d]
Ice Cream		
Single-Deck	[c]	–24°F[d]
Multideck	[c]	–12°F[d]

[a]These temperatures are air temperatures, with the thermometer in the outlet of the refrigerated airstream and not in contact with the product displayed.

[b]Unwrapped fresh meat should only be displayed in the closed, service-type display case. The meat should be precooled to 36°F internal temperature prior to placing on display. The case air temperature should be adjusted to keep the internal meat temperature at 36°F for minimum dehydration and optimum display life. Display case air temperature varies with manufacturer.

[c]Minimum temperatures for frozen foods and ice cream are not critical (except for energy conservation); maximum temperature is important for proper preservation of product quality.

[d]The differences in display temperatures among the three different styles of frozen food and ice cream display cases are a result of the orientation of the refrigeration air curtain and the size and style of the opening. The single-deck has a horizontal air curtain and opening of 30″. The open multishelf has a vertical air curtain and opening of 42″ to 50″. The glass door reach-in has a vertical air curtain protected by a multipane insulated glass door.

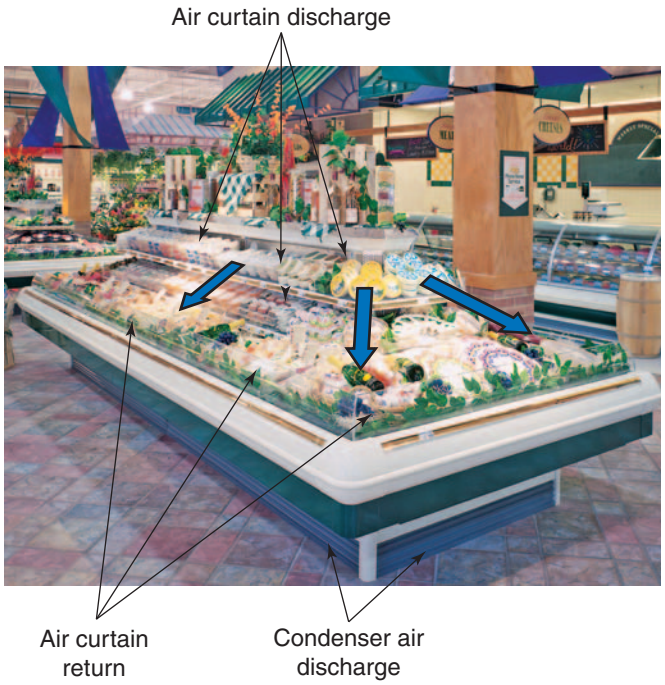
inside. The walls, or the upper part of the walls, may be enclosed in three to four layers of glass, **Figure 47-21**. Evaporators are usually below the conditioned space with ducts circulating chilled air, **Figure 47-22**.

Upright cabinet-style open display cases use forced-draft evaporators to distribute cold air through ducts. These ducts connect to grilles at the rear of the case that may be at the level of the refrigerated products or above the products. The warm air returns down the front of the case.



Hill Phoenix, Inc.

Figure 47-21. Multilevel open display case using a refrigerated air curtain to maintain low temperatures and separate its contents from ambient air.

Many supermarkets have upright cabinet-style open display cases for produce. These cases are kept at about 40°F (4°C) and at a high humidity level. If dry air circulates over the contents, some of the moisture will be removed. This dry air spoils the appearance and decreases the weight of the produce. To keep humidity high, misting systems are often installed in open display cases, which include nozzles that spray water droplets over the produce, **Figure 47-23**. Produce that is sensitive to humidity includes cabbage, celery, carrots, radishes, herbs, and leafy greens, such as kale, chard, cress, and collard greens.

To maintain a low-temperature, high-humidity atmosphere, produce is isolated from ambient air using an air curtain. An air curtain is a stream of air that blows between a conditioned space and an unconditioned space to isolate the two spaces. Some cabinets use two or three air curtains. The principle of operation is shown in **Figure 47-24**.

Open display cases must be protected from drafts produced by grilles, unit heaters, and fans. Drafts will interfere with the air curtain of the case. This will cause higher operating costs and defrosting problems. Since several open display cases are usually connected end-to-end in supermarkets, the total electrical load must be carefully checked to see if it will provide enough service to avoid any overloads.

47.2.6 Quick Chillers and Blast Chillers/Freezers

Food preparation and food safety are extremely important aspects of health and human safety. Refrigeration continues to play a significant role in reducing health-related problems due to bacteria or

13

Hill Phoenix, Inc.

Figure 47-22. Notice the air curtain across the top of this open frozen foods case.

mold growth in foods. Cases of food poisoning around the world are often the result of improper food preparation and storage.

The US Department of Agriculture (USDA) has issued guidelines on food preparation and storage. The USDA requires hot foods to be cooled to 70°F (21°C) within two hours and then to 41°F (5°C) within the next four hours. It is critical that food not be cooled too slowly or too quickly. Cooling the food too slowly will allow the growth of bacteria. If food is cooled too rapidly, there will be a loss of flavor.

Controlled rapid cooling of foods is necessary to meet these requirements. In large kitchens, such as cafeterias and banquet halls, mass quantities of food are cooked in advance and stored for future use. Hot food must be brought from its oven temperature of up to 450°F (232°C) down to 70°F (21°C) within two hours. It must then be cooled to 41°F (5°C) within the next four hours. This type of cooling is performed by a quick chiller or blast chiller.

Standard refrigerators and freezers are designed to operate as refrigerated storage cabinets. They are not designed to displace the heat load required to safely and quickly lower the temperature of hot, cooked foods. Placing cooked food in a standard refrigerator or freezer could cause its compressor to operate continuously to remove the high heat load. Continuous operation could cause a standard refrigerator-freezer's evaporator to become frosted, which reduces heat transfer efficiency. A standard refrigerator-freezer's defrost function would stop the compressor to defrost the evaporator, which would prolong the cooling of the cooked food. Unlike standard refrigerator-freezers, quick chillers and blast chillers are designed to handle the large heat load required to cool hot, cooked food.

A ***quick chiller*** is a type of refrigeration system that cools hot food rapidly and uniformly without freezing the product. Bacteria and germs can grow and spread quickly in the temperature range of 40°F to 140°F (4°C to 60°C). Food products are much safer from bacteria and germs at temperatures below 40°F (4°C)

Hussmann Corporation

Figure 47-24. Upright frozen foods display case has three air curtains, each flowing at a different speed.

and above 140°F (60°C). To safeguard food products and consumers, the cooling process must be carefully controlled using a quick chiller, **Figure 47-25**.

Like a quick chiller, a ***blast chiller*** cools hot food rapidly and uniformly without freezing the product. However, a ***blast freezer*** cools and *freezes* hot food rapidly and uniformly. An alternative name for blast freezer is *shock freezer*. Some units can be programmed to function as either blast chiller or blast freezer, **Figure 47-26**.

Modern quick chillers and blast chillers/freezers use microprocessor controls for chilling, defrosting, and maintaining food temperature. Many units also have keypads and built-in printers. These controls and options may be used to record food-cooling operations and provide a printed report of system operation. Some chilling units use temperature probes that are inserted into the food. The temperature probes provide accurate measurement of each tray of food placed in the cabinet.

47.2.7 Refrigerated Dispensers

Refrigeration systems are often incorporated into food and drink dispensing machines. Such systems cool and prepare products for convenient and immediate consumption. These machines are extensively used in restaurants and cafeterias.

Copyright Goodheart-Willcox Co., Inc. 2017

Traulsen Refrigeration

Figure 47-25. This undercounter quick chiller is capable of rapidly and uniformly cooling hot food in two hours or less. Note the microprocessor control.

Beverage Dispensers

Many restaurants, convenience stores, and fast-food establishments use beverage dispensers to dispense both carbonated and noncarbonated soft drinks. These generally fall into two categories, passively chilled and mechanically chilled. Industry standard is for the delivered beverage to be 40°F (4°C) or below.

Passively chilled beverage dispensers transport syrup and water through stainless steel tubing that is surrounded by the same ice that is dispensed for individual drinks. The tubing is encased in an aluminum cold plate that is situated at the bottom of an insulated bin filled with ice. The ice provides for both chilling of the product (through heat exchanged from the cold plate to the ice) and for being served with the individual drink.

There are two ice options for passively chilled beverage dispensers:

- A mechanism that automatically dispenses ice on demand.
- Manually scooping ice from the bin.

The automatic type is typically equipped with an ice machine installed on top of the unit that dispenses ice directly into the ice bin, to provide for a constant supply of ice, **Figure 47-27**. The manual type requires ice to be loaded into the ice bin by hand, **Figure 47-28**.

For mechanically chilled beverage dispensing equipment, syrup and water pass through stainless steel tubing located in an insulated water bath. The refrigeration system's evaporator coil is also immersed in the water bath. Heat from the syrup and water is absorbed into the water bath, and the refrigerant in the evaporator coil absorbs heat from the water bath. For more information on these types of evaporators, see Chapter 21, *Heat Exchangers*.

Traulsen Refrigeration

Figure 47-26. This blast chiller's condensing unit is in its base. Controls and a report printer are along its side.

In operation, the coil becomes covered with 3″ to 4″ (76 mm to 100 mm) of ice across its entire surface, providing for the cooling of the water bath (32°F to 34°F, 0°C to 1°C). A motor agitates the water constantly, keeping colder water in contact with the product tubing to allow for heat exchange. The compressor is controlled by a device that senses the size of the ice bank, not the temperature of the water bath. This device

Lancer Corporation

Figure 47-28. A passively chilled beverage dispenser with a bin where the ice is stored.

switches the compressor off to prevent the ice bank from coming into contact with the product tubing. It will then switch the compressor on when the ice bank has been depleted from absorbing heat due to product being dispensed.

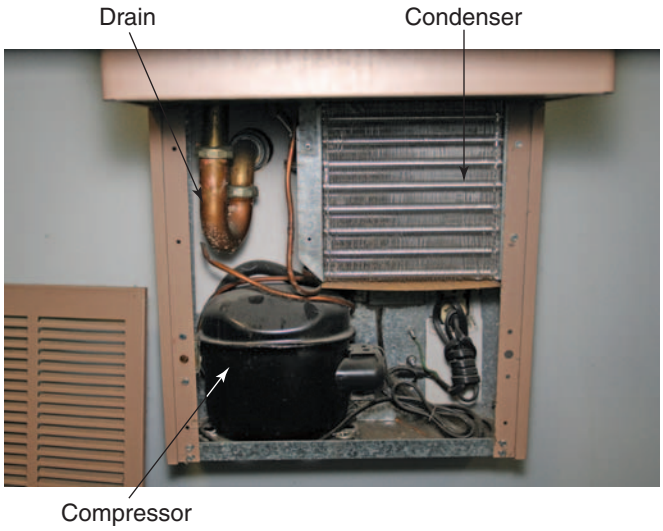
Mechanically chilled equipment is generally sized by compressor capacity, which ranges from 1/4 hp to 3/4 hp (186 to 560 watts). As a rule, these systems use capillary tubes as opposed to expansion valves. Refrigerant charge amounts are usually less than 1 lb (454 grams), making for a delicately balanced system.

Water Coolers

Water coolers are refrigeration units designed to cool and dispense drinking water. Water coolers chill water using mechanical refrigeration. Evaporator tubing absorbs heat from the dispensing water. This heat is expelled through a condenser into ambient air. The water-cooling section containing the evaporator is insulated. Removing an access panel from a unit reveals a small hermetic compressor, a condenser, and controls, **Figure 47-29**.

Since the cooling demand on water coolers is very irregular, they must have some hold-over capacity. However, they must not overcool the water. Hold-over capacity is provided either by using a large insulated cooled water storage tank or having a large water-cooling surface in the evaporator that quickly chills water.

Different water cooler models are used in different applications. In many schools, hospitals, and businesses, plumbed tap water coolers are used and commonly called *drinking fountains*. In office buildings



Goodheart-Willcox Publisher

Figure 47-29. A water cooler usually contains a small hermetic compressor and small condenser for the low heat load it handles.

Copyright Goodheart-Willcox Co., Inc. 2017

and homes, self-contained or standalone (with no plumbing) water coolers are used and commonly called *water coolers*.

A ***tap water cooler*** is a water cooler that has a plumbed water supply and drain connections. A tap water cooler's supply and drain connections must be installed according to local codes. The plumbing should be concealed. A hand shutoff valve should be installed in the water supply line. A drain pipe, at least 1 1/4" (3 cm) in diameter, should be provided.

Code Alert

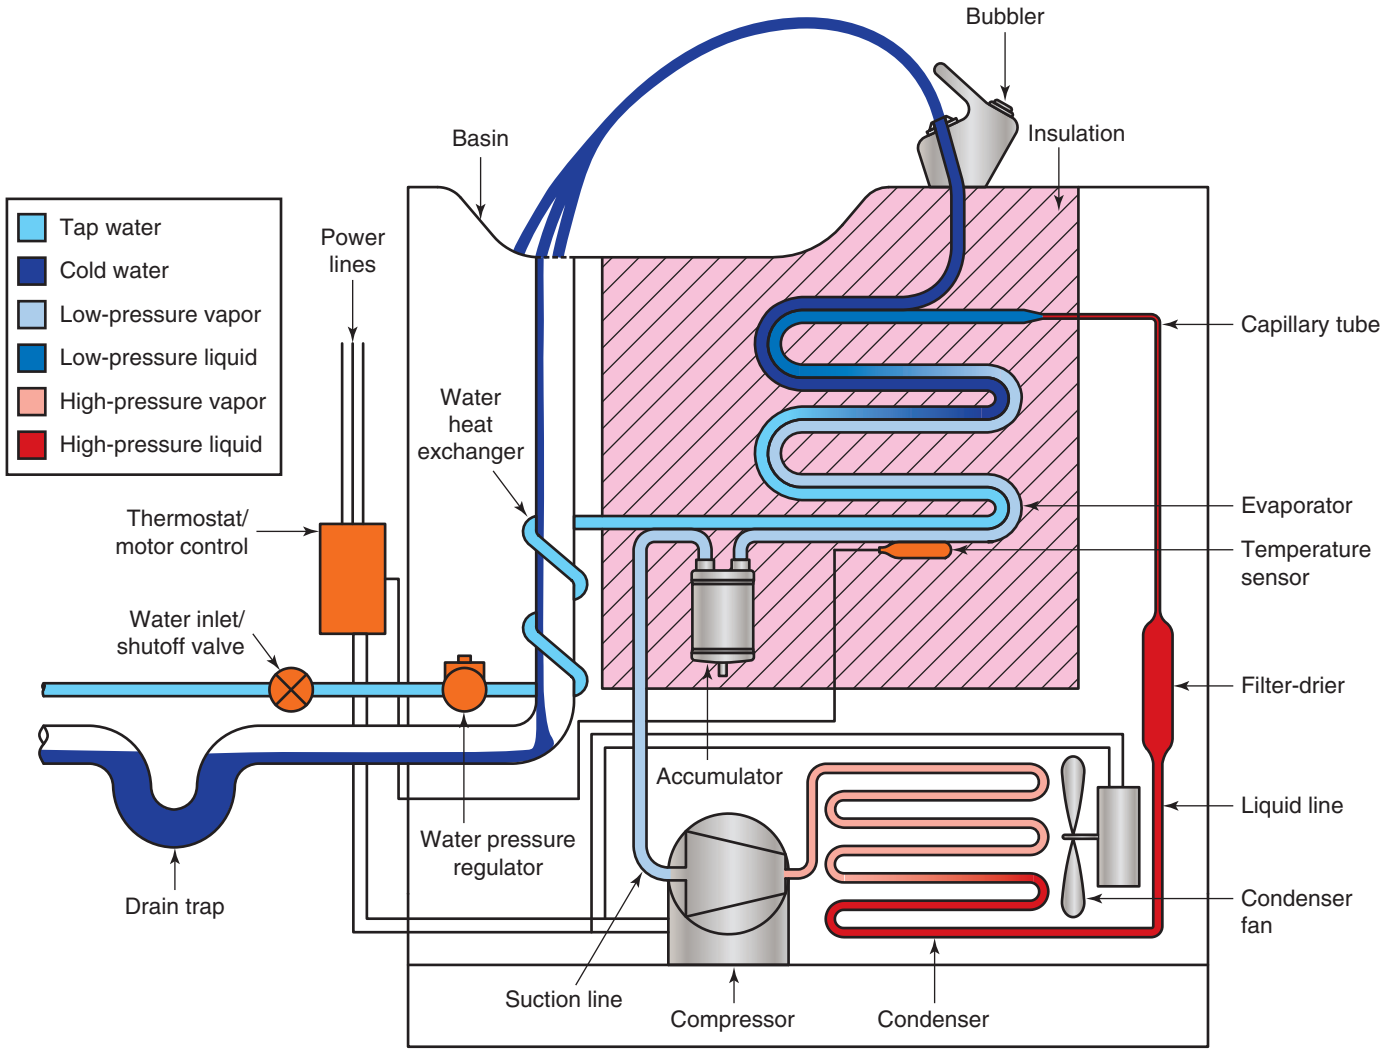
Water Cooler Requirements

Section 410 of the International Plumbing Code (IPC) covers drinking fountains (water coolers). Section 405 of the IPC covers the installation of fixtures.

Tap water cooler basins are generally porcelain-coated cast iron, porcelain-coated steel, or stainless steel. The lowest part of the basin is where the water enters the drain piping. Water is dispensed from a valve called a bubbler. The bubbler opening must be above the drain. This eliminates accidental siphoning of the drain water back into the fresh water system.

A water pressure regulator determines the water flow. Tap water coolers frequently use heat exchangers to cool tap water before chilling it with refrigeration. Fresh tap water is precooled in a heat exchanger by the chilled waste water going down the drain. Refer to the water cooler diagram in **Figure 47-30**.

A thermostat with a sensing bulb is attached to the water-dispensing tube. It maintains the desired drinking water temperature in the water cooler by communicating with the thermostat motor control, which cycles



Goodheart-Willcox Publisher

Figure 47-30. Diagram illustrating a drinking fountain cooled by a compression refrigeration system.

Copyright Goodheart-Willcox Co., Inc. 2017

the compressor on and off as needed. Water leaving the fountain should be approximately 50°F (10°C). Water cooler condensers generally use a fan to increase heat transfer with ambient air. The condenser fan is connected into the electrical circuit and runs whenever the compressor is running.

Article 410.2 of the International Plumbing Code (IPC) and its exception state that where a drinking fountain is required, at least one drinking fountain must comply with requirements for people who use a wheelchair. **Figure 47-31** shows a water cooler universally designed for easy access for people who use wheelchairs. This water cooler incorporates a low-profile design with a large touch pad to permit ease of use.

A ***self-contained water cooler*** is a standalone water cooler that has its own water supply from a tank and does not have a drain. Self-contained water coolers are especially desirable in locations where a building's plumbing cannot be easily tapped. Large plastic containers of water are used for the supply. The refrigeration system used is similar to that found in other water cooler models, **Figure 47-32**.

Multiple water coolers, instead of individual ones, are popular for certain applications. These coolers have one large condensing unit supplying refrigeration to many water cooler bubblers. They are often used for large business establishments, office buildings, or factories.

Goodheart-Willcox Publisher

Figure 47-31. Chilled water cooler drinking fountain with a barrier-free design for easy access by people who use wheelchairs.

Figure 47-32. Water coolers with self-contained water supplies often have an outlet for chilled water and another for room temperature or heated water.

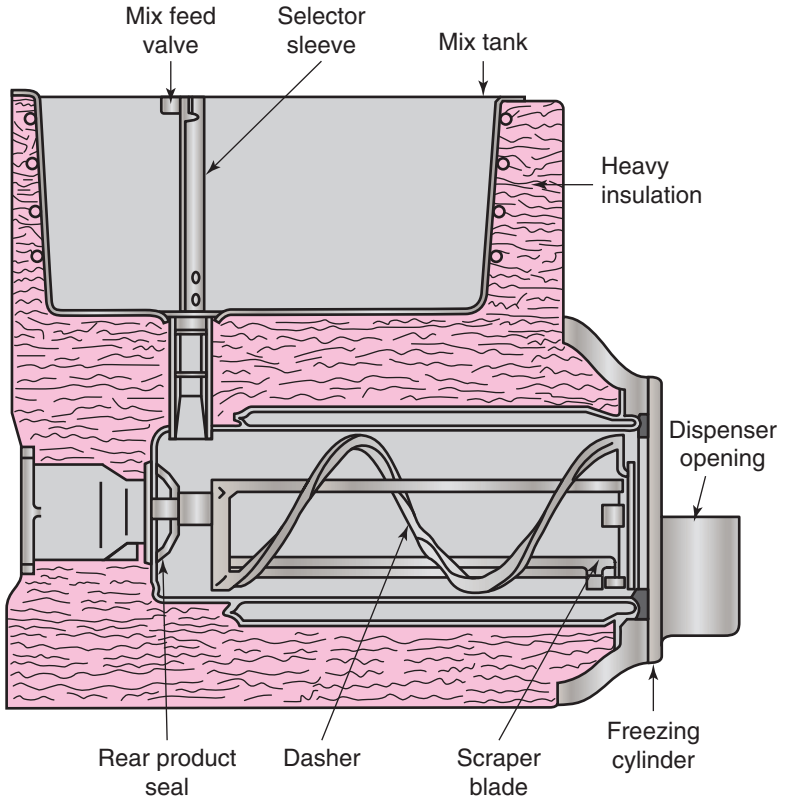
Milk Dispensers

Many food service businesses dispense milk from bulk containers. Cans or plastic bags holding 3 to 5 gallons (11 L to 19 L) of milk are installed in dispensers. These units must meet all health and sanitation codes. Milk is kept at about 36°F (2°C) by a hermetic refrigeration system. Reserve milk containers are kept in a walk-in cooler or in a milk storage refrigerator.

Dispensing Freezers

Special applications of refrigeration systems are used in dispensing freezers. ***Dispensing freezers*** are refrigeration systems that cool or fast-freeze and

Copyright Goodheart-Willcox Co., Inc. 2017



Sweden-Alco Dispensing Systems, a Div. of Alco Foodservice Equipment Co.

Figure 47-33. Components of a dispensing freezer.

dispense liquid mixes into soft serve or batch ice cream, shakes, or frozen beverages. The liquid mix is cooled or frozen under agitation and then dispensed for immediate consumption.

The mix is typically purchased from a local dairy or other mix supplier. The liquid mix is poured into a refrigerated mix storage (either a hopper above the freezing cylinder or a lower mix cabinet). The mix is then fed into a freezing cylinder, where it is frozen and dispensed. Inside the freezer cylinder, a beater or dasher is driven by a separate motor. Dispensing freezers typically freeze about one gallon of soft serve in 5–10 minutes. A typical hopper attached to the freezing cylinder and dispensing door is shown in **Figure 47-33**.

Most dispensing freezers can operate virtually continuously, as long as liquid mix to the freezing cylinder is replenished. The freezer is kept within a narrow temperature range, usually within 1°F or 2°F (0.5°C to 1°C) of its set temperature. Either automatic or thermostatic expansion valves are used as the refrigerant metering device. Since temperature requirements vary depending on the mix formulation, many freezers use some type of viscosity control instead of temperature controls, **Figure 47-34**.

Refrigeration systems for dispensing freezers should be rated by Btu/hr, since the compressors usually operate at medium- or low-temperature ranges. Rating dispensing freezers using horsepower or tons of refrigeration is misleading, since those ratings are for high-temperature refrigeration. In a high-temperature application, one ton of refrigeration is

Dispensing Freezer Temperatures

Dispenser Freezer Product	Temperature Requirements
Low-fat soft-serve ice cream	17°F to 20°F (–8.3°C to –6.7°C)
Soft-serve ice cream (10% fat)	20°F to 23°F (–6.7°C to –5.0°C)
Milkshakes	24°F to 28°F (–4.4°C to –2.2°C)
Sherbets	14°F to 18°F (–10.0°C to –7.8°C)
Fruit or water ices	14°F to 18°F (–10.0°C to –7.8°C)
Slushes	24°F to 28°F (–4.4°C to –2.2°C)
Frozen carbonated beverages (FCB)	24°F to 28°F (–4.4°C to –2.2°C)

Goodheart-Willcox Publisher

Figure 47-34. Table showing common temperature requirements for products used in dispensing freezers.

Copyright Goodheart-Willcox Co., Inc. 2017

equivalent to 12,000 Btu/hr. A dispensing freezer with a product capacity of 15 gallons (56.8 L) per hour usually has a 9,500 Btu/hr refrigeration system and a dasher motor of 1.5 hp (1119 W). Most dispensing freezers are available either in air- or water-cooled systems.

The quality of the mix is very important. Many problems thought to be in the refrigeration system have turned out to be poor mixes. Health codes require keeping the mix in the mix storage and freezing cylinder at safe temperatures, usually by maintaining temperatures below 41°F (5°C). Daily cleaning may be required, and local health code rules must be followed. Heat treatment soft-serve and shake dispensing freezers are commercially available that go through a timed heating and cooling cycle every 24 hours and only require complete disassembly and cleaning once every 14 to 28 days, depending on local health codes.

Another commercial application of the dispensing freezer is the *shake maker*. This machine is filled with the desired shake mix. While some shake makers are still controlled by temperature, the newer styles are usually viscosity controlled. As the mix is frozen, the torque required to drive the dasher increases. When the amperage reaches a certain set point, the refrigeration system shuts off at servable consistency.

Some dispensing freezers are used to make slush drinks. Slush is typically a sugar-water mixture, often containing some flavoring or color. A frozen carbonated beverage is about one part syrup and four parts carbonated water. Most frozen beverages are served at 24°F to 28°F (–4.4°C to –2.2°C).

Vending Machines

Refrigerated vending machines for foods or beverages are becoming increasingly popular. They may be used to automatically dispense canned or bottled drinks, packaged ice cream or cold food, frozen desserts, and other foods. Some machines are satellite vending units that are controlled by an accompanying snack vendor. Such vending machines are not coin operated but are connected and housed in the same cabinet as a machine that is coin operated, **Figure 47-35**.

The refrigeration process allows food to maintain health and safety requirements. Cabinets often have an injected foam design and pump R-134a or R-404 through a standard 1/3 horsepower (120 Vac) hermetically sealed compressor to maintain temperatures. Vending machines are equipped with temperature sensors and health safety timers that disable sales of any product if the unit temperature rises above certain set points:

- 41°F (5°C) for cold foods.
- 0°F (–18°C) for frozen food.

Wittern Group

Figure 47-35. A—A satellite unit that maintains 41°F (5°C). B—A vending machine that is capable of offering a variety of beverages in cans and plastic containers. C—A frozen food vendor using R-404. This unit can maintain temperatures between –12°F (–24°C) and 41°F (5°C).

Frozen food vending machines typically hold temperatures between –12°F (–24°C) and 41°F (5°C). To clear condensation, heated glass is used, as is a top-mounted evaporator, which provides airflow from top to bottom.

Refrigeration systems used in vending machines typically have capillary tube refrigerant controls, hermetic motor compressors, and defrosting devices. The electrical system transfers the materials and operates the coin and currency devices. Some of the vending components of refrigerated vending machines include the following: coin and currency devices (acceptors, rejectors, changers, and steppers and accumulators), cup dispensers, heating systems, transfer systems, and card readers. The automatic operation of vending machines involves motors, magnets, signal lights, and relays. Thus, an elaborate wiring system is necessary, **Figure 47-36**.

47.2.8 Milk Coolers

Raw milk for pasteurization should be cooled to 50°F (10°C) or less within four hours after the completion of milking and down to 45°F (7°C) or less within two hours after the completion of milking. The blended temperature after the first milking and any subsequent milkings should not exceed 50°F (10°C).

Copyright Goodheart-Willcox Co., Inc. 2017

Figure 47-36. Ladder diagram for a refrigerated bottled beverage vending machine. Top—Vending unit wiring. Bottom—Refrigeration unit wiring.

BouMatic

Figure 47-37. A—A flow control monitors variables to adjust the flow of milk through a heat exchanger for optimal energy efficiency. B—Water-cooled plate heat exchangers precool milk before bulk storage and cooling.

Milk coolers are refrigeration systems that cool fresh milk to the legally required temperatures in a large tank. Bacterial growth in milk is dramatically affected by temperature. During a 24-hour period, bacteria count will increase as follows:

- To 2400 at 32°F (0°C).
- To 2500 at 39°F (4°C).
- To 3100 at 46°F (8°C).
- To 11,600 at 50°F (10°C).
- To 180,000 at 60°F (16°C).
- To 1,400,000,000 at 86°F (30°C).

Some milk cooling systems incorporate precooling heat exchangers and flow controls to reduce the heat load on the bulk cooler, **Figure 47-37**. Some stainless steel bulk coolers have their evaporator in their base. Coolers of this type have a 600 to 8000 gallon (2300 L to 30 300 L) capacity.

A bulk milk cooler will usually have its condensing unit mounted outside the room where the milk

Copyright Goodheart-Willcox Co., Inc. 2017

cooler is located (milk room), **Figure 47-38**. Since it is usually air-cooled, the condensing unit should not be put in the same room as the vacuum pump. Air flowing over the condenser can be drawn from the milk room. In winter, where permitted, this warm air can be ducted to heat the milk room. All milk coolers and condensing units must be installed by qualified technicians, following applicable plumbing and electrical codes.

47.2.9 Ice Machines

Ice machines are refrigeration systems that automatically freeze and form water into ice and dispense it for consumer use. They deposit the ice in storage bins and automatically cycle off when the storage space is full.

A

B

BouMatic; Danfoss

Figure 47-38. A—This bulk milk cooler has a direct expansion evaporator located in its base. B—Air-cooled condensing unit draws low-pressure refrigerant through the evaporator coils in a bulk milk cooler at a dairy farm.

The ice formed is clear and sanitary, since only flowing water is used. Cloudy ice cubes are caused by entrapped air or poor water quality.

Ice machines are widely used in commercial refrigeration. Different models are available depending on the type and amount of ice required for a given application. Ice production capacity can vary among units from a few pounds up to many tons per day. Daily capacity decreases as water temperature or ambient air temperature increases.

Once ice is formed, it is removed from the freezing surfaces in various ways. These include use of electrical heating elements, hot water, hot-gas defrosting, or mechanical devices. A quick inspection of an ice machine should reveal its ice removal method, **Figure 47-39**.

Urethane foam, polystyrene, or fiberglass may be used for cabinet insulation. The freezing surface is usually made from stainless steel or nickel-plated copper. An ice machine's water circuits and ice-freezing parts should be cleaned regularly. The storage bin can

Scotsman Ice Systems

Figure 47-39. Ice machine using hot-gas defrosting to remove ice from its mold.

Copyright Goodheart-Willcox Co., Inc. 2017

be made of stainless steel or plastic. Ice machines are often self-contained, having all parts of the system in a single cabinet, **Figure 47-40**. Other ice machines use remote condensing units located outside. All ice machines require a water supply and drain plumbing.

Ice Machine Controls

Ice machines have refrigerant and motor controls located throughout the cabinet to operate the system safely and efficiently. In addition to regular refrigeration system controls, ice machines have controls for ice-making and harvesting. Floats and solenoids control water flow. Different types of sensors and switches monitor the amount of ice in a machine's storage bin. A few of the control devices used for bin capacity include mechanical levers, temperature-sensing bulbs, and photo sensors.

For bin capacity using mechanical controls, as the ice bin fills, the accumulated ice pushes against a diaphragm or actuates a lever. This opens a switch that stops the ice machine. Temperature controls for bin capacity shut off the ice machine when the ice comes into direct contact with a temperature-sensing bulb in the storage bin. Both mechanical and temperature controls are located at the top of the ice storage bin. Bin capacity photo sensors detect a light beam that is sent out across the top of the bin. When the ice reaches the top of the bin, the light beam is broken, and the ice machine stops harvesting ice.

Some ice machines have a variety of additional controls. These include sensors that measure compressor discharge temperature, water temperature, and cube size. **Figure 47-41** shows a microprocessor-based controller used to monitor all processes of operation.

An ice machine controller receives inputs from the machine's sensors and controls the reservoir fill time, starting time, harvest cycle time, and unit shut-off time. **Figure 47-42** shows a schematic wiring diagram of an ice machine with a hot-gas defrost harvesting function.

Ice Machine Evaporators

Ice machines produce ice in different shapes and forms for different purposes. The two main forms are cube and flake. While flakes are relatively consistent, cubes can vary greatly in size and shape depending on the type of evaporator an ice machine has.

Vertical Cube Evaporators

An ice machine with a vertical evaporator is shown in **Figure 47-43**. In this ice machine, evaporator tubing is located just behind cube molds. A water distribution

Ice-O-Matic

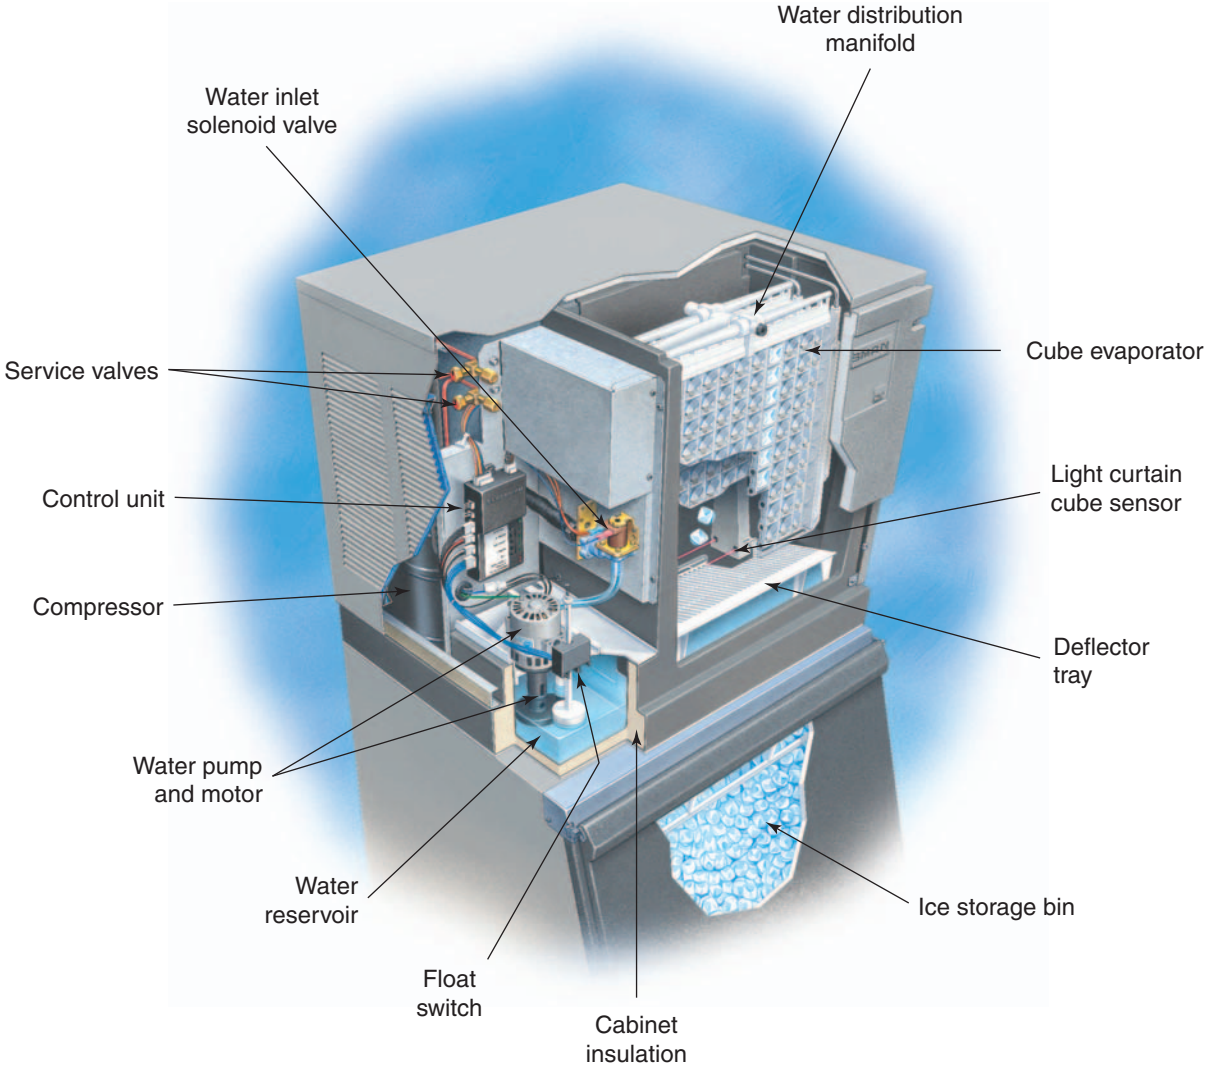
Figure 47-42. Note the number of devices controlled in this ladder diagram: hot-gas defrost, probe motor, harvest motor, fan, water purge valve, and water pump.

manifold continuously streams water down across the molds where ice gradually forms and builds up. Eventually, ice fills each cell in the mold and connects with the other cubes along their edges.

A sensor monitors ice thickness and informs the control unit when to switch from the refrigeration cycle to the hot-gas defrost cycle for harvesting. Hot-gas from the compressor's discharge line is pumped through the evaporator. Once the sheet of ice cubes is loosened, it falls and breaks apart into individual cubes in the storage bin.

A large portion of ice is used for beverage cooling. Cubed ice is usually created for serving in drinks or may be bagged for bulk sale. These hard cubes are long lasting. However, ice in other shapes and sizes is frequently desirable.

Copyright Goodheart-Willcox Co., Inc. 2017



Scotsman Ice Systems

Figure 47-43. In this vertical cube evaporator ice machine, water flows into the top of the evaporator and over cube molds. Finished cubes fall into the ice storage bin below.

Inverted Cube Evaporators

Another method of producing cubed ice uses an evaporator above an inverted mold. Cold water is sprayed upward into the inverted molds. The temperature of the molds is cooled very low by the nearby evaporator coils. Water strikes the mold surface and freezes there, **Figure 47-44**.

Frozen water gradually builds up until complete ice cubes are formed. Next, the ice cube molds are warmed until the cubes fall out. The warming is done by electric heating elements or hot-gas defrosting. The cubes drop down onto a deflector trap, slide through a chute, and arrive in the ice cube storage bin. This ends the ice production cycle. Review the system diagram in **Figure 47-45**.

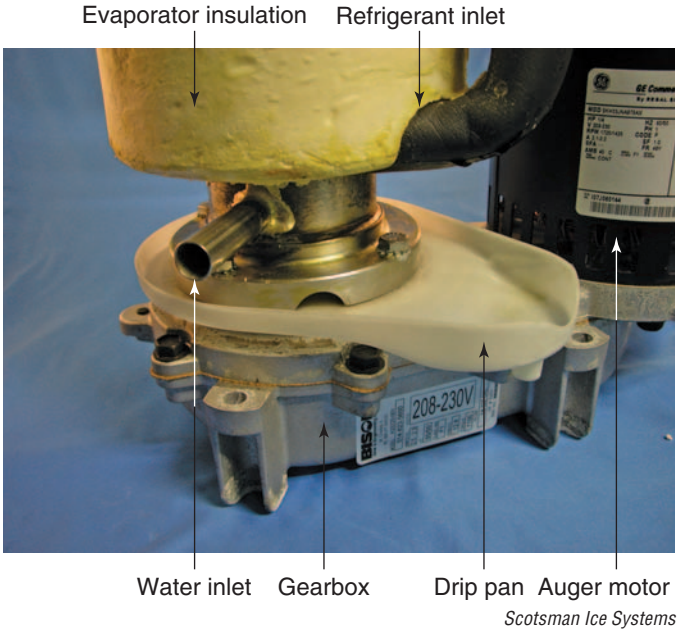
Figure 47-45. In an ice machine with an inverted mold evaporator, water is sprayed upward into ice cube molds to produce clear ice cubes.

Flaked Ice Evaporators

Flaked ice is preferred for cooling produce, fish, and poultry. It can be packed tightly around an item and will maintain the freshness of the product even as the ice melts.

Ice machines that produce ice flakes have evaporators unlike those of cube ice machines. In a flake ice machine, water fills a cylindrical evaporator at 0°F (–18°C) that freezes the water very rapidly. A heavy steel auger driven by an electric motor cuts and scrapes ice from the surface, **Figure 47-46**.

Figure 47-47 shows a diagram and a photo of a flake ice machine. Water from a reservoir enters the evaporator at the water inlet and fills to the level control in the water reservoir. Water freezes, and the auger rotates to cut and move the flaked ice upward. Above the auger, the flaked ice is directed into a chute where it drops into a storage bin. When the bin is full, a sensor or switch shuts off the machine until needed again. **Figure 47-48** is a ladder diagram for a flake ice machine.



Scotsman Ice Systems

Like flake ice machines, extruded cubelet ice machines use an auger in their evaporators. Cubelet ice machines are frequently used in fast-food restaurants. These small commercial units produce an extruded cubelet of ice rather than a solid cube. Cubelet ice machines are very similar to flake ice machines, but these machines compress the ice flakes into small cubelets before dispensing them.

47.3 Industrial Applications

Refrigeration has a variety of applications in industrial and manufacturing processes. The production of high concentrations of heat is often the result of many industrial processes. To minimize or eliminate the negative consequences that could result from high heat, refrigeration is often incorporated into the process.

47.3.1 Industrial Processes

While refrigeration is often concerned with food preservation, it can also be used in manufacturing and industrial processing. A few common uses include the following:

- Cooling of water, which, in turn, cools electrodes on resistance welders.
- Cooling of quenching liquids used to cool metals in heat-treating applications.
- Cooling compressed air.

Since moisture may rust and corrode air tools or spoil paint spraying, compressed air must be dry. Therefore, air is cooled to keep the coldest spot in the air system below air's dew point. Remember that a gas's *dew point* is the temperature at atmospheric pressure at which water begins condensing. Cooling the air below that temperature prevents moisture from forming in the lines.

Remember that Gay-Lussac's law states that in a fixed volume, as pressure rises or falls, temperature correspondingly rises or falls. Therefore, gas in a fixed volume at a higher pressure will have a higher temperature dew point.

Pressure dew point is the temperature at which moisture condenses in pressurized air (air that is not at atmospheric pressure). In industrial compressed air systems, a refrigeration system cools the compressed air below its pressure dew point. Then the air is reheated. Pressure dew points are about 50°F (28°C) above atmospheric dew points at 100 psi (700 kPa) air pressure. Generally, the compressed air is cooled to about 35°F to 50°F (2°C to 10°C). A 3000 cfm (1.42 m^3/s) air compressor will need a refrigeration system with about 20 tons (55.2 kW) of cooling capacity.

Caution

Explosion-Proof Systems

Safety refrigerators and explosion-proof refrigerators are used for flammable liquid and substance storage. Ordinary household refrigerators are not appropriate. Standard refrigerator components (thermostat, relays, and switches) can cause a spark capable of igniting vapors from flammable liquids. Do not locate flammable storage refrigerators in areas containing explosive vapors. However, chemicals that produce explosive vapors can be stored inside these systems.

Refrigerators and freezers of all types are used in research. They are used to maintain constant temperature, constant humidity, and low-temperature control. Low-temperature units are capable of maintaining –140°F (–96°C). These systems usually use 5″ (13 cm) of insulation and a cascade refrigeration system. A cascade refrigeration system is two refrigeration systems connected in series with one system's evaporator absorbing heat expelled by the other system's condenser. For more information on cascade refrigeration systems, see Chapter 49, *Commercial Refrigeration System Configurations*.

47.3.2 Industrial Freezing of Foods

Refrigeration of food is commonly seen in home kitchens and grocery stores. However, the refrigeration of food occurs before such food products even hit the shelves. Industrial freezing of food is performed in two principal types of establishments:

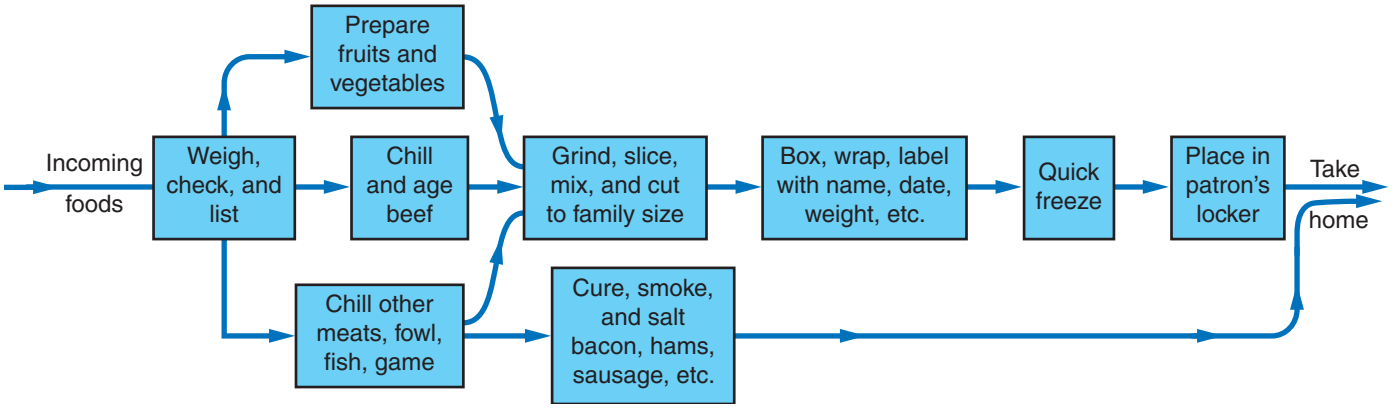
- Processing plants.
- Locker plants.

Processors of frozen foods have freezing centers in many large food-producing areas. For example, fish is packed and frozen along a seacoast and then shipped to all parts of the country.

A ***locker plant*** is smaller than a processing plant and is designed to prepare, freeze, and store various food products. Refrigeration equipment in processing and locker plants varies considerably. However, the plan for freezing the food is similar.

Figure 47-49 shows the flow of food products through a typical plant. The food is weighed and checked for purity and suitability for freezing. Then, it moves to the processing room. There, meat is cut, fowl cleaned and dressed, vegetables blanched, and

Copyright Goodheart-Willcox Co., Inc. 2017



Goodheart-Willcox Publisher

Figure 47-49. Flow chart showing each step for food moving through its preparation process in a freezing plant.

the various items packaged. The packed foods are next sent to the freezing section, where they are completely frozen and readied for storage.

High humidity is very important in rooms where food is cured and stored. Meat tastes better and keeps its weight if relative humidity is kept close to 100%. The temperature should be near 39°F (4°C). This gives the best humidity results with a non-frosting evaporator.

A ***processing plant*** freezes food rapidly by exposing as much of the food as possible to the lowest possible temperature using a fast-freezing system. This is usually done by moving produce along a track through an ultra-low-temperature chamber.

Some fast-freezing systems use liquid nitrogen or carbon dioxide. This turns perishable fresh food into long-lasting frozen food. This process is commonly referred to as ***cryogenic food freezing***. Temperatures of –320°F (–196°C) are obtained, causing freezing to be instantaneous. This method of quick freezing causes little or no damage to the food.

Chapter Review

Summary

- Commercial refrigeration systems may use multiple compressors, condensing units with multiple fans and flow controls, and specialized evaporators based on the build of the cabinet. These systems are found in supermarkets, convenience stores, bakeries, restaurants, and other businesses.
- During periods of low cooling demand, some commercial refrigeration systems form an ice bank. It absorbs heat and prevents system overload during periods of high demand. Generally, ice banks are used in drink dispensers and other liquid-cooling systems.
- Supermarkets, restaurants, and other businesses often have walk-in cabinets, which are large refrigerated spaces with specially insulated walls, doors, and floors. These units can be used to cool or freeze a variety of products. Walk-in cabinets are specially designed and must be installed to meet various building codes.
- Florist cabinets use low-velocity evaporators and refrigeration systems that maintain specific temperature and humidity requirements to prolong product quality. Special filters (EGF) are used to remove ethylene gas that would otherwise accelerate plant aging.
- Hot and cold merchandisers are commercial units built with two separate temperature compartments. One section keeps products cool, and the other section keeps products warm.
- Display cases can be used to refrigerate or freeze products and can be open or closed. Open display cases may use one or more air curtains to thermally isolate products from ambient air. An air curtain is a stream of air that blows between a conditioned space and an unconditioned space to isolate the two areas.
- Quick chillers, blast chillers, and blast freezers cool cooked food quickly for storage.
- Beverage dispensers chill products passively with ice or actively using mechanical refrigeration. Water coolers chill drinking water using a compact mechanical refrigeration system. Milk coolers are large refrigerated tanks used to cool milk after being taken from a cow. Flow controls and precooling heat exchangers reduce the heat load prior to storage.
- Ice machines may form small ice nuggets, ice flakes, or ice cubes in a variety of sizes. The design of the evaporator determines the shape of the ice produced. Common ice machine evaporators include vertical cube, inverted cube, and flaked ice (auger).
- Other than food processing, industrial applications of refrigeration include cooling water used to cool welding electrodes, cooling of quenching liquids used for heat-treating, and cooling of compressed air.
- Processing plants and locker plants prepare, freeze, and store various food products in bulk. Cryogenic food freezing is the use of liquid nitrogen or carbon dioxide to instantly fast-freeze and preserve perishable food at temperatures of –320°F (–196°C).

Review Questions

Answer the following questions using the information in this chapter.

1. A parallel compressor rack is an arrangement of compressors piped in parallel sharing the following devices in common, *except* a(n) _____.
   A. air curtain
   B. liquid line
   C. liquid receiver
   D. suction line
2. A distributed system is a commercial refrigeration unit that circulates refrigerant through nearby coolers and contains only _____.
   A. compressors
   B. condensers
   C. evaporators
   D. refrigerant metering devices
3. During periods of low cooling demand, some liquid-cooling refrigeration systems form a solid block of ice around the evaporator called an _____.
   A. ice advantage
   B. ice bank
   C. ice block
   D. ice cube

Copyright Goodheart-Willcox Co., Inc. 2017

4. The rapid controlled cooling of cooked food to inhibit bacteria and germ growth is performed by _____.
   A. blast chillers and quick chillers
   B. blast dispensers and quick merchandisers
   C. distributed systems and ice machines
   D. open and glass-enclosed display cases
5. Floral refrigeration systems typically use a(n) _____ evaporator to account for floral item fragility.
   A. flooded
   B. high-velocity
   C. immersed
   D. low-velocity
6. Open display cases and some glass-enclosed display cases use a(n) _____, which is a stream of air that blows between a conditioned space and an unconditioned space to isolate the two areas.
   A. air barrier
   B. air curtain
   C. blast chiller
   D. sneeze guard
7. A beverage dispenser that cools its dispensing liquid using the same ice that is dispensed for drinks is _____ chilled.
   A. actively
   B. cryogenically
   C. passively
   D. subcooler
8. A water cooler that has a plumbed water supply and drain connections is a(n) _____ water cooler.
   A. ice
   B. self-contained
   C. tap
   D. walk-in
9. A standalone water cooler that has its own water supply from a tank and does not have a drain is a(n) _____ water cooler.
   A. ice
   B. self-contained
   C. tap
   D. walk-in
10. Refrigeration systems that cool or fast-freeze and then dispense a mix for consumption are _____.
    A. dispensing freezers
    B. ice machines
    C. milk dispensers
    D. processing plants
11. Refrigeration systems that cool fresh milk to the legally required temperatures in a large tank are _____.
    A. blast chillers
    B. milk coolers
    C. milk dispensers
    D. ultraviolet coolers
12. An ice machine that produces flaked ice has an evaporator that uses a(n) _____.
    A. auger
    B. extruding process
    C. inverted mold
    D. vertical evaporator and mold
13. An ice machine that distributes flowing water using a manifold also uses a(n) _____.
    A. auger
    B. extruding process
    C. inverted mold
    D. vertical evaporator and mold
14. Ice machine controls used for bin capacity include the following, *except* a _____.
    A. diaphragm or mechanical lever switch
    B. float control and solenoid valve
    C. photo sensor
    D. temperature-sensing bulb
15. The process of fast freezing food using liquid nitrogen or carbon dioxide is called _____.
    A. blast cooling
    B. cascade preservation
    C. cryogenic food freezing
    D. ice bank freezing

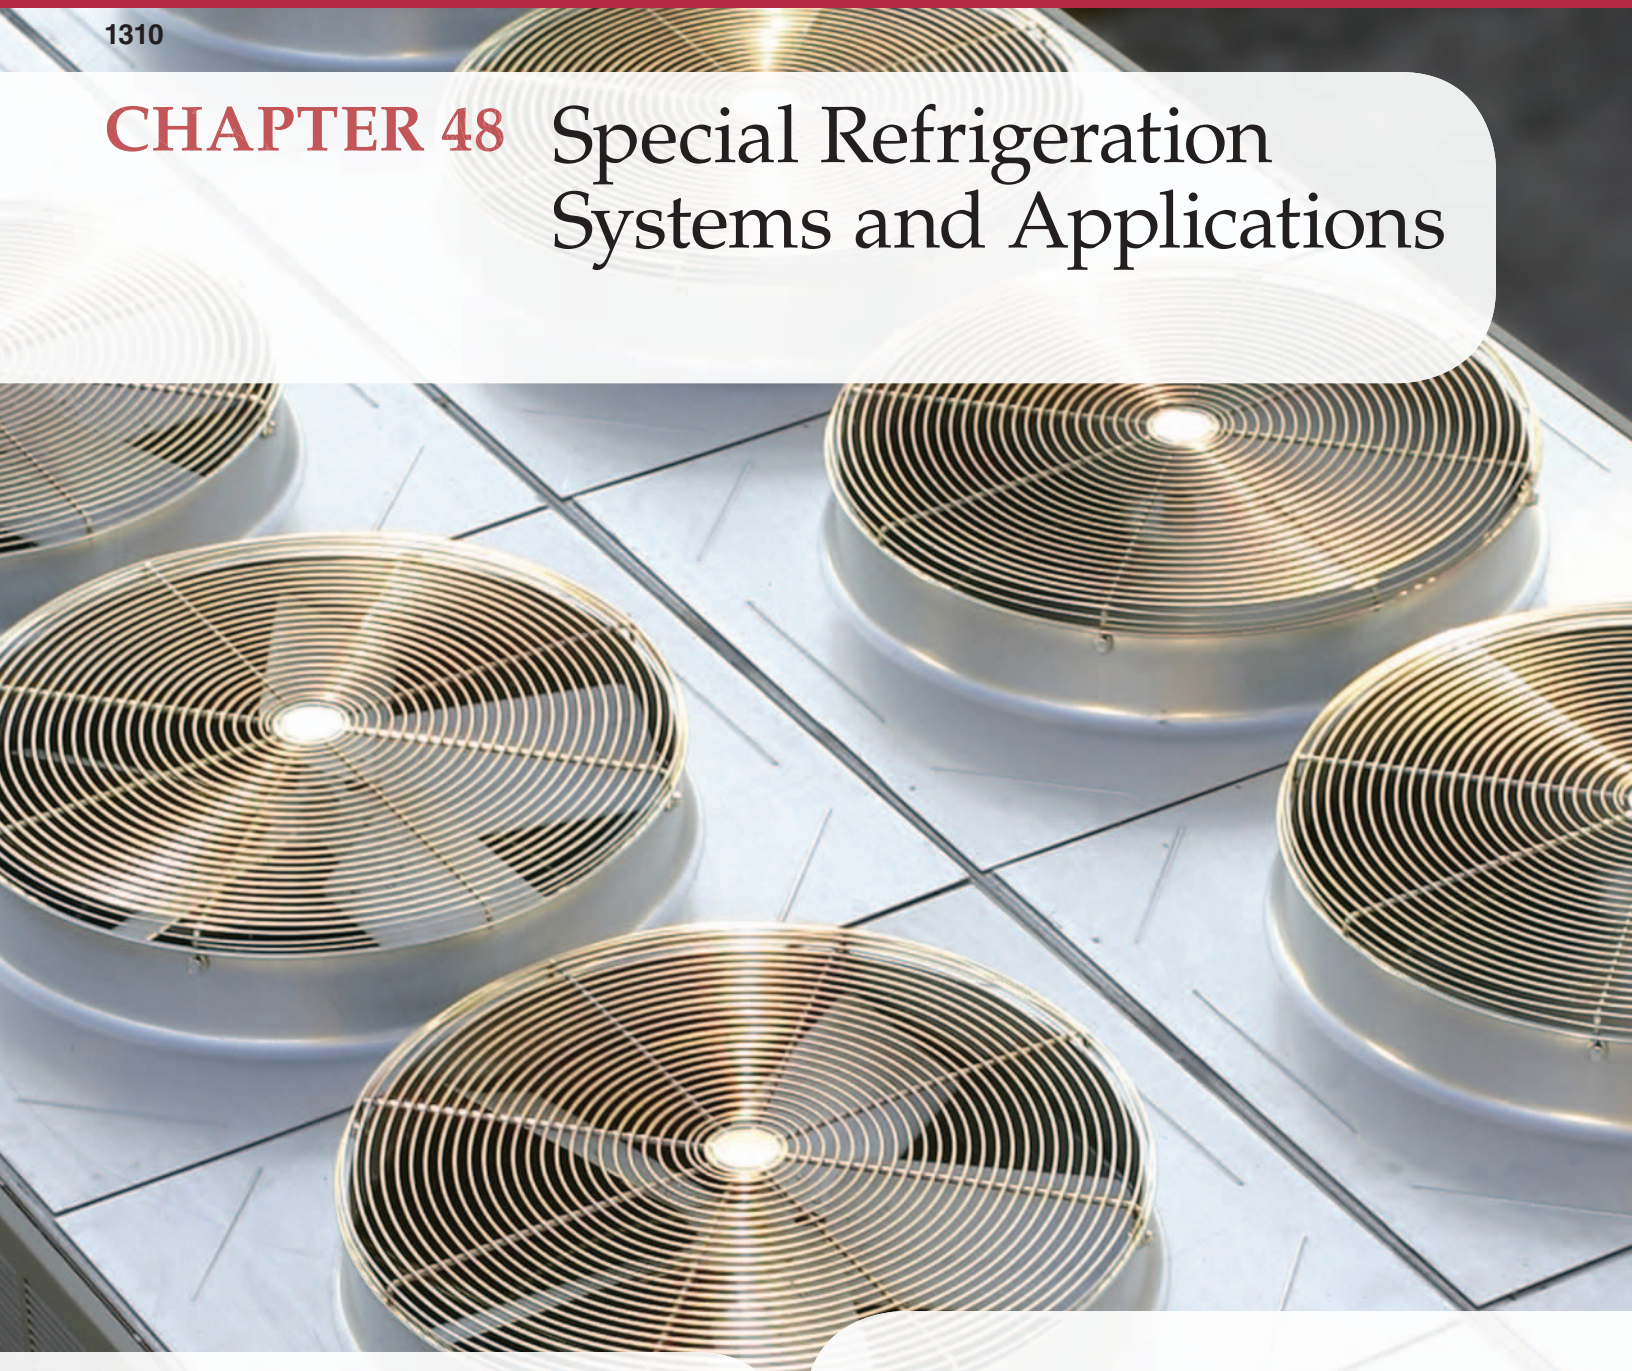
CHAPTER 48 Special Refrigeration Systems and Applications



Chapter Outline

48.1 Transportation Refrigeration
- 48.1.1 Truck and Trailer Refrigeration
- 48.1.2 Railcar Refrigeration
- 48.1.3 Intermodal Shipping Container Refrigeration
- 48.1.4 Marine Refrigeration

48.2 Alternative Refrigeration Methods
- 48.2.1 Expendable Refrigeration Systems
- 48.2.2 Dry Ice Refrigeration
- 48.2.3 Thermoelectric Refrigeration
- 48.2.4 Vortex Tubes
- 48.2.5 Jet Cooling Systems
- 48.2.6 Stirling Refrigeration Cycle

Learning Objectives

Information in this chapter will enable you to:

- Identify the different types of refrigerant metering devices, evaporators, compressors, and condensers used in transportation refrigeration systems.
- Summarize the operation of various expendable refrigeration systems.
- Explain how thermoelectric couples produce heating and cooling using electricity.
- Summarize the operation of vortex tubes, steam jet systems, and refrigerant jet systems.
- Describe the operation of a basic Stirling refrigeration system.

Review of Key Concepts

Reviewing these concepts from earlier chapters will help you understand new concepts presented in this chapter:

- A hot-gas defrost system redirects hot, compressed vapor from the compressor through the evaporator to defrost it. A bypass line equipped with a solenoid valve connects the compressor discharge line to the evaporator inlet. (Chapter 21)
- An expendable refrigerant is used only once in a system and then released into the atmosphere. It is not collected and recondensed for additional refrigeration cycles, as is the case with most compression refrigeration systems. (Chapter 9)
- Rupture discs are protective devices for refrigerant cylinders that are designed to open under excessive pressure, but they do not close again. They allow a cylinder's entire refrigerant charge to vent before the cylinder bursts. (Chapter 10)
- When impurities are added to a pure semiconductor, such as silicon, it is called doping. Doping produces either N-type or P-type material depending on whether the impurity causes an excess or a shortage of electrons in the material. (Chapter 14)
- Electronic circuits include semiconductor devices. These devices can also be called solid-state devices, because there are no moving parts in a semiconductor. They switch roles from acting as an insulator to acting as a conductor on the atomic level, rather than using moving contacts. (Chapter 14)

Introduction

The refrigeration systems that have been described up to this point have mainly been mechanical compression systems used in stationary locations, such as supermarkets. This chapter covers systems that are designed to be mobile, systems used in spaces with limited access, and systems that achieve extremely cold temperatures. Some of the specialized systems covered are adaptations of compression refrigeration systems. Others use methods other than mechanical compression to produce refrigeration temperatures.

Copyright Goodheart-Willcox Co., Inc. 2017

48.1 Transportation Refrigeration

There is minimal difference between transportation refrigeration systems and other types of commercial refrigeration systems. Transportation refrigeration systems are designed for various ambient temperatures and operating temperatures. The systems must also be designed to withstand the stress and vibrations that occur during transport. Depending on the type, size, and purpose of the primary refrigeration system, a backup system may be installed to prevent loss of cooling in case the primary refrigeration system fails.

48.1.1 Truck and Trailer Refrigeration

The main components of truck and trailer refrigeration systems are the compressor, air-cooled condenser, thermostatic expansion valve (TXV), and direct-expansion evaporator. These systems typically use 1 1/2 hp to 2 hp (1120 W to 1490 W) compressors and R-134a or R-404A as a refrigerant. Whereas R-134a is used for medium- and high-temperature refrigeration, the properties of R-404A make it suitable for use in medium- and low-temperature applications. Both refrigerants have low toxicity and low flammability, making them safe for transportation refrigeration. Components specific to truck and trailer refrigeration include the following: a quench valve, a subcooler, hot-gas solenoid valves, and vibration absorbers. See **Figure 48-1**.

The ***quench valve*** is a thermostatic expansion valve (TXV) that acts as a liquid injection valve from the liquid line to the suction line. During periods of low load, not much refrigerant is required for cooling, so less refrigerant is passed into the evaporator from the high side.

Heat-Defrost Cycle

Carrier Transicold Division, Carrier Corp.

Figure 48-1. Continued.

Remember that suction vapor is often used to cool the compressor. When less refrigerant is available, compressor temperature can rise, and it could begin to overheat. The quench valve monitors this with a sensing bulb on the discharge line. When necessary, the quench valve opens to inject a small amount of liquid refrigerant into the suction line. This refrigerant quickly evaporates and flows into the compressor to cool it.

The subcooler, which occupies a portion of the condenser, removes additional heat from refrigerant leaving the liquid receiver to help ensure that only liquid refrigerant enters the thermostatic expansion valve. Vibration absorbers are placed in the suction and discharge lines to decrease vibration.

When energized, hot-gas solenoid valves open to allow heated vapor refrigerant discharged by the compressor to enter the evaporator. This is done to initiate the heating cycle or defrost cycle. The main difference between heating and defrosting is that the evaporator fans continue to run during the heating cycle to blow air over the evaporator coil. During the defrost cycle, the evaporator fans stop to allow the heated refrigerant vapor to defrost any ice buildup on the evaporator.

Refrigerated Trailers

Refrigerated trailers, also called reefers, require special trailer bodies that are typically 28′ to 53′ (8.5 m to 16 m) long. The trailer bodies should be light and well insulated. The boxes on most refrigerated trailers have fiberglass, composite, or metal walls. Various thicknesses and types of insulation fill the space between the inner and outer walls, depending on the application. Spray foam insulation is most often used. The insulation limits heat transfer through the trailer walls and also gives the trailer body added rigidity. Constant vibration and rough handling may reduce the insulating value of the trailer walls if they are not constructed soundly.

Because there are numerous applications for trailer refrigeration, the trailer must be properly insulated for its intended use. A trailer carrying frozen goods must be insulated for –15°F (–26°C). Fresh foods require insulation for temperatures in the range of 32°F

Copyright Goodheart-Willcox Co., Inc. 2017

to 35°F (0°C to 2°C). Fresh produce, flowers, and fruits also need accurate control of humidity and ventilation because these products have a tendency to lose fluids to the surrounding air.

The refrigeration systems used in most refrigerated trailers are similar to other compression refrigeration systems. The major difference is the method used to drive the compressor. There are two common ways of driving the compressor:

- A diesel-powered generator on a trailer supplies electrical power to the compressor motor. See **Figure 48-2**.
- The refrigeration system is plugged into the electrical grid while the trailer is idle. This is referred to as ***standby power***.

Refrigerated Trucks

Refrigerated trucks are similar to refrigerated trailers. A cube-style or flat-plate evaporator is mounted on the wall inside the box of the truck. The condenser and condenser fans are mounted in a case on the roof or on the front of the box. In small-capacity trucks, the compressor is typically mounted in the engine compartment and driven by the vehicle engine, **Figure 48-3**.

In some larger-capacity trucks, an externally mounted generator provides the power for the compressor, condenser fans, and evaporator fans. Some trucks include both a compressor driven off the vehicle's engine and a separate engine, generator, and standby compressor. Having an external generator allows the refrigeration system to continue running when the vehicle's engine is shut down. **Figure 48-4** shows a finished installation mounted over a truck cab.

A remote control module inside a refrigerated truck allows the driver to control the refrigeration system. The remote control module includes an electronic temperature controller, temperature selector, and defrost controls. Most truck refrigeration systems use hot gas for the defrost process.

Figure 48-4. A condensing unit mounted above a truck cab is called a nose-mount or front-mount unit. The unit contains a small engine, a generator, a compressor, and a condenser.

Copyright Goodheart-Willcox Co., Inc. 2017

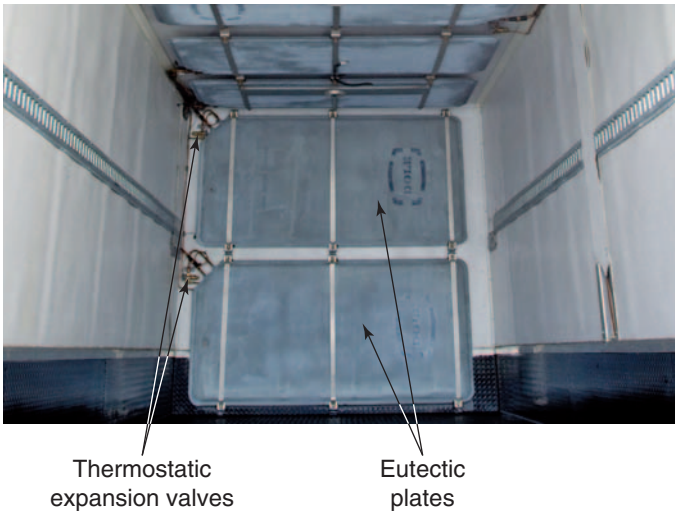
Eutectic Plates

Another type of truck and trailer refrigeration system uses eutectic plates to provide passive refrigeration. A ***eutectic plate*** is a thin, rectangular tank containing an evaporator surrounded by a solution that freezes at a desired temperature. Refrigerant flow through the evaporator freezes the solution, called a eutectic solution. Once the eutectic solution is frozen, the refrigeration system can be shut off, and the eutectic plates alone provide many hours of passive cooling, **Figure 48-5**.

Eutectic plates may be housed inside a shroud with blower fans at the top. The fans draw in warm box air and force it over the surface of the eutectic plate. The air is cooled as it passes over the plate. The chilled air then exits through the bottom of the housing and circulates throughout the box.

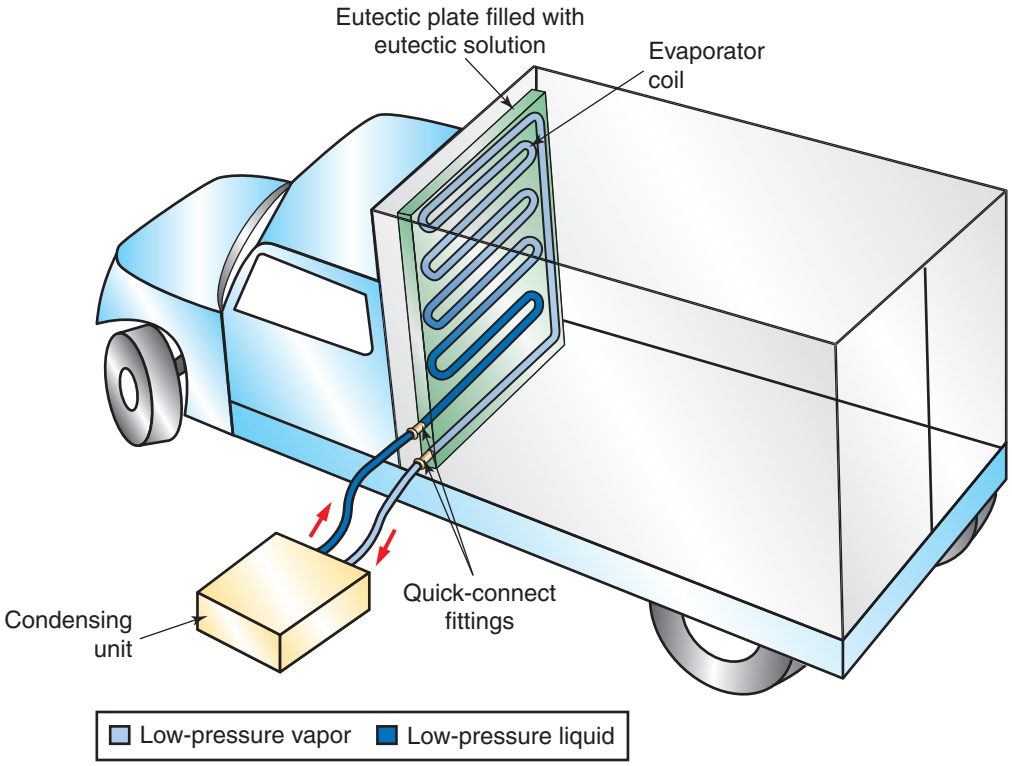
The condensing unit for a refrigeration system with eutectic plates may be permanently mounted on a truck, like the nose-mount units already described. However, for smaller delivery trucks that return to the shop at the end of the day, the condensing unit is often a small, portable unit that is separate from the truck.

When the truck has completed its deliveries for the day and returns to the shop, the portable condensing unit is connected to the eutectic plate. The condensing unit contains a compressor, condenser, filter-drier, and metering device. The ends of the evaporator coil protrude from the eutectic plate and are equipped with quick-connect fittings. The quick-connect fittings allow the condensing unit to be connected and disconnected from the evaporator without refrigerant loss, **Figure 48-6**.



Transcold Distribution, Ltd.

Figure 48-5. A trailer equipped with multiple eutectic plates. Note the thermostatic expansion valves on each plate, which meter the refrigerant flow to the evaporators contained inside the plates.



Goodheart-Willcox Publisher

Figure 48-6. Eutectic plate installed in a refrigerated truck. At night, a condensing unit is connected to the eutectic plate and circulates refrigerant to freeze the eutectic solution inside the plate. In the morning, the condensing unit is disconnected.

Copyright Goodheart-Willcox Co., Inc. 2017

The condensing unit is allowed to operate through the night, circulating refrigerant through the evaporator to freeze the eutectic solution. As refrigerant vaporizes inside the evaporator coil, heat is absorbed from the eutectic solution. As sensible heat is removed from the eutectic solution, the temperature of the solution falls. When the freezing point of the solution is reached, additional latent heat is absorbed from the solution as it freezes. In the morning, when the solution in the eutectic plate is fully frozen, the plate is disconnected from the condensing unit. Throughout the rest of the day, the eutectic plate absorbs heat from inside the truck box as the eutectic solution slowly melts. At night, the truck returns to the shop to repeat the process.

Pro Tip

Eutectic Plate Terminology

Eutectic plates are also commonly referred to as cold plates, holding plates, and hold plates.

48.1.2 Railcar Refrigeration

Railcar refrigeration is used for two general purposes: to refrigerate cargo and to provide comfort cooling to passengers. Railcar construction and insulation is similar to that of a refrigerated trailer. While most railcar refrigeration is provided by compression refrigeration systems, some railcar refrigeration systems are absorption systems. Others use steam jet systems, which are discussed later in this chapter.

Compressors are usually driven from the railcar axle while the train is in motion. An electric motor is used when the railcar is stopped. Some trailer refrigeration systems with a diesel-powered generator and motor-driven compressor have been modified to be used in railcars. These systems are very similar to the one shown in **Figure 48-2**. The main differences are additional structural elements to protect the refrigeration system and the use of remote communications (by satellite, cell phone, or radio frequency) to monitor and control the system.

48.1.3 Intermodal Shipping Container Refrigeration

Intermodal shipping containers are used aboard ships, trucks, railcars, and airplanes to transport perishable goods. For short distances, a container can be cooled by a eutectic plate or dry ice. Before the goods are put into the container, the eutectic solution is frozen using a detachable condensing unit. Once frozen, the eutectic solution provides enough cooling capacity to keep the cargo at the desired temperature for the short time the shipment is in transit.

Pro Tip

Intermodal Shipping Container Dimensions

The International Standards Organization (ISO) has issued standards for the dimensions of intermodal shipping containers. The most common lengths are 20′, 40′, and 45′. The height may be 8′-6″ or 9′-6″, and the width is typically 8′.

For longer trips, intermodal shipping containers require a compression refrigeration system to keep the cargo at the desired temperature. The condensers in most shipping container refrigeration systems are water cooled because there may be inadequate airflow for an air-cooled condenser. The compressor is usually driven by a diesel-powered generator on the container. On a ship, the container can be plugged into the ship's power. For warehouse or dock storage, the local power grid may be used to power the container's refrigeration system, **Figure 48-7**.

48.1.4 Marine Refrigeration

Marine refrigeration equipment is basically the same as land-based refrigeration equipment, but designed for the marine environment. System components must also be designed to withstand exposure to saltwater and high humidity. The demands of the marine environment have led to increasingly

Carrier Transicold Division, Carrier Corp.

Figure 48-7. An intermodal shipping container equipped with a compression refrigeration system.

Copyright Goodheart-Willcox Co., Inc. 2017

specialized designs, especially for smaller systems used on yachts. Many yachts, especially sailboats, are constrained by the amount of available electrical power. The most efficient systems use hermetic compressors that can operate on the power supplied by a solar panel. An important aspect to consider in all marine applications is that the available space on a ship or boat for refrigeration equipment is limited, **Figure 48-8**.

Refrigerated storage spaces aboard yachts, commonly called cold boxes, are frequently exposed to tropical conditions. The cold box insulation and refrigeration system are often sized for 90°F (32°C) ambient conditions. As a result, the recommended insulation values are R-20 for refrigerator space and R-30 for freezer space. This can be achieved with 4" (10 cm) of conventional foam insulation around the refrigerator or 6" (15 cm) around the freezer. However, many insulating foams, such as polyurethane and polyisocyanurate foams, absorb water easily. If these materials become wet, they lose much of their insulating ability. Extruded polystyrene is preferred as an insulating material for marine applications because it does not absorb water.

The required thicknesses of insulating foams for good thermal performance take up valuable space in a space that is already limited. In some cases, adequate space is unavailable. To solve this dilemma, a technician can use vacuum insulation panels for cold box insulation because of their ability to save space while still maintaining R-values ranging up to R-50. Vacuum insulation panels allow for much thinner box walls, which can double or triple the usable space in a given box. The material is also stable and can provide good thermal performance for the life of the boat.

Cold boxes should be designed to minimize the damage that can occur to them during use. Any damage to the cold box's exterior can lead to unwanted condensation, especially around hatches and behind cushions. Access lids and doors should have latches to prevent spillage of the box contents when rough weather is encountered.

Marine refrigeration systems are typically assembled from converted industrial or automotive refrigeration or air-conditioning equipment. Although there is some mixing of types, larger systems tend to use open-drive compressors and eutectic plates while smaller systems are more likely to use flat-plate evaporators and hermetic compressors, similar to the type used in domestic refrigerators. See **Figure 48-9**.

There are three common methods for cooling a system's condenser. An air-cooled condenser is the

least expensive. However, as the ambient air temperature increases, the amount of energy required by the compressor to maintain high enough head pressure for proper cooling becomes excessive. Water is about 20 times more thermally conductive than air, and an endless supply is available on the other side of the boat's hull. For these reasons, many boats use keel coolers or heat exchangers cooled by pumped-in seawater.

Keel coolers run the condenser tubing outside the hull in the vicinity of the keel to take advantage of seawater's ability to absorb heat. Keel coolers must be properly sized for their application. If a keel cooler is oversized, it may operate efficiently in warm water but provide too much subcooling when the boat is in cold water. If a keel cooler is undersized, the head pressure can become excessively high in warm water, leading to high energy use, **Figure 48-10**.

Unlike standard air-cooled condensers at a residence or on top of a building, keel coolers are submerged in water. This subjects them to a wide range of temperature and any chemicals or substances that may be in the water. Many keel coolers are equipped with zinc anodes to minimize corrosion of the condensing coil's housing. See **Figure 48-11**.

Heat exchangers provide economical operation across a wide range of operating temperatures. A pump draws in water through an inlet in the hull of the boat. The water is passed through a heat exchanger where it absorbs heat from high-pressure refrigerant inside the compressor's discharge line. The heated water is then released back outside the boat. See **Figure 48-12**.

48.2 Alternative Refrigeration Methods

To this point, the focus of this book has been largely on compression and some absorption refrigeration systems. However, a number of different refrigeration methods have been developed to meet specific commercial and industrial refrigeration needs. The following sections address some of these alternative refrigeration methods.

48.2.1 Expendable Refrigeration Systems

An expendable refrigeration system, sometimes called an open-cycle refrigeration system, is one in which the refrigerant is discarded after it has evaporated. In one variation of an expendable refrigeration system, liquid nitrogen is sprayed directly into a conditioned space. As the nitrogen evaporates, it absorbs heat from the space and is then vented to the atmosphere. This simple system is used in the storage of refrigerated or frozen foods and in trucks and other vehicles in the transportation industry, **Figure 48-13**.

The liquid nitrogen is kept under high pressure in an insulated cylinder inside the conditioned space. A control box is connected to a temperature-sensing element and to a liquid control valve. When the temperature in the conditioned space rises above the cut-in temperature, the control box operates the liquid control valve, allowing some of the liquid nitrogen out of the cylinder. The pressure of the liquid nitrogen drops as it passes through the restriction in the valve. As the low-pressure liquid nitrogen is forced out through the spray nozzles, it rapidly evaporates into low-pressure nitrogen vapor, absorbing heat from the air inside the conditioned space.

The temperature-sensing element constantly monitors the temperature in the conditioned space and relays information to the control box. With this information, the control box can regulate the liquid control valve to increase or decrease the flow of liquid nitrogen to the spray nozzles as needed. In this way, these devices work together to maintain the desired temperature in the conditioned space.

Because liquid nitrogen evaporates at –320°F (–196°C) at atmospheric pressure, it is well suited for shipping frozen foods. The temperature may be kept as low as desired, usually about –20°F (–29°C). An advantage of expendable refrigeration systems that use liquid nitrogen is their ability to operate without a power source. Also, because of their simple design, these types of expendable refrigeration systems require very little maintenance. However, the liquid nitrogen cylinder must be replaced or recharged periodically.

Containers or spaces refrigerated by liquid nitrogen must be equipped with safety devices to shut off the flow of nitrogen when a person opens a door to the space. Heat surrounding the cylinder may cause the liquid nitrogen inside to evaporate rapidly, increasing

the cylinder's internal pressure. If the cylinder pressure rises above a safe limit, an automatic pressure-relief valve on the cylinder opens to allow nitrogen vapor to escape until the cylinder pressure is back below a safe level. Liquid nitrogen cylinders are also equipped with rupture discs. If cylinder pressure becomes excessively high, the rupture disc bursts to vent nitrogen vapor and prevent the cylinder from exploding.

Safety Note

Liquid Nitrogen Safety

Exposure to liquid nitrogen can result in severe burns and frostbite. Always wear a long-sleeve shirt, insulated gloves, and safety goggles or a face shield when handling or operating a liquid nitrogen cylinder. Use a cart, crane, or lift to move the cylinder. Do not roll a liquid nitrogen cylinder. Keep it in a vertical position at all times.

48.2.2 Dry Ice Refrigeration

Dry ice is carbon dioxide (CO_2) frozen solid. It is pressed into various sizes and shapes, typically blocks or slabs. As dry ice absorbs heat, it changes directly from a solid to a vapor. It does not go through the liquid state. The process of a solid changing directly into a vapor is called ***sublimation***. At atmospheric pressure, solid carbon dioxide sublimates at –109°F (–78°C), **Figure 48-14**.

Figure 48-15 shows a common method of using dry ice to refrigerate frozen food. Dry ice is packed either beside or on top of the food packages. As the dry ice changes to carbon dioxide vapor, it keeps the food frozen by absorbing ambient heat. The carbon dioxide vapor replaces the air in the container or cabinet as the dry ice sublimates. This also helps to preserve the food.

One type of expendable refrigeration system, often used on aircraft, uses dry ice as an expendable

secondary refrigerant in conjunction with a primary refrigerant that is not expended. A closed refrigeration circuit is connected to an evaporator in the conditioned space and to a condenser located in an insulated bin. This heavily insulated bin holds the condenser and dry ice pellets, **Figure 48-16**.

Since dry ice sublimates at a very low temperature (–109°F or –78°C), it causes refrigerant vapor entering the condenser to condense quickly to a liquid. The liquid refrigerant flows by gravity through the condenser and into the evaporator. A thermostatically operated metering device located in the liquid line controls the flow of refrigerant into the evaporator. In the evaporator, the liquid refrigerant absorbs heat as it vaporizes and flows upward into the condenser. At that point, the cycle repeats.

Safety Note

Dry Ice

Always wear heavy, insulated gloves when handling dry ice. Touching dry ice with bare skin can cause severe burns and instant frostbite.

48.2.3 Thermoelectric Refrigeration

Thermoelectric refrigeration is the process of transferring heat energy from one place to another using the movement of electrons. Heat is transferred on a subatomic level using semiconductor devices. In 1834, French physicist Jean-Charles Peltier discovered that when current was passed through the junction of two dissimilar metals, heat was absorbed in one part of the junction and moved to another part of the junction. This phenomenon, called the ***Peltier effect***, is the basis of modern thermoelectric refrigeration.

The thermoelectric refrigeration process removes heat from one area and puts it in another area. Electrical energy, rather than a refrigerant, serves as the heat-transfer medium. Thermoelectric refrigeration requires none of the conventional equipment necessary in a mechanical compression system. There is no compressor, evaporator, condenser, or refrigerant metering device. In fact, there are no moving parts because the cooling process is performed by semiconductors (solid-state components).

Semiconductors are processed into either N-type or P-type materials. N-type materials have a surplus of electrons and a negative (–) charge. P-type materials carry a positive (+) charge because they have electron holes, which are positively charged gaps that are ready to receive electrons. A ***thermoelectric couple*** is formed by connecting one N-type material and one P-type material. See **Figure 48-17**.

When current flows from the P-type material toward the N-type material, the junction where the materials are connected absorbs heat. The opposite end of each segment becomes hot and gives off heat.

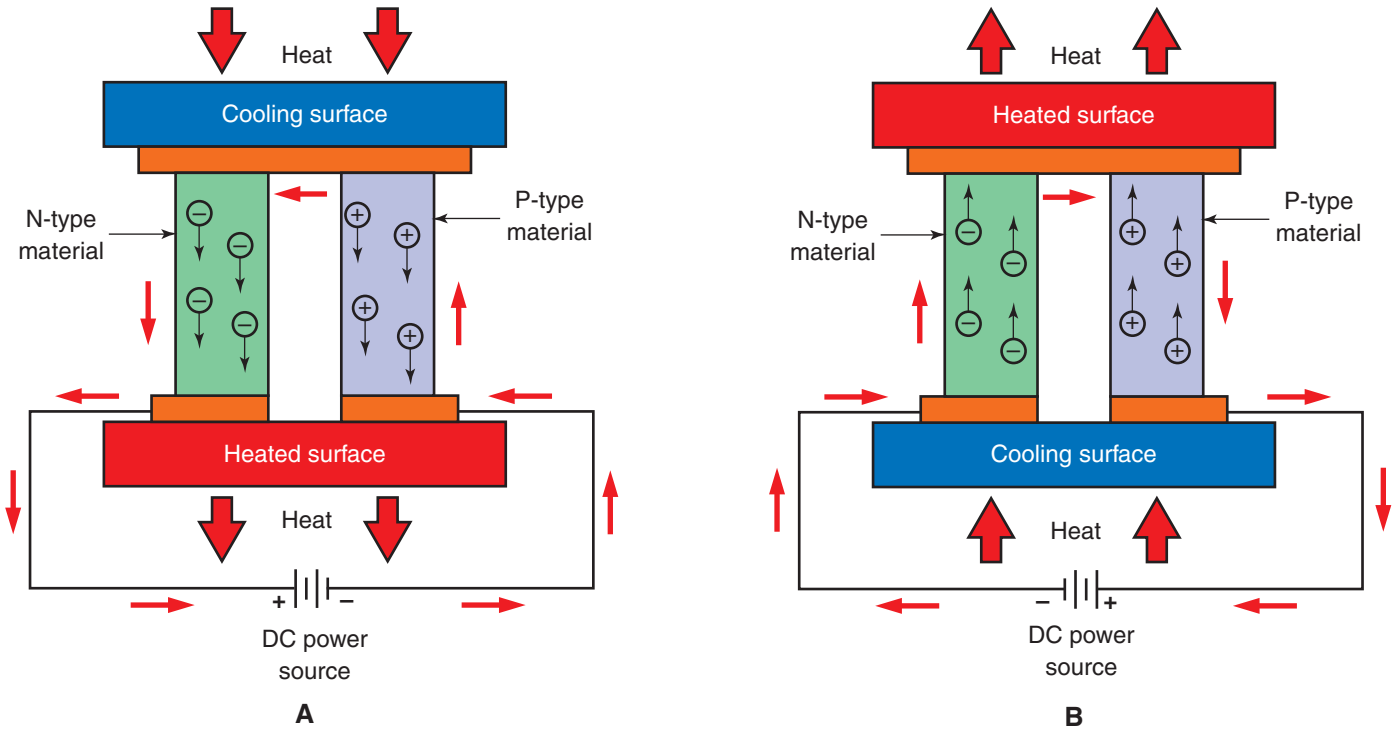
Goodheart-Willcox Publisher

Figure 48-16. One type of expendable refrigeration system uses dry ice in an insulated bin to absorb heat from the condenser. The primary refrigerant flows by gravity and does not require a compressor.



Goodheart-Willcox Publisher

Figure 48-17. Diagram showing how a thermoelectric couple absorbs and rejects heat when current is applied. A—When current from the power source flows from the P-type material to the N-type material, the surface at their junction absorbs heat. B—When the flow of current is reversed, the cooling surface and heated surface are switched.

Copyright Goodheart-Willcox Co., Inc. 2017

Reversing the direction of current through a thermoelectric couple switches the hot and cold surfaces. Thus, the same device can be used for either heating or cooling a conditioned space, depending on the direction of current flow through the device.

Pro Tip

Thermoelectric Couples and Thermocouples

Although both thermoelectric couples and thermocouples are similar in construction, they are not interchangeable. While thermoelectric couples are engineered to move heat when electric current is applied, thermocouples are designed to produce an electric current when heat is applied. Thermoelectric couples operate under the principle of the Peltier effect, and thermocouples operate under the principle of the Seebeck effect.

Since a single thermoelectric couple produces a minimal cooling effect, several thermoelectric couples are connected in series to form a ***thermoelectric module***, which produces significant cooling. Groups of modules can be connected together in parallel to further increase the cooling capacity. Fins on the cooling surface increase its heat flow. Fins on the outside of the heated surface help reject heat into the surrounding air more quickly. A rectifier supplies a controlled dc current to the module, and a thermostat inside the conditioned space controls the current flow through the rectifier. In this manner, the temperature inside the conditioned space is regulated, **Figure 48-18**.

Pro Tip

Thermoelectric Module Terminology

The following are some of the terms that can refer to thermoelectric or Peltier modules: Peltier device, Peltier cooler, thermoelectric cooler, thermoelectric heat pump, and semiconductor heat pump.

Benefits of using thermoelectric modules include silent operation, compact size, and low maintenance. Although the operation of thermoelectric modules is simple, their thermal efficiency is low. The amount of refrigeration obtained for the electrical energy spent is less than with a conventional compression refrigeration system.

Thermoelectric modules are used for the cooling and heating of nuclear submarines and for controlling temperatures in electronic equipment, such as computers and aerospace devices. Other applications for thermoelectric modules include water coolers, portable refrigerators, and medical applications, such as blood analyzers. See **Figure 48-19**.

48.2.4 Vortex Tubes

A ***vortex tube*** is a simple device that can provide cold air by separating it from hot air. It has no moving parts and does not use refrigerants. When compressed air is released into a vortex tube, a large volume of hot air comes out one end of the tube, and a smaller volume of cold air comes out the other end of the tube.

A vortex tube assembly consists of a compressed-air supply line, a jet, a swirl chamber, a tube, and a deflector cone (control valve). See **Figure 48-20**. Compressed air from the supply line passes through the jet and into the swirl chamber. The jet acts as an internal venturi. It restricts the flow of compressed air, causing the air to accelerate and creating a pressure drop. The air passes into the swirl chamber at an acute angle to the chamber wall. This angle causes the airflow to hug the wall of the swirl chamber as it moves through the tube, creating a vortex. The swirling motion continues and intensifies as the air flows through the tube.

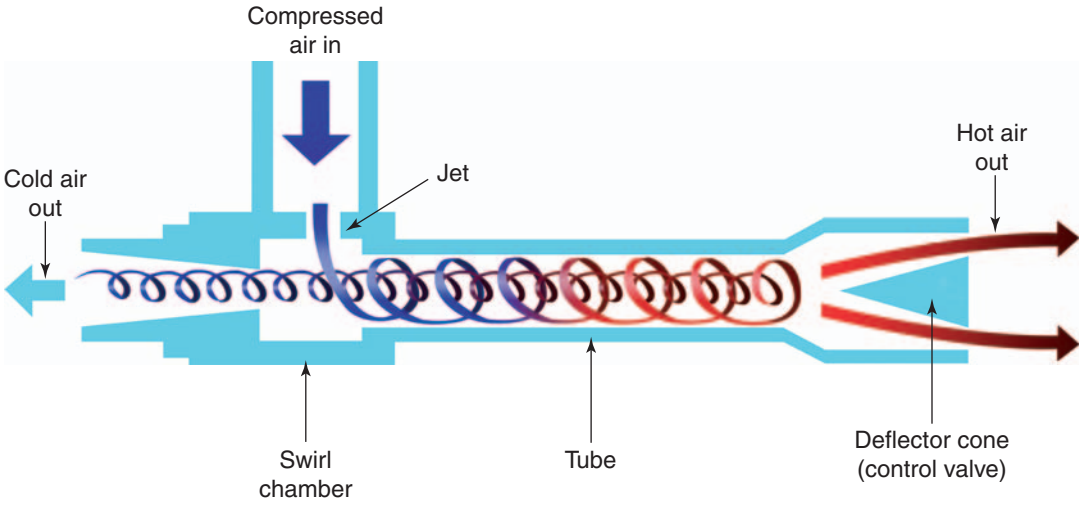
Due to centrifugal force, the air hugging the wall of the tube compresses slightly. This decreases the pressure of the air closer to the center of the tube, allowing it to expand and cool. When the air reaches the end of the tube, the hot air hugging the tube wall flows past the deflector cone. The cold air in the center of the tube hits the cone and deflects. High pressure forces the deflected cold air to reverse direction and flow back through the tube in the opposite direction. This cold air forms a column in the center of the tube as it flows backward through the swirl chamber and out the other end of the tube.

The deflector cone essentially acts as a control valve at the hot air outlet and determines how much air is allowed to escape from that end of the tube. When the cone is fully open, most of the air in the tube flows out through the hot air outlet. However, the small amount of air that does reverse direction and flows out the other end of the tube is cooled as much as possible. On the other hand, when the deflector cone is nearly closed, much more air reverses direction and flows out the other end of the tube. Since very little hot air is removed, the cooling effect is greatly reduced.

Vortex tubes are designed to operate on a continuous basis. Therefore, a large quantity of compressed air is required. No thermostatic control of any type is used to regulate the output temperature of a vortex tube. However, the output of the vortex tube can be changed manually by adjusting the deflector cone. This allows the vortex tube operator to adjust outlet air temperature as needed.

When supplied with compressed air at 100 psi (700 kPa) and 70°F (21°C), vortex tubes can be easily adjusted to deliver cold air with temperatures as low as –50°F (–46°C) or hot air with temperatures as high as 250°F (121°C). These temperatures, however, cannot be arrived at simultaneously. As the temperature at the cold air outlet is reduced so is the temperature at the hot air outlet. Similarly, when the temperature at the hot air outlet is increased so is the temperature at the cold air outlet.

Different types of vortex tubes are used for different cooling applications. In scientific work, vortex tubes can be used to dehumidify gas samples. Vortex tubes can also be used to cool environmental chambers and



ITW Vortec

Figure 48-20. Cross section of a vortex tube.

Copyright Goodheart-Willcox Co., Inc. 2017

electronic cabinets. Vortex tubes are commonly used in various machining and manufacturing processes to spot cool materials, **Figure 48-21**.

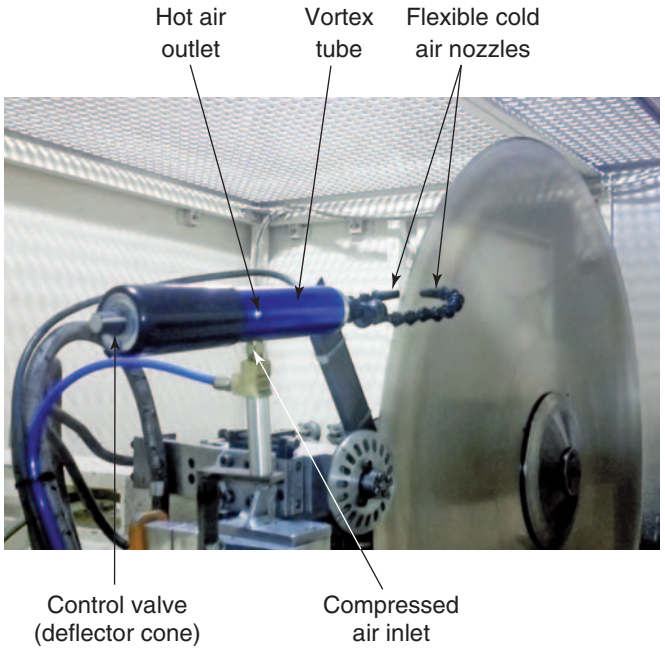
A common application of vortex tubes is personal air conditioning. Suits cooled by vortex tubes can be worn by people working in very hot environments or in environments that require heavy, protective clothing. The vortex tube is attached to a diffuse-air vest. Cold air is distributed over the upper body through tiny holes in the vest, cooling the person, **Figure 48-22**.

48.2.5 Jet Cooling Systems

There are two types of jet cooling systems: steam jet systems and refrigerant jet systems. These systems use a jet pump instead of a compressor to provide air conditioning or refrigeration. A jet pump consists of a centrifugal pump and ejector. A steam jet system uses water as the working fluid whereas a refrigerant jet system uses a refrigerant, such as R-134a. Older units may use R-11 or R-12 as the working fluid.

Steam Jet Systems

A ***steam jet system*** provides cooling by using high-pressure steam to induce low pressure in an evaporator. The low pressure causes water in the evaporator to evaporate, cooling the remaining water.



ITW Vortec

Figure 48-21. A vortex tube being used to cool a large saw blade in a paper mill.

ITW Vortec

Figure 48-22. Vortex tubes can be used to provide personal air conditioning in hot environments.

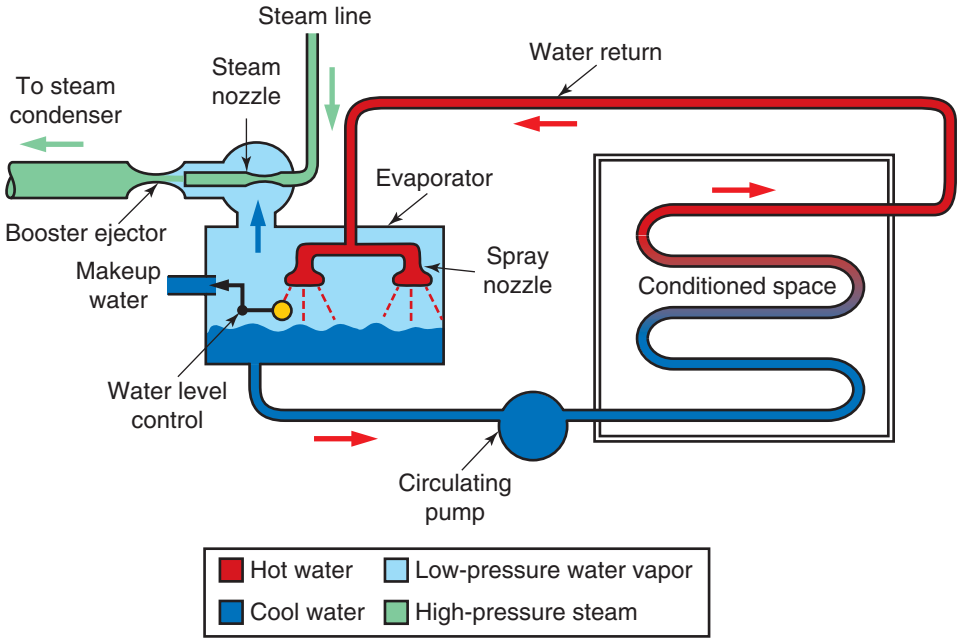
The cooled water is then used to absorb heat as it circulates through tubing in a conditioned space. See **Figure 48-23**.

In a steam jet system, the bottom part of the evaporator is filled with water, and the rest is filled with water vapor. A steam-fed booster ejector creates suction that draws water vapor out of the evaporator, causing a pressure drop in the evaporator. Since the pressure decreases, the temperature at which the remaining water evaporates also decreases.

As the water in the evaporator begins to evaporate, it absorbs heat from the remaining water. The heat being absorbed by the evaporating water lowers the temperature of the remaining water. This process lowers the temperature of the remaining water to between 40°F and 70°F (4°C and 21°C). Temperatures below 40°F (4°C) are impractical due to the risk of water freezing in the system.

A pump circulates the cooled water from the evaporator through tubing in the conditioned space.

Copyright Goodheart-Willcox Co., Inc. 2017



Goodheart-Willcox Publisher

Figure 48-23. A steam jet system uses steam to create low pressure in the evaporator. The low pressure causes water to evaporate and absorb heat.

As the cooled water passes through the tubing, it absorbs heat from the conditioned space. The water then returns to the evaporator where it is forced through spray nozzles.

After the steam passes through the booster ejector, it is condensed at another location for the following reasons:

- To recover some heat from the steam.
- To recover the water in the steam.
- To reduce the pressure so that it will not back up into the evaporator.

Steam pressure at the steam nozzle should be about 150 psia (1030 kPa). Although the steam condenser is not shown in the illustration, the steam pressure inside the condenser is about 3 psia (21 kPa). Knowing this, a technician can review a pressure-temperature (P/T) chart to find the corresponding condensing temperature for water at 3 psia, which happens to be 141°F (61°C).

Steam jet systems usually have a capacity of 100 tons or more. A capacity of this size requires a large supply of steam under a fairly high pressure. Exhaust steam from a high-pressure, steam-operated machine is often used to supply a steam jet system. Steam jet systems also require a large supply of water to keep the evaporator filled and to cool the steam condenser.

Steam jet systems are typically used to condition air. They are also used to cool water in certain chemical plants. Another application of steam jet systems is removing water from diluted solutions that contain juices. Orange juice can be concentrated in this way. Steam jet systems accomplish this by evaporating the water in the orange juice at a relatively low temperature. Since the juice remains cool as the water is boiled out, the vitamins in the juice are kept at full strength.

Refrigerant Jet System

A ***refrigerant jet system*** uses waste heat to help pressurize refrigerant and drive it from the evaporator to the condenser. Like a steam jet system, a refrigerant jet system uses a jet pump instead of a compressor. After refrigerant has released heat in the condenser, a circulating pump moves it through the metering device. The metering device reduces both the pressure and temperature of the refrigerant. At this point, the refrigerant splits and follows two different paths. Some refrigerant flows to the evaporator, and the rest flows through a heat exchanger where it absorbs waste heat, **Figure 48-24**.

The refrigerant passing through the evaporator cools the conditioned space by absorbing heat. The refrigerant path to the heat exchanger runs parallel to the evaporator. As the refrigerant in the heat exchanger absorbs high-temperature waste heat, it vaporizes and increases in temperature significantly. The temperature of the refrigerant leaving the heat exchanger is much higher than the temperature of the refrigerant leaving the evaporator. As a result, the speed at which the refrigerant from the heat exchanger flows through

Copyright Goodheart-Willcox Co., Inc. 2017

the jet pump creates suction. This pulls refrigerant from the evaporator into the jet pump and then on to the condenser.

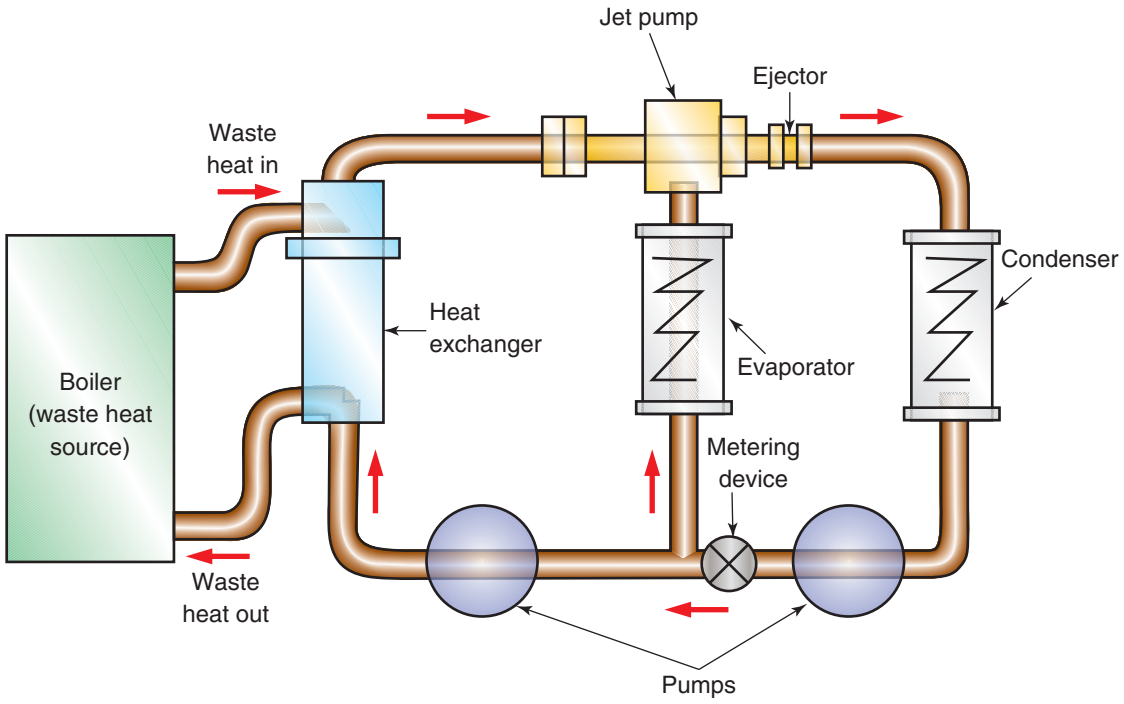
Compared to conventional compression refrigeration systems, refrigerant jet systems have a lower coefficient of performance and require a large condenser to remove heat. However, because the energy input into the system comes from waste heat, this type of system can be very economical in some applications. Refrigerant jet systems are often found in commercial installations where a large amount of waste heat produced by other commercial processes is readily available. Both steam jet and refrigerant jet systems demonstrate how energy conservation can be incorporated into high-waste commercial processes.

48.2.6 Stirling Refrigeration Cycle

The ***Stirling cycle*** is a closed thermodynamic cycle that can convert thermal energy into mechanical energy and vice versa. It was originally developed in 1816 by Robert Stirling who hoped to create an engine that would be a safer alternative to the steam engine. When heat is applied to a Stirling engine, the heat energy is converted into motion. Conversely, if mechanical energy is applied to a Stirling engine, heat is transferred from one area of the engine to another. This causes one area of the engine to heat up and the other to cool off.

The Stirling cycle was adapted for refrigeration by John Herschel in 1834. It is now used in some refrigeration installations designed to reach very low temperatures. This cycle, when used in a three-stage system, can produce temperatures as low as –450°F (–268°C). In theory, an ideal Stirling refrigeration cycle picks up heat only at the lowest temperature and discards heat only at the highest temperature. There would be no heat gain or heat loss between these two temperatures. In actuality, a practical Stirling refrigeration cycle is almost as good. It conserves the heat energy produced during one part of the cycle and uses it in another part of the cycle.

A simple Stirling refrigeration system consists of one cylinder and two pistons with a stationary regenerator between them. The entire space between the pistons is charged with a gas, usually helium. The cylinder walls are insulated to prevent heat transfer. The heat exchangers are uninsulated and are the only places where heat can be added or removed from the system. The cylinder has two heat exchangers: one for rejecting heat and the other for absorbing heat. The regenerator is filled with a porous material that allows the gas in the cylinder to pass freely through it. The material must also



Goodheart-Willcox Publisher

Figure 48-24. The flow of refrigerant vapor from the heat exchanger through the jet pump creates a siphoning effect that draws refrigerant vapor from the evaporator into the jet pump.

Copyright Goodheart-Willcox Co., Inc. 2017

have good thermal storage capacity and be able to transfer heat effectively, **Figure 48-25**.

The four steps of the Stirling refrigeration cycle are shown in **Figure 48-26**. In Step A, the refrigeration system is at its starting point. Both the hot piston and the cold piston are as far to the left as they can go. The hot piston begins moving to the right while the cold piston remains stationary. This compresses the gas. Some of the heat generated by the compression is rejected through the heat exchanger in the compression area.

In Step B, the cold piston begins moving to the right at the same speed as the hot piston. During this time, the volume of gas in the cylinder does not change. The gas from the compression area of the cylinder is forced through the regenerator, which absorbs heat from the gas.

In Step C, the hot piston is at the end of its stroke and remains stationary. The cold piston continues moving to the right, increasing the volume of gas in the expansion area. As the gas expands, it begins to cool off. Heat is absorbed through the heat exchanger in the expansion area to maintain a constant gas temperature.

In Step D, both the hot piston and the cold piston begin moving to the left at the same speed. The volume of gas does not change. As the gas is forced back through the regenerator, it reabsorbs the heat that it had given up to the regenerator in Step B. At the end of Step D, the system is in the same state it was at the beginning of Step A. The cycle is ready to begin again.

In practice, the left end of the cylinder is water cooled. The right end of the cylinder is the cooling unit. There are many different designs used to apply the Stirling refrigeration cycle. Although the systems may vary widely in their mechanics, they all operate on the same basic principles described here.

Chapter Review

Summary

- Truck and trailer refrigeration systems have many of the same components as other mechanical refrigeration systems: compressor, condenser, refrigerant metering device, and direct-expansion evaporator. Components specific to truck and trailer refrigeration include a quench valve, a subcooler, solenoid valves, and vibration absorbers.
- A diesel-powered generator and plug-in standby power are the two common methods used to drive the compressor in a refrigerated trailer. In refrigerated trucks, the compressor may be driven by the vehicle engine or an external generator.
- A eutectic plate is a thin, rectangular tank containing an evaporator surrounded by a solution that freezes at a desired temperature. For smaller trucks with eutectic plates, a portable condensing unit is plugged into the plates at night to freeze the solution inside them. During the day, the condensing unit is removed, and the eutectic plates provide passive cooling inside the truck box.
- The compressors in railcar refrigeration systems are typically driven off the railcar's axle while the train is in motion. Intermodal shipping containers can be cooled by eutectic plates or dry ice for short trips. For longer trips, a generator powers the refrigeration system.
- Due to the climates in which many boats travel, the cold boxes used in marine refrigeration systems require water-resistant insulation with a high R-value. Larger systems may use an open-drive compressor, while smaller systems typically use hermetic compressors. The three main methods for cooling the condenser are air, pumped-in seawater, and keel coolers.
- An expendable refrigeration system vents its refrigerant after it has evaporated. One type of expendable refrigeration sprays liquid nitrogen into a conditioned space. As the liquid nitrogen evaporates, it cools the space and is then vented.
- Dry ice refrigeration relies on the sublimation of solid carbon dioxide to absorb heat from a conditioned space. The dry ice may be used alone, or it may be used as a secondary refrigerant to condense another refrigerant in an adjacent but physically isolated circuit.
- A thermoelectric couple is made of N-type and P-type semiconductor materials. When direct current flows through a thermoelectric couple, one side of the thermoelectric couple transfers heat to the other side. The hot and cold sides can be switched by reversing the direction of the current.
- A vortex tube can provide cold air without any refrigerant or moving parts. Compressed air is fed into the vortex tube, which direct airflow in a certain manner. Hot air leaves one outlet in the tube, and cold air leaves the other outlet.
- Refrigerant jet systems use waste heat to help drive refrigerant from the evaporator to the condenser. Steam jet systems use high-pressure steam to siphon off water vapor inside an evaporator. The resulting drop in pressure increases evaporation, which cools the remaining water in the evaporator.
- The Stirling refrigeration cycle converts mechanical energy into heat energy. A simple Stirling refrigeration system uses a cylinder with two pistons, a stationary regenerator, and heat exchangers. As the pistons move, they transfer heat by compressing and expanding a gas, usually helium.

Review Questions

Answer the following questions using the information in this chapter.

1. In truck and trailer refrigeration systems, hot-gas solenoid valves open to initiate the _____ cycle.
   A. defrost
   B. passive cooling
   C. quenching
   D. transportation
2. A quench valve is a TXV that opens based on _____ temperature.
   A. discharge line
   B. liquid line
   C. subcooler
   D. suction line

Copyright Goodheart-Willcox Co., Inc. 2017

3. Which of the following statements regarding compressors in transportation refrigeration systems is *not* true?
   A. The compressor in railcar refrigeration is usually driven by the railcar axle.
   B. For longer trips, intermodal shipping containers use dry ice as the sole means of refrigeration.
   C. In small-capacity trucks, the compressor may be driven by the vehicle's engine.
   D. Some refrigerated trucks use a portable condensing unit that is removed before the truck is put into service for the day.
4. Which of the following types of insulation would be best suited for use in a marine cold box where space is severely limited?
   A. Extruded polystyrene
   B. Loose cellulose insulation
   C. Polyurethane foam
   D. Vacuum insulation panels
5. Which of the following statements regarding keel coolers is *not* true?
   A. Air-cooled condensers are less efficient than keel coolers.
   B. Keel coolers run the condenser tubing outside the hull.
   C. Pumps must be used to draw in and discharge the cooling water.
   D. Zinc anodes are used on keel coolers to minimize corrosion of their housings.
6. Which of the following refrigerants is commonly used in expendable refrigeration systems?
   A. Liquid ammonia
   B. Liquid argon
   C. Liquid carbon dioxide
   D. Liquid nitrogen
7. The process of dry ice changing from a solid directly into a vapor is called _____.
   A. condensation
   B. desiccation
   C. evaporation
   D. sublimation
8. Which of the following phenomena is the basis of thermoelectric refrigeration systems?
   A. The Electric effect
   B. The Peltier effect
   C. The Seebeck effect
   D. The Watt effect
9. Several thermoelectric couples connected in series form a _____.
   A. rectifier
   B. thermocouple
   C. thermoelectric module
   D. vortex tube
10. Eutectic plates designed for smaller delivery truck refrigeration on shorter trips provide _____ cooling.
    A. active
    B. expendable
    C. keel
    D. passive
11. In a vortex tube, the air at the center of the tube is cooled due to _____.
    A. change of polarity
    B. compression
    C. eutecticity
    D. expansion
12. In a vortex tube, the jet acts as an internal venturi, which restricts the flow of compressed air. This causes the air to accelerate and creates a(n) _____.
    A. electric spark
    B. N-type material
    C. pressure drop
    D. pressure increase
13. In a steam jet system, the steam jet _____.
    A. carries heat away from the condenser
    B. forces refrigerant into the condenser
    C. lowers the pressure in the evaporator
    D. spins a compressor turbine
14. Which of the following components is *not* part of a refrigerant jet system?
    A. Compressor
    B. Condenser
    C. Evaporator
    D. Heat exchanger
15. A Stirling refrigeration system uses mechanical energy to transfer _____ energy.
    A. electrical
    B. magnetic
    C. sublimation
    D. thermal

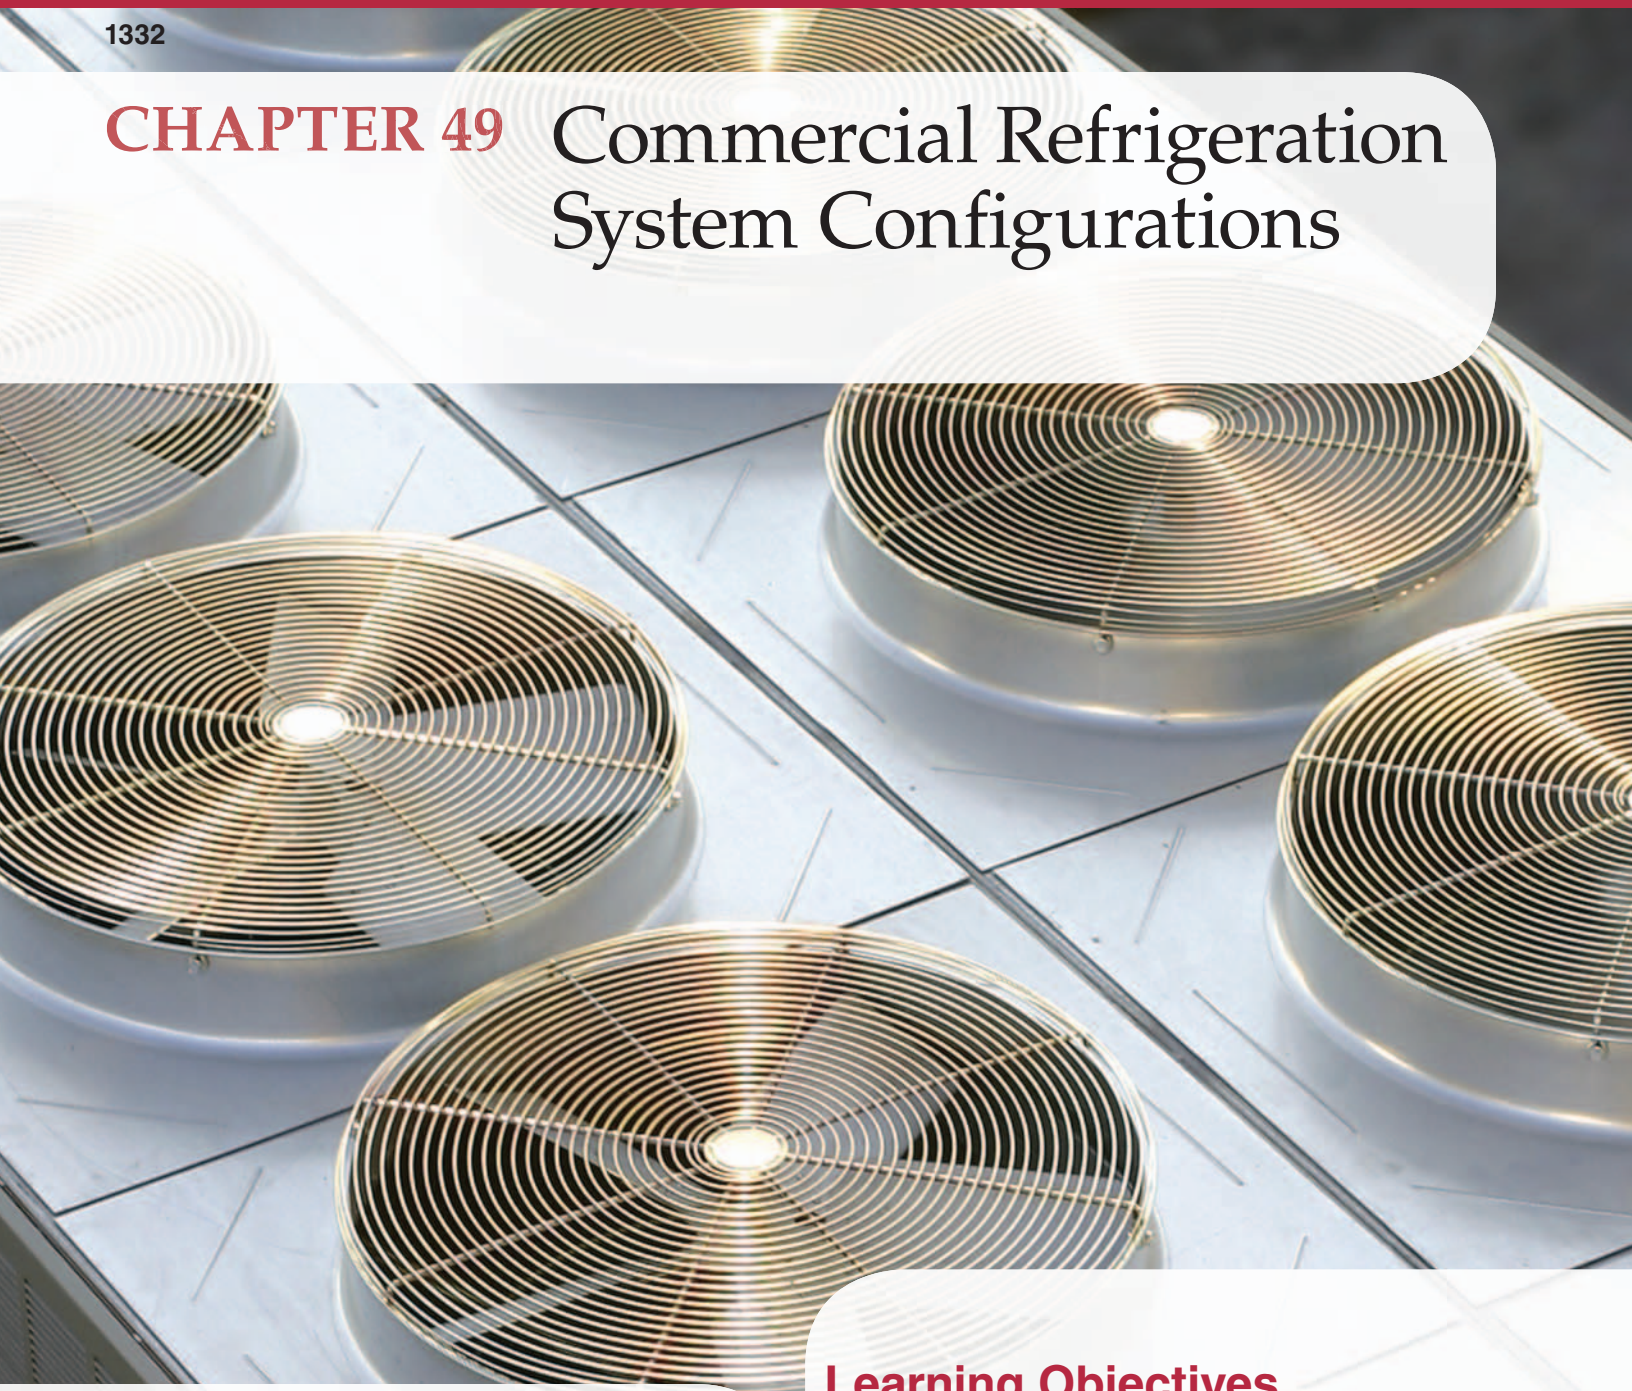
CHAPTER 49 Commercial Refrigeration System Configurations



Chapter Outline

49.1 Commercial Systems Configuration Overview
49.2 Multiple-Evaporator Systems
49.3 Modulating Refrigeration Systems
- 49.3.1 Multiple-Compressor Systems
- 49.3.2 Variable-Capacity, Single-Compressor Systems
- 49.3.3 Hot-Gas Bypass Capacity Control

49.4 Multistage Systems
- 49.4.1 Compound Refrigeration Systems
- 49.4.2 Cascade Refrigeration Systems

49.5 Secondary Loop Refrigeration Systems

Learning Objectives

Information in this chapter will enable you to:

- Explain the difference between packaged and split commercial refrigeration systems.
- Understand the operation and purpose of various components used in sophisticated commercial refrigeration systems.
- Identify applications for multiple-evaporator systems.
- Summarize the different methods of achieving variable capacity in modulating refrigeration systems.
- Explain the refrigeration cycle in compound and cascade systems.
- Describe the purpose and operation of secondary loop refrigeration systems.

split system

Review of Key Concepts

Reviewing these concepts from earlier chapters will help you understand new concepts presented in this chapter:

- A crankcase pressure regulator (CPR) is a valve with an adjustable pressure setting that prevents crankcase pressure from exceeding a preset safe value. It throttles suction pressure above its setting to maintain a safe pressure level in the compressor crankcase. (Chapter 19)
- Since high head pressure can cause problems for a compressor, a normally closed pressure switch is installed in the compressor discharge line between the compressor and condenser. If head pressure rises too high, the discharge line pressure switch opens to shut off the system. (Chapter 19)
- A mechanical air-conditioning or refrigeration system can modulate its cooling capacity through different means. A method called variable refrigerant flow (VRF) involves changing the amount of refrigerant pumped through the system. In single-compressor systems, this is usually done with an inverter-driven compressor and electronic expansion valve (EEV). (Chapter 32)
- An evaporator pressure regulator (EPR) is a pressure-regulating valve that restricts the flow of refrigerant coming out of the evaporator. It maintains a set minimum pressure in the evaporator, which corresponds to a desired temperature setting. (Chapter 22)
- Head pressure control valves operate to maintain a minimum head pressure during periods of low ambient temperature, when head pressure can drop too low. (Chapter 22)
- Large commercial refrigeration systems often use parallel compressor racks or distributed systems, which have more than one compressor, to serve display cases and other cooling units. (Chapter 47)
- Refrigeration systems with multiple evaporators require additional controls and components, such as manifold valves, evaporator pressure regulators (EPRs), check valves, different piping arrangements, and multiple refrigerant metering devices. (Chapter 22)
- Different types of HVACR systems can be designed for multistage operation. Thermostats control the operation of components to manage heating or cooling capacity. (Chapter 36)
- R-717 (ammonia, NH_3) has a low boiling point, making it ideal for low-temperature refrigeration. R-717 refrigeration systems are constructed of iron or steel, as ammonia attacks copper in the presence of moisture. (Chapter 9)
- A chiller system uses water as its secondary refrigerant and another fluid for its primary refrigerant. A secondary refrigerant absorbs heat from the conditioned space and transfers it to a primary refrigerant to reject outside the conditioned space. (Chapter 33)

Introduction

Because of the broad range of applications for commercial refrigeration, a wide variety of system configurations have been developed. Commercial refrigeration systems may be custom designed and constructed to meet the specific needs of the customer. These systems may use any of a number of methods to achieve the desired cooling capacities under the expected operating conditions.

Copyright Goodheart-Willcox Co., Inc. 2017

49.1 Commercial Systems Configuration Overview

There are two basic types of commercial systems: packaged and split. ***Packaged systems*** are whole refrigeration units designed, built, and shipped by the manufacturer. They include all of the major refrigeration components, piping, and electrical wiring of a complete system. Such units arrive charged, tested, and ready for operation. Before using a packaged system, check manufacturer instructions to see if any further tasks are necessary, such as connection to a drain for condensate.

Split systems are "site engineered." Components, such as the condensing unit, conditioned cabinets, tubing, and various control components, are purchased separately and assembled at the jobsite. Split systems are often custom designed for specific applications.

Earlier chapters of this text showed many compression refrigeration systems that were quite simple. For real-world applications however, operating conditions and refrigeration requirements may require that additional components be installed in a system. Various pressure regulators, flow controls, and sensors make refrigeration systems efficient and safe. A small commercial refrigeration system equipped with a variety of typical commercial refrigeration components is shown in **Figure 49-1**.

These components have been explained separately in various earlier chapters. Refer back to these chapters as referenced in the Review of Key Concepts section at the beginning of this chapter. An understanding of their purpose and operation is necessary when servicing and maintaining complex commercial refrigeration systems.

49.2 Multiple-Evaporator Systems

A ***multiple-evaporator system*** is a refrigeration system with two or more evaporators connected to only one condensing unit. These systems are commonly used in commercial refrigeration applications, **Figure 49-2**.

Liquid refrigerant flows through the thermostatic expansion valves (TXVs) to the evaporators. Each evaporator will have its own TXV. The evaporators may have identical or different evaporator temperatures. If the evaporator temperatures are identical, the system may use only low-side floats or TXVs to control the refrigerant. If the evaporators are intended to maintain different temperatures, the higher-temperature branch of the system must be equipped with an evaporator pressure regulator (EPR). **Figure 49-2**.

In a fixed volume, temperature and pressure both rise and fall together. If one evaporator operates at a higher temperature than another equally sized evaporator, the higher temperature evaporator must operate at a higher pressure also.

Since evaporators in a multiple-evaporator system share a suction line, they would normally have the same pressure. In order for one of these evaporators to have a higher pressure, a restriction must be placed between the low-pressure suction line and the evaporator. When suction line pressure drops below the pressure setting of an evaporator pressure regulator (EPR), the EPR closes or throttles its opening. Since less refrigerant can pass out through the EPR, evaporator pressure rises. Keeping an evaporator at a higher pressure will cause evaporator temperature to rise correspondingly. In this manner, EPRs allow evaporators sharing the same suction line to operate at different temperatures.

Just as the higher temperature evaporator must maintain a higher pressure than the lower temperature evaporator, the lower temperature evaporator must maintain a lower pressure than the higher temperature evaporator. During the Off cycle, refrigerant from the warmer evaporator can backflow into the colder evaporator. This could raise the temperature, which could short-cycle the system or begin thawing frozen products. To prevent the warmer evaporator's refrigerant from flowing into the cold evaporator, a check valve is installed. This will allow refrigerant to flow out of the cold evaporator but not back into it.

49.3 Modulating Refrigeration Systems

Most refrigeration systems are designed to have enough cooling capacity to maintain the desired temperature under the heaviest load. To maintain this temperature, the compressor operates when cooling (heat removal) is required and shuts off as soon as the desired temperature is reached. In other words, most refrigeration systems are either on or off. This means full power cooling operation or no cooling.

However, if the heat load is light, a simple on-off system may be oversized for the job. The operating cost for this oversized system is higher than for a system whose capacity more closely matches the needed load. The overcapacity system tends to cool the conditioned area too fast, resulting in short cycling. The term short cycling refers to a refrigeration system turning on and off too quickly. Short cycling causes extra wear and tear on the equipment, consumes excessive energy,

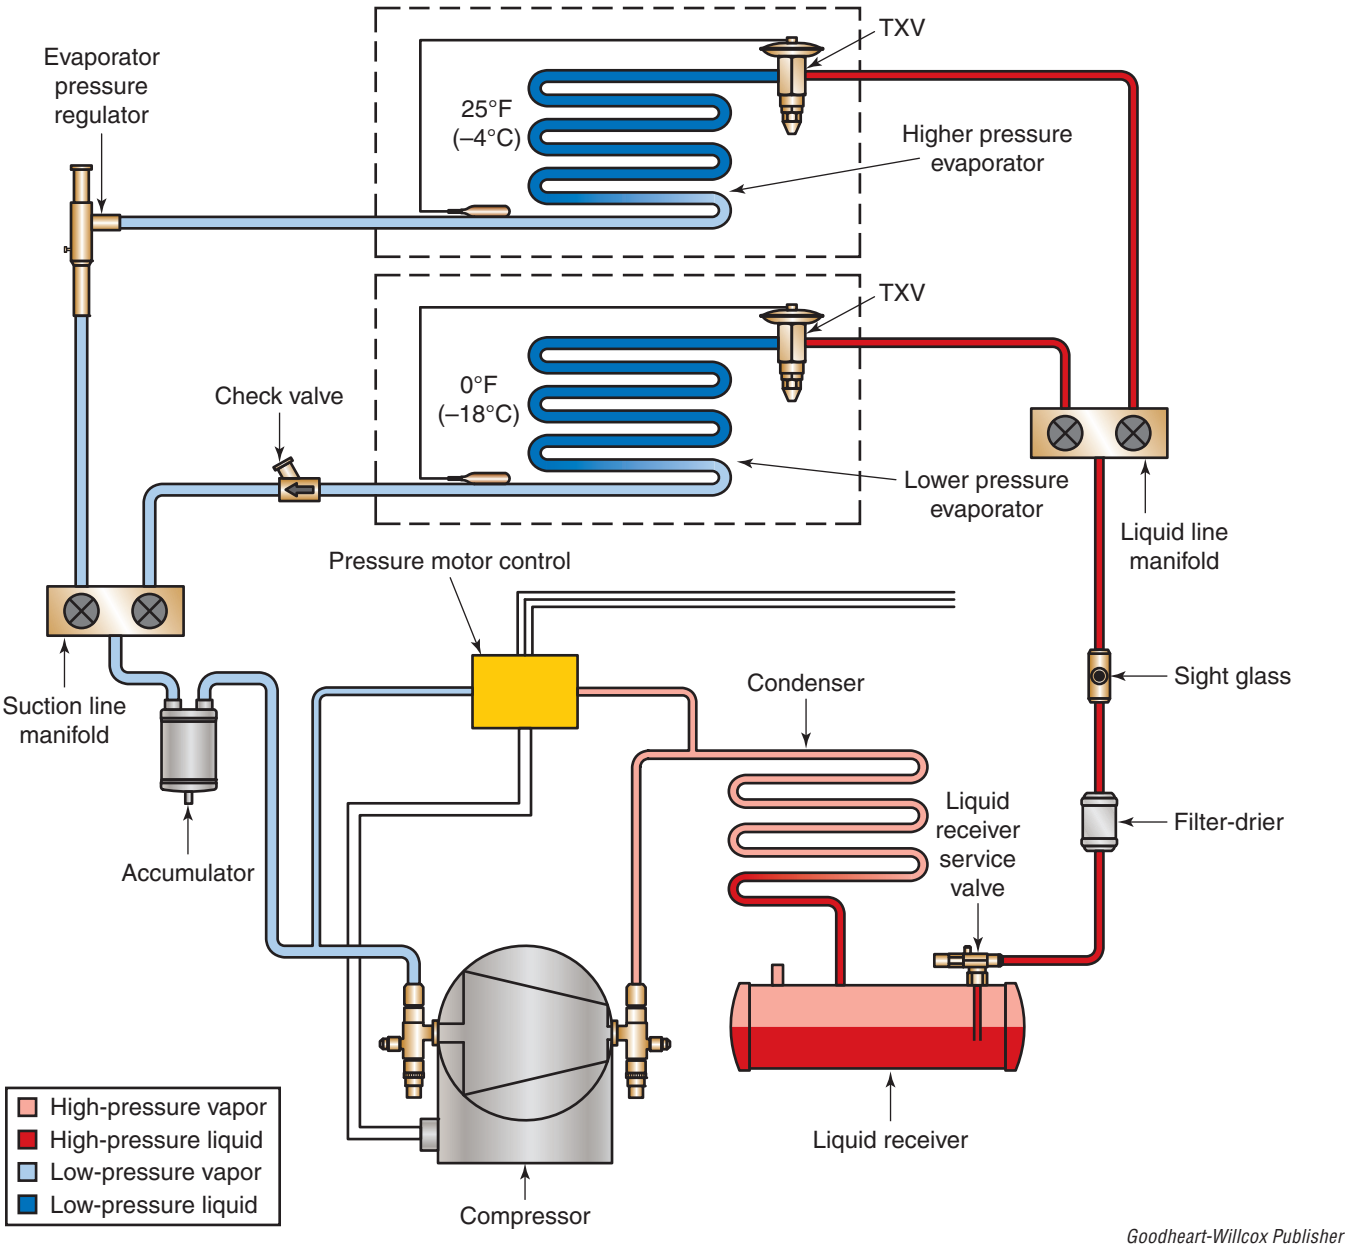
13

and prevents the system from providing proper dehumidification.

A ***modulating refrigeration system*** is a system that is able to adjust its capacity to more closely match a variable heat load. Several methods of modulating refrigeration are available. The most common methods of modulating refrigeration system capacity will be addressed in the following sections.

Copyright Goodheart-Willcox Co., Inc. 2017



Goodheart-Willcox Publisher

Figure 49-2. This multiple-evaporator system maintains a temperature of 0°F (–18°C) in one evaporator and 25°F (–4°C) in the other evaporator. The 0°F (–18°C) evaporator operates at a lower pressure than the 25°F (–4°C) evaporator.

49.3.1 Multiple-Compressor Systems

A ***multiple-compressor system*** is a modulating refrigeration system in which two or more compressors operate in parallel. The compressors are said to operate in parallel because each compressor provides a separate path for carrying refrigerant from the evaporator to the condenser. This is similar to the way two or more resistors wired in parallel allow current to follow separate paths from one end of a voltage source to the other, **Figure 49-3**.

Each of these parallel compressors is operated by a separate contactor or motor starter. By turning the individual compressors on and off, more or less refrigerant can be pumped, and different operating pressures can be achieved in the evaporators. As a result, the system can operate at different cooling capacities as needed.

In a multiple-compressor system, if the heat load remains constant and the temperature holds steady, a single compressor may provide adequate capacity. However, if the temperature rises to the second motor control's set point, a second compressor will start to operate along with the first. Additional compressors continue to cut in until enough cooling capacity is obtained.

Figure 49-4 shows a typical refrigeration cycle for a multiple-compressor modulating refrigeration system. Notice how this installation has three compressors

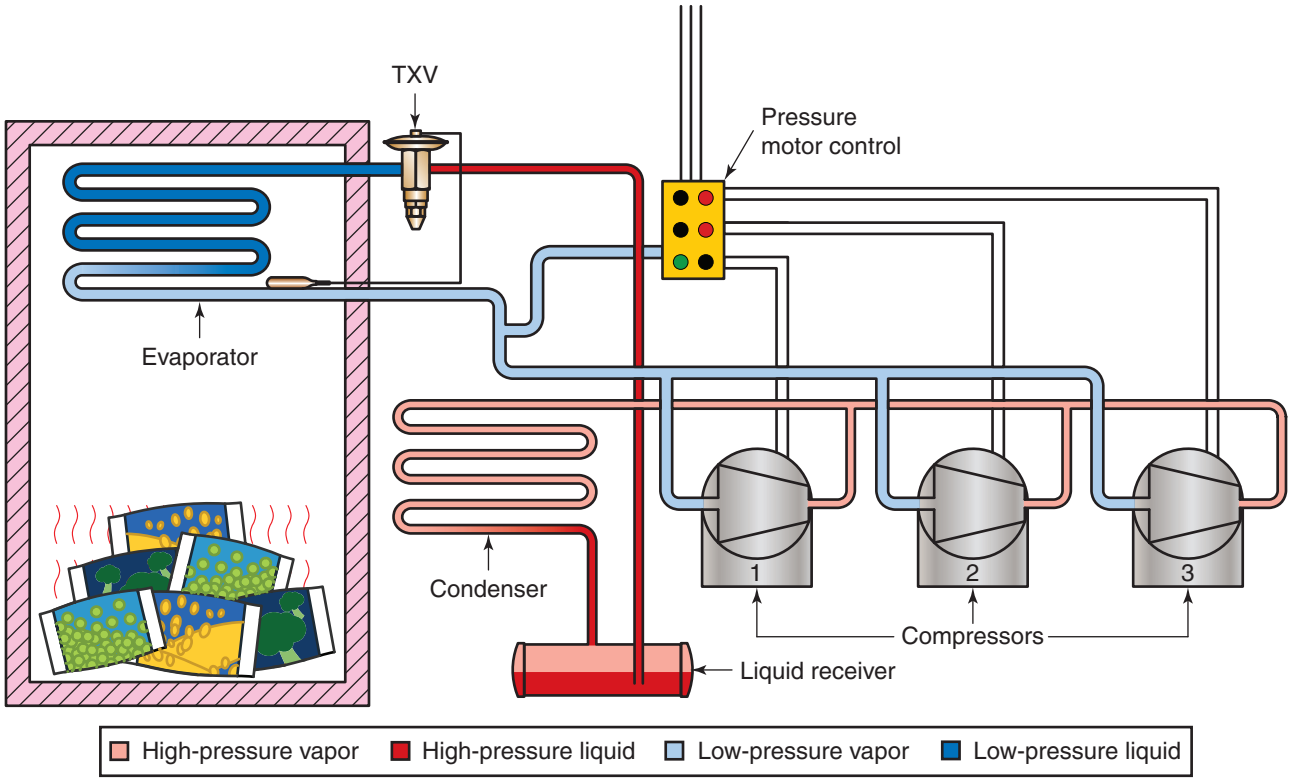
Goodheart-Willcox Publisher

Figure 49-3. A multiple-compressor system allows refrigerant to carry heat from the evaporator to the condenser along separate parallel paths. Each path leaves the evaporator and arrives at the condenser. Likewise, a parallel electrical circuit allows current to flow from one end of a voltage source to the other through separate parallel paths.



Goodheart-Willcox Publisher

Figure 49-4. Modulating refrigeration system that uses a single pressure motor control to operate up to three compressors to maintain the appropriate temperature.

but only one evaporator and one condenser. The compressors are cycled on and off based on signals from a pressure motor control connected to the suction line. The control contains a special switching device that alternates the operation of the compressors, so that each compressor runs for about the same amount of time. The modulating cycle maintains uniform temperatures and operates economically.

Many conventional refrigerant controls can be used. However, thermostatic expansion valves (TXVs) are the most common type. The same evaporator is connected to all the compressors. The same condenser and liquid receiver may be used by all the compressors, or each compressor may have its own condenser and receiver.

49.3.2 Variable-Capacity, Single-Compressor Systems

A second method of modulating system capacity is to vary the output from a single compressor. This can be accomplished in a number of ways, depending on the type of compressor installed in the system. Common methods of varying capacity in single compressor systems are as follows:

- Change the speed of the compressor (variable speed motor)
- Unload one of the cylinders (of a reciprocating compressor)
- Change the effective displacement of the compressor
- Bypass some of the refrigerant to the low side of the system.

Detailed information about variable-capacity compressors can be found in Chapter 18, *Compressors* and Chapter 32, *Residential Central Air-Conditioning Systems*.

49.3.3 Hot-Gas Bypass Capacity Control

The variable speed, variable displacement, and compressor unloading methods of adjusting capacity all work by changing the amount of refrigerant that passes through the compressor. The hot-gas bypass method of varying system capacity does not vary the output of the compressor. Instead, the system capacity is reduced during low-load periods by allowing some of the discharge line refrigerant vapor to bypass the condenser and metering device or evaporator. See **Figure 49-5**.

In some systems, like the one shown in **Figure 49-5A**, when the heat load in the conditioned space decreases and the temperature starts to decrease, hot gas can be diverted directly into the evaporator, bypassing the metering device. The hot gas entering the evaporator creates an additional heat load. This allows the system to continue running while maintaining the desired temperature. The result is more precise temperature and humidity control than would be attained by normally cycling the system on and off.

In other systems, like the one shown in **Figure 49-5B**, hot gas is bypassed into the suction line. This prevents the refrigerant in the suction line from condensing as the flow of refrigerant through the evaporator slows down. In many cases where the hot gas is bypassed to the suction line, a desuperheating circuit is combined with the hot-gas bypass circuit. In these designs, a liquid injection (desuperheater) valve injects a small amount of liquid refrigerant into the bypass line as needed. The liquid evaporates in the bypass line, cooling the hot bypass gas, which in turn prevents the compressor from overheating. More information on hot-gas bypass and desuperheating is provided in Chapter 22, *Refrigerant Flow Components*.

Pro Tip

Hot-Gas Bypass

In most cases, hot-gas bypass to the evaporator inlet is preferred over bypassing to the suction line. If hot gas is bypassed to the suction line instead of the evaporator, flow rates through the evaporator and suction line can slow to the point where the refrigerant flow is unable to help distribute oil. In such cases, the system relies on gravity alone to return oil to the compressor. Any hot-gas bypass system must be carefully designed to provide adequate oil flow under all operating conditions.

Because the bypass gas produces no cooling effect, both methods of hot-gas bypass reduce the overall efficiency of the system. For this reason, a system modulated by hot-gas bypass may be more expensive to operate than systems that use other methods to modulate refrigeration effect.

49.4 Multistage Systems

Some refrigeration systems must produce temperatures that are so low they can only be obtained using multiple stages of compression or refrigeration. A single compressor would simply be unable to achieve the compression ratios required. In such cases, a multistage system is used.

A ***multistage system*** is any refrigeration system with more than one stage of compression. There are two general types: cascade and compound. Either type of multistage system can be used to achieve much lower temperatures than can be reached with a single-stage system.

49.4.1 Compound Refrigeration Systems

A ***compound refrigeration system*** is a multistage system that has two or more compressors connected

in series. In a compound system, each successive compressor builds on the work performed by the previous compressor. **Figure 49-6** shows the refrigeration cycle of a compound system.

The compressor connected to the suction line that pumps the lower temperature and lower pressure refrigerant is the ***low-stage compressor***. The compressor that discharges into the condenser and pumps higher temperature and higher pressure refrigerant is the ***high-stage compressor***.

As shown in **Figure 49-6**, the low-stage compressor discharges into the intake of the high-stage compressor. The low-stage compressor discharge line carries the vapor through an intercooler and then into the high-stage compressor. An ***intercooler*** is a heat exchanger in a compound refrigeration system that removes the superheat from the low-stage discharge vapor. The refrigerant vapor is cooled (but not condensed) between the compressors.

Pro Tip

Desuperheating in Compound Refrigeration Systems

The intercooler between low-stage and high-stage compressors in a compound refrigeration system is a desuperheating heat exchanger. Superheat (all sensible heat) in the refrigerant is absorbed and carried away by a coolant flowing through the intercooler. However, some systems remove superheat from the low-stage using direct liquid injection rather than an intercooler. Liquid injection desuperheating of discharge line hot-gas vapor bypassed into the suction line is covered in Chapter 22, *Refrigerant Flow Components*. The same principles apply to liquid injection desuperheating of vapor between compressor stages in a compound refrigeration system.

The high-stage compressor discharges the refrigerant into the condenser, where it condenses into a high-pressure liquid and flows into the liquid receiver. From the liquid receiver, the liquid refrigerant flows through the liquid line to the TXV. The TXV regulates how much liquid refrigerant enters the evaporator. In the evaporator, the low-pressure liquid refrigerant absorbs heat and boils into low-pressure vapor. From the evaporator, the refrigerant vapor flows back to the low-stage compressor, and the cycle repeats.

A compound system provides increased capacity, which is needed in applications where extremely low evaporator pressures (and corresponding low temperatures) are required. A compressor's efficiency is inversely proportional to its compression ratio. In other words, as the compression ratio of a compressor increases, its volumetric efficiency decreases. A single compressor would have difficulty producing the pressure differences required to achieve extremely low evaporator temperatures. However, a compound system divides the required work between two compressors.

For example, imagine a two-stage compound system in which the low-stage compressor has a 4.5:1 compression ratio and the high-stage compressor has a 4:1 compression ratio. The vapor enters the low-stage compressor at 15 psia and leaves the compressor at a pressure of 67.5 psia (15 psia × 4.5 = 67.5 psia). The refrigerant is cooled to remove superheat and then enters the high-stage compressor. The vapor leaves the high-stage compressor at a pressure of 270 psia (67.5 psia × 4 = 270 psia). The net result is a compression ratio of 18:1 (4 × 4.5 = 18, or 270 psi divided by 15 psi equals 18).

If a single compressor was capable of achieving this compression ratio, it would operate at extremely low efficiency. However, since the two compressors in the compound system have relatively low compression ratios, they work together to achieve the 18:1 compression with relatively high efficiency.

Another problem of using a single compressor to reach very high compression ratios is that the discharge temperature would be excessively high. The discharge temperature may be so high that it would cause the oil in the compressor to vaporize, ruining its lubricating properties. When two compressors are used to achieve the same very high compression ratio, the refrigerant can be cooled between the two stages.

In a typical compound system, a single temperature motor control operates all motors. A thermostatic expansion valve controls the flow of liquid refrigerant into the evaporator. Refrigerants commonly used include R-22, R-404A, and R-507. The pressures do not balance during the Off cycle, and the system remains pressurized, with a low side and a high side isolated from each other. Therefore, the compressor motors used in compound systems must be capable of starting under load. Compound installations usually operate under heavy service requirements. Condensers and refrigerant must be kept clean. Compressor valves must be kept in good condition.

Thinking Green

Intermediate Pressure in a Compound Compression System

The compressors in a compound compression system maintain three different pressures: the low-stage intake pressure, the intermediate pressure (low-stage discharge and high-stage intake), and the high-stage discharge pressure. To maximize the compressors' energy efficiency, the intermediate pressure should be set so that the percentage of pressure increase at compressor outlet is the same for both compressors.

49.4.2 Cascade Refrigeration Systems

Cascade systems are often used in industrial processes where objects must be cooled to temperatures below –50°F (–46°C). A ***cascade refrigeration system*** is a multistage system that consists of two or more separate refrigeration subsystems with separate, isolated refrigerant circuits that work together to multiply cooling effect. The evaporator of the first-stage (high-stage) subsystem cools the condenser of the second-stage (low-stage) subsystem. The refrigerant circuit in each subsystem is completely separate, so the refrigerant in one subsystem never mixes with the refrigerant in the other subsystem. Although the refrigerant lines of the subsystems are not interconnected, the subsystems are said to be in series because the flow of heat has only one path to follow on its way from the conditioned space to the place where it is rejected. Like compound refrigeration systems, a cascade refrigeration system is divided into low and high stages based on pressure and temperature.

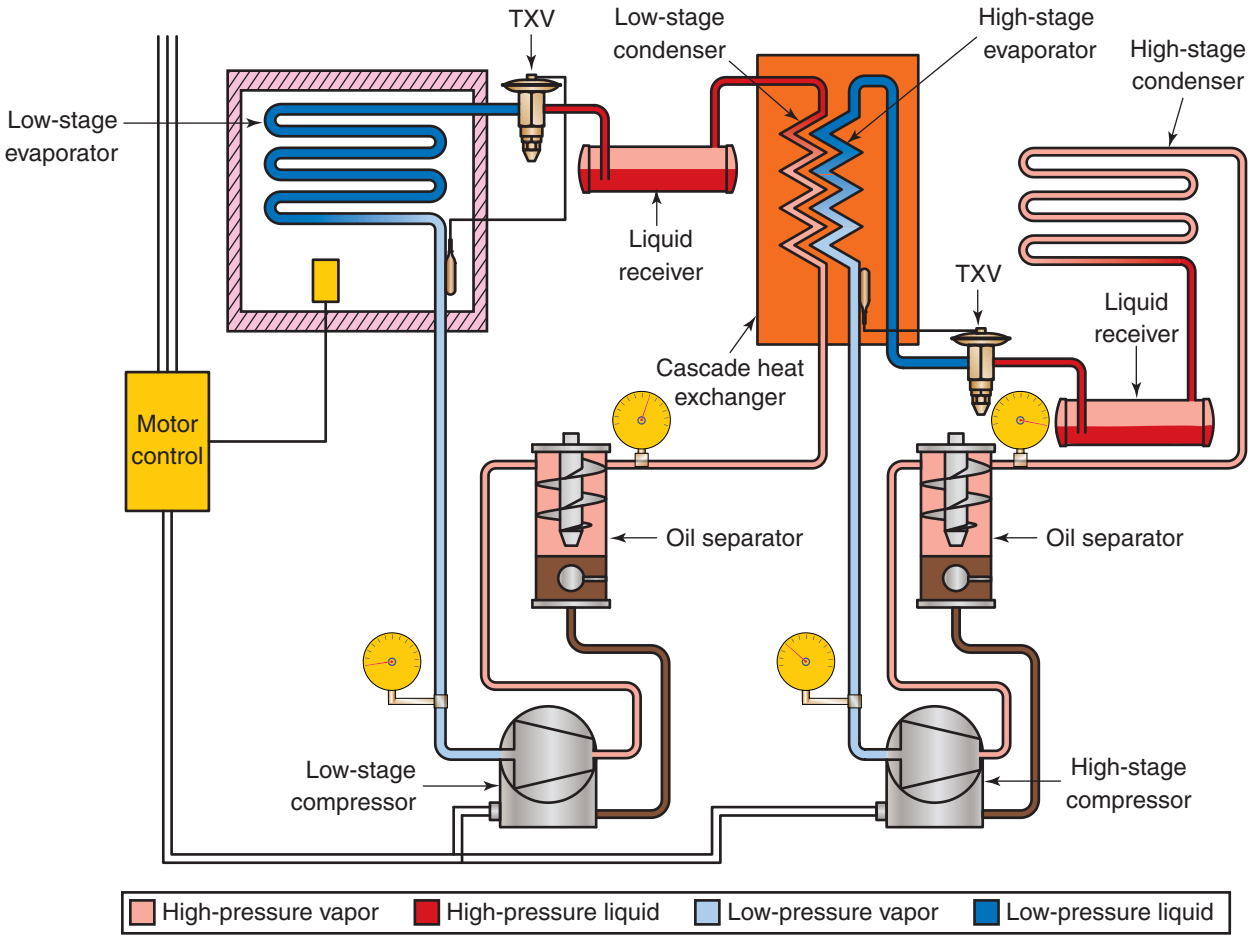
Figure 49-7 shows a cascade refrigeration system. Note that the two separate refrigeration subsystems interface at the cascade heat exchanger. The cascade heat exchanger contains the low-stage condenser and the high-stage evaporator. As the low-pressure liquid refrigerant in the high-stage evaporator vaporizes, it absorbs heat from the refrigerant in the low-stage condenser. This causes the low-stage refrigerant to condense.

Pro Tip

Moisture in Cascade Systems

Since cascade systems operate at very low temperatures, the refrigerant must be very dry. Any moisture in a cascade system would freeze at the needle seat of the TXV, stopping refrigerant flow.

The biggest advantage of cascade systems is that they have two separate refrigerant circuits, each charged with a different refrigerant. The refrigerant used in



Goodheart-Willcox Publisher

Figure 49-7. A cascade refrigeration system combines two complete refrigeration subsystems in order to achieve temperatures below –50°F (–46°C).

Copyright Goodheart-Willcox Co., Inc. 2017

the high-stage has a higher condensing and evaporating temperature. The refrigerant in the low-stage has a lower condensing and evaporating temperature. The refrigerant in the low-stage subsystem is called the *secondary refrigerant*. This refrigerant provides cooling to the conditioned area. The refrigerant in the high-stage subsystem is called the *primary refrigerant*. This refrigerant cools the secondary refrigerant and rejects the heat from the system. Having two refrigerants allows the use of the best refrigerant for each application. As a result, the compressors in the two subsystems each operate at an efficient compression ratio.

Pro Tip

Cascade System Refrigerants

In many cascade systems, CO_2 (R-744) is used as the secondary refrigerant and ammonia (R-717) is used as the primary refrigerant. Other popular secondary refrigerants include R-23 and R-508h. Other popular primary refrigerants include R-134a, R-22, and R-507.

Both the low-stage subsystem and the high-stage subsystem of a cascade system operate at the same time. The low-pressure liquid refrigerant in the high-stage evaporator cools the high-pressure vapor in the low-stage condenser. The evaporator of the low-stage subsystem supplies the cooling effect to the conditioned space.

Pro Tip

Cascade Heat Exchangers

Although there are different designs for cascade heat exchangers, the most common combine the functions of a shell-and-tube condenser and a flooded evaporator.

Each subsystem in a cascade system has a thermostatic expansion valve (TXV) for refrigerant control. TXVs close during the Off cycle; therefore, the pressures on the high and low sides of the subsystems do not balance. This means that the compressor motors used on cascade systems must be capable of starting under load. A temperature-sensing bulb on the low-stage evaporator provides input to the motor control, which is used to control both compressor motors.

Pro Tip

Off Cycle Balancing

When replacing a TXV in a cascade system, be certain to look at all its specifications. If the subsystems are not to balance during the Off cycle, ensure that the replacement TXV does not have a bleed port or means of balancing pressures. These features may be internal and difficult or impossible to tell by looking at the valve. Thoroughly review system requirements and product specifications.

The low-stage subsystem must use special refrigerant oil that is wax-free, moisture-free, and able to flow at extremely low temperatures. Oil separators should be installed in the discharge lines on both subsystems. This will help keep adequate oil in the compressors.

Caution

Oil Return Piping Practices

The oil that is carried by the refrigerant must be returned to the compressor. Since the viscosity of oil increases inside an evaporator, special attention should be given to proper suction piping installation. The piping design should allow oil to gradually flow back to the compressor oil sump due to gravity.

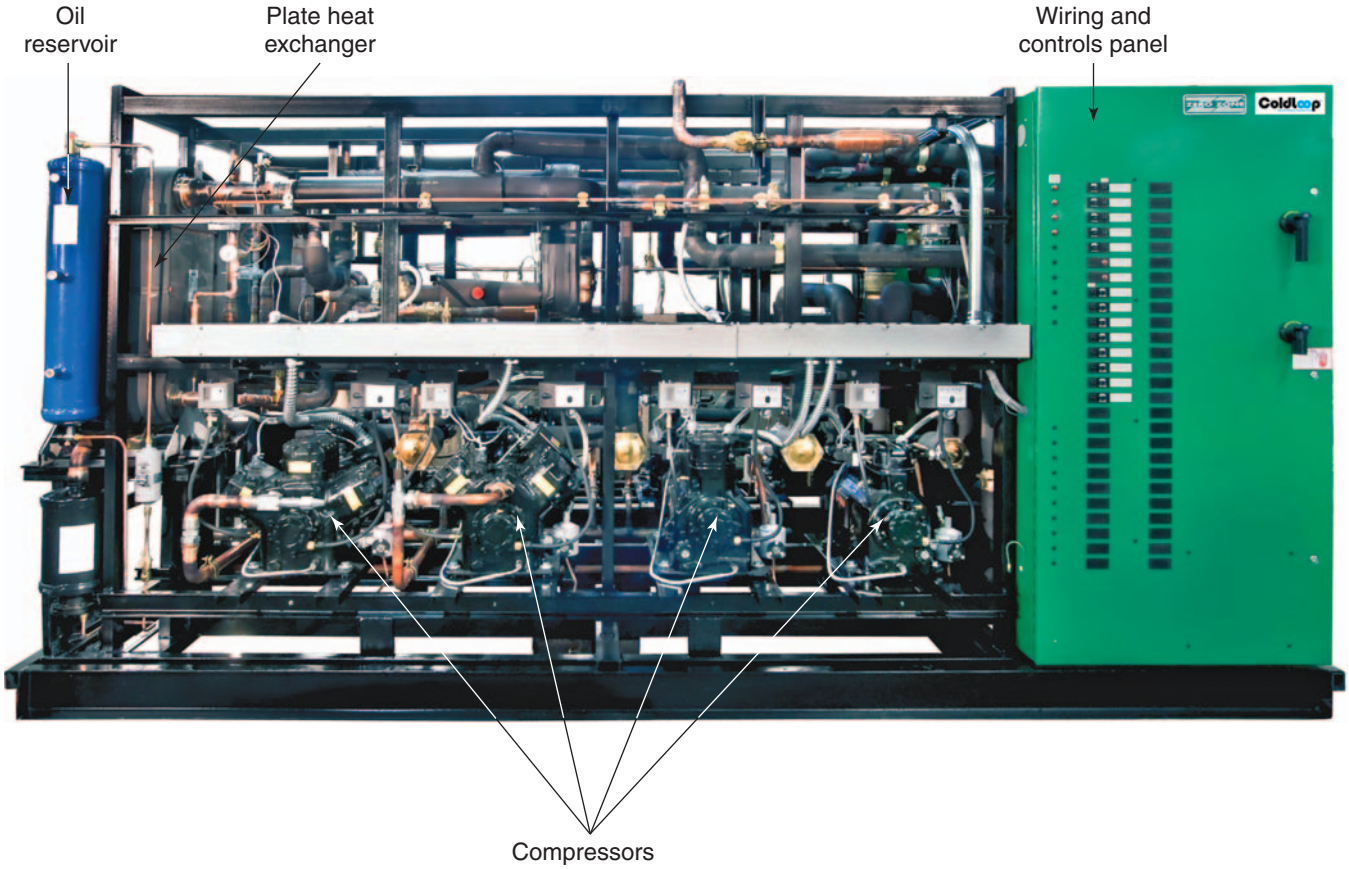
49.5 Secondary Loop Refrigeration Systems

An emerging trend in commercial refrigeration installations and retrofits is secondary loop refrigeration systems. These are comparable to cascade refrigeration systems; however, the secondary refrigerant is generally a fluid that does not change phases during normal operation. A ***secondary loop refrigeration system*** is a commercial refrigeration system in which a secondary loop circulates a nonphase-changing fluid for absorbing heat from a conditioned space and transfers that heat through a heat exchanger to a phase-changing refrigerant in a direct expansion refrigeration circuit, **Figure 49-8**.

Secondary loops stretch from a heat exchanger in the mechanical room throughout the entire building to each of the different conditioned spaces, such as display cases and walk-in coolers. From the mechanical room, the secondary refrigerant is pumped and distributed to each cooling coil where it absorbs heat from the conditioned spaces. When the secondary refrigerant flows back to the mechanical room, it passes through a heat exchanger that functions as the primary loop's evaporator. Heat absorbed into the secondary loop from the conditioned spaces is absorbed into the primary loop in the heat exchanger. A compressor in the primary loop pumps the primary refrigerant to a condenser that displaces the heat.

A traditional direct expansion commercial refrigeration system has only a single refrigerant circuit with a large charge of expensive refrigerant. A secondary loop refrigeration system uses an expansive, building-wide secondary loop. This means that the primary loop (a direct expansion circuit) can be confined to a smaller area, such as the mechanical room or roof. Reducing the size of the primary loop greatly reduces the amount of direct expansion (phase changing)

Copyright Goodheart-Willcox Co., Inc. 2017



Zero Zone, Inc.

Figure 49-8. A secondary loop refrigeration system is often paired with a parallel compressor rack to provide cooling for the secondary refrigerant. This system has multiple compressors, secondary loop pumps, heat exchangers, and numerous control devices.

refrigerant necessary for a secondary loop refrigeration system. Since secondary loops use a refrigerant that costs much less than a primary loop direct expansion refrigerant, the total refrigerant cost for the entire system is greatly reduced. This lower cost for refrigerant is a great incentive for using a secondary loop refrigeration system.

While primary loops are built with copper ACR tubing, secondary loops are often built using plastic piping, such as ABS. This results in far fewer copper joints, which reduces the chance of a direct expansion-type refrigerant leak. Also, the cost of plastic pipe is less than copper tubing. However, to maximize efficiency by minimizing the absorption of heat from an unconditioned space, secondary loop piping should be insulated, **Figure 49-9**.

Secondary loop pipes operate under lower pressure than copper pipes. The secondary loop usually circulates a nonphase-changing refrigerant, such as a glycol solution, that absorbs the heat from the conditioned spaces. The secondary refrigerant does not evaporate, but it still absorbs sufficient heat for refrigeration. Instead of an expansion valve or traditional

Zero Zone, Inc.

Figure 49-9. The piping and components circulating the secondary refrigerant are heavily insulated to maximize system efficiency.

Copyright Goodheart-Willcox Co., Inc. 2017

refrigerant control, secondary loops use balance valves that control the flow of the secondary refrigerant through the flooded evaporators. Rather than compressors, secondary loops use circulating pumps to move the secondary refrigerant, **Figure 49-10**.

In a secondary loop refrigeration system, the temperature of a conditioned space is controlled by the flow of the secondary refrigerant. The flow of secondary refrigerant and the temperature of a conditioned space have an inverse relationship. As one increases, the other decreases. The greater the flow of secondary refrigerant, the greater the heat absorption and the lower the conditioned space temperature. Reducing the flow reduces heat absorption and allows conditioned space temperature to increase, **Figure 49-11**.

The secondary loop has a few additional components not normally found in direct expansion systems. One of these is an air separator, which traps air that is circulating with the secondary refrigerant. Another secondary loop component is an expansion tank, which is a cylinder containing a pressure responsive bladder that is used to account for changes in secondary loop pressure, **Figure 49-12**.

Secondary loop refrigerant pressure can change due to thermal expansion, a small leak, or during service. Thermal expansion occurs when a secondary refrigerant warms during the Off cycle or long shutdowns when operating temperature may rise to ambient temperature. Secondary refrigerants are often dyed so that leak detection is less difficult.

Thinking Green

GreenChill Certification

The EPA's GreenChill Store Certification Program for Food Retailers is a voluntary program that recognizes stores that use environmentally friendly refrigeration systems. The refrigerant emission rates for GreenChill certified stores are estimated to be only 50% of the industry average.

To participate in the program, the store must submit information about its heat load, refrigeration system, and refrigerant usage and loss. The EPA will review the application and certify the store if it is GreenChill compliant. The certification lasts for one year, and stores can refer to the certification as part of their marketing strategy to environmentally conscious customers.

Chapter Review

Summary

- The two basic types of commercial systems are packaged systems and split systems. Packaged systems are refrigeration units designed, built, and shipped by the manufacturer. Split systems are assembled at the jobsite.
- Large commercial refrigeration systems use various pressure regulators, flow controls, and sensors to achieve accurate temperature control and efficient operation. Understanding the operation and purpose of the many components used in a commercial refrigeration system is necessary to service and maintain these complex systems.
- Commercial refrigeration systems with more than one evaporator are called multiple-evaporator systems. These may be designed so one evaporator maintains a lower temperature than the other evaporator. A higher temperature evaporator must be equipped with an evaporator pressure regulator (EPR).
- Modulating refrigeration systems are designed to handle varying heat loads. Instead of merely cycling on or off, a modulating refrigeration system operates at different capacities based on the heat load.
- One method of modulating refrigeration is to use multiple compressors operating in parallel. The compressors are cycled on and off in combination as needed to match the load. Another method of modulating refrigeration is to use a single, variable capacity compressor. A third method of modulating refrigeration is to use hot-gas bypass to reduce the capacity of the system as needed to match the heat load.
- Multistage refrigeration systems have more than one stage of compression and are used to reach extremely cold temperatures. The two types of multistage refrigeration are cascade and compound.
- A compound refrigeration system uses two compressors connected in series. The low-stage compressor discharges into the inlet of the high-stage compressor. An intercooler between stages reduces high superheat. This arrangement achieves a higher compression ratio than a single compressor with fewer complications and can produce extremely low temperatures.
- A cascade refrigeration system consists of two or more refrigeration subsystems with separate, isolated refrigerant circuits connected in series. They are joined in a heat exchanger in which the high-stage evaporator cools the low-stage condenser.
- A secondary loop refrigeration system has two refrigerant loops. The secondary loop absorbs heat from a conditioned space into a nonphase-changing fluid. The primary loop circulates a phase-changing refrigerant that absorbs heat from the secondary loop.
- The benefits of a secondary loop refrigeration system include a reduced direct expansion refrigerant charge, less chance of refrigerant leaks, and a lower cost of refrigerant and piping.

Review Questions

Answer the following questions using the information in this chapter.

1. A commercial refrigeration system that is designed, built, charged, tested, and shipped ready for operation by the manufacturer is referred to as a _____ system.
   A. bundled
   B. compound
   C. packaged
   D. split
2. What is the benefit of using an EPR on one of two evaporators that share a suction line and a liquid line?
   A. An EPR eliminates the need for pressure and temperature controls.
   B. Each evaporator can maintain a different temperature.
   C. The EPR will prevent backflow during the Off cycle.
   D. The two evaporators can share a single TXV.
3. A multiple-compressor system used for modulating refrigeration _____.
   A. actually only includes one compressor
   B. can only operate all or none of the compressors at once
   C. uses two or more compressors connected in series
   D. uses two or more compressors connected in parallel

Copyright Goodheart-Willcox Co., Inc. 2017

4. Unloading one or more compressor cylinders in a variable-capacity, single-compressor system can only be done in a _____ compressor.
   A. centrifugal
   B. reciprocating
   C. screw
   D. scroll
5. A primary method of modulating a system's capacity using a single compressor is by _____.
   A. closing the liquid line solenoid valve
   B. changing the speed of the compressor
   C. restricting flow into the condenser
   D. reversing the flow of refrigerant
6. The hot-gas bypass method of capacity control is mainly used for _____.
   A. high-load periods
   B. high-side pressure relief
   C. low-load periods
   D. Off cycle system balancing
7. Which of the following statements about compound refrigeration systems is *not* true?
   A. Compound systems can achieve high compression ratios more efficiently than single compressor systems.
   B. A compound system may have a single evaporator.
   C. Multiple compressors are used in parallel.
   D. All of the above.
8. Which of the following best describes the purpose of an intercooler in a compound refrigeration system?
   A. The intercooler performs the same function as the condenser (subcooling) on a single-compressor refrigeration system.
   B. The intercooler performs the same function as the evaporator on a single-compressor refrigeration system.
   C. The intercooler removes superheat from the suction gas before it enters the low-stage compressor.
   D. The intercooler removes superheat from the compressed gas as it flows from the low-stage compressor into the high-stage compressor.
9. Which of the following statements regarding cascade refrigeration systems is *not* true?
   A. The high-stage and low-stage subsystems typically use different refrigerants.
   B. The high-stage evaporator cools the low-stage condenser.
   C. The high-stage subsystem is normally off and only switched on if the heat load increases.
   D. A single motor control controls both the high-stage and low-stage compressors.
10. A commercial refrigeration system that absorbs heat from a conditioned space into a nonphase-changing fluid and transfers that heat through a heat exchanger into a separate circuit that circulates a phase-changing refrigerant is a(n) _____ system.
    A. compound refrigeration
    B. multiple-compressor
    C. multiple-evaporator
    D. secondary loop refrigeration

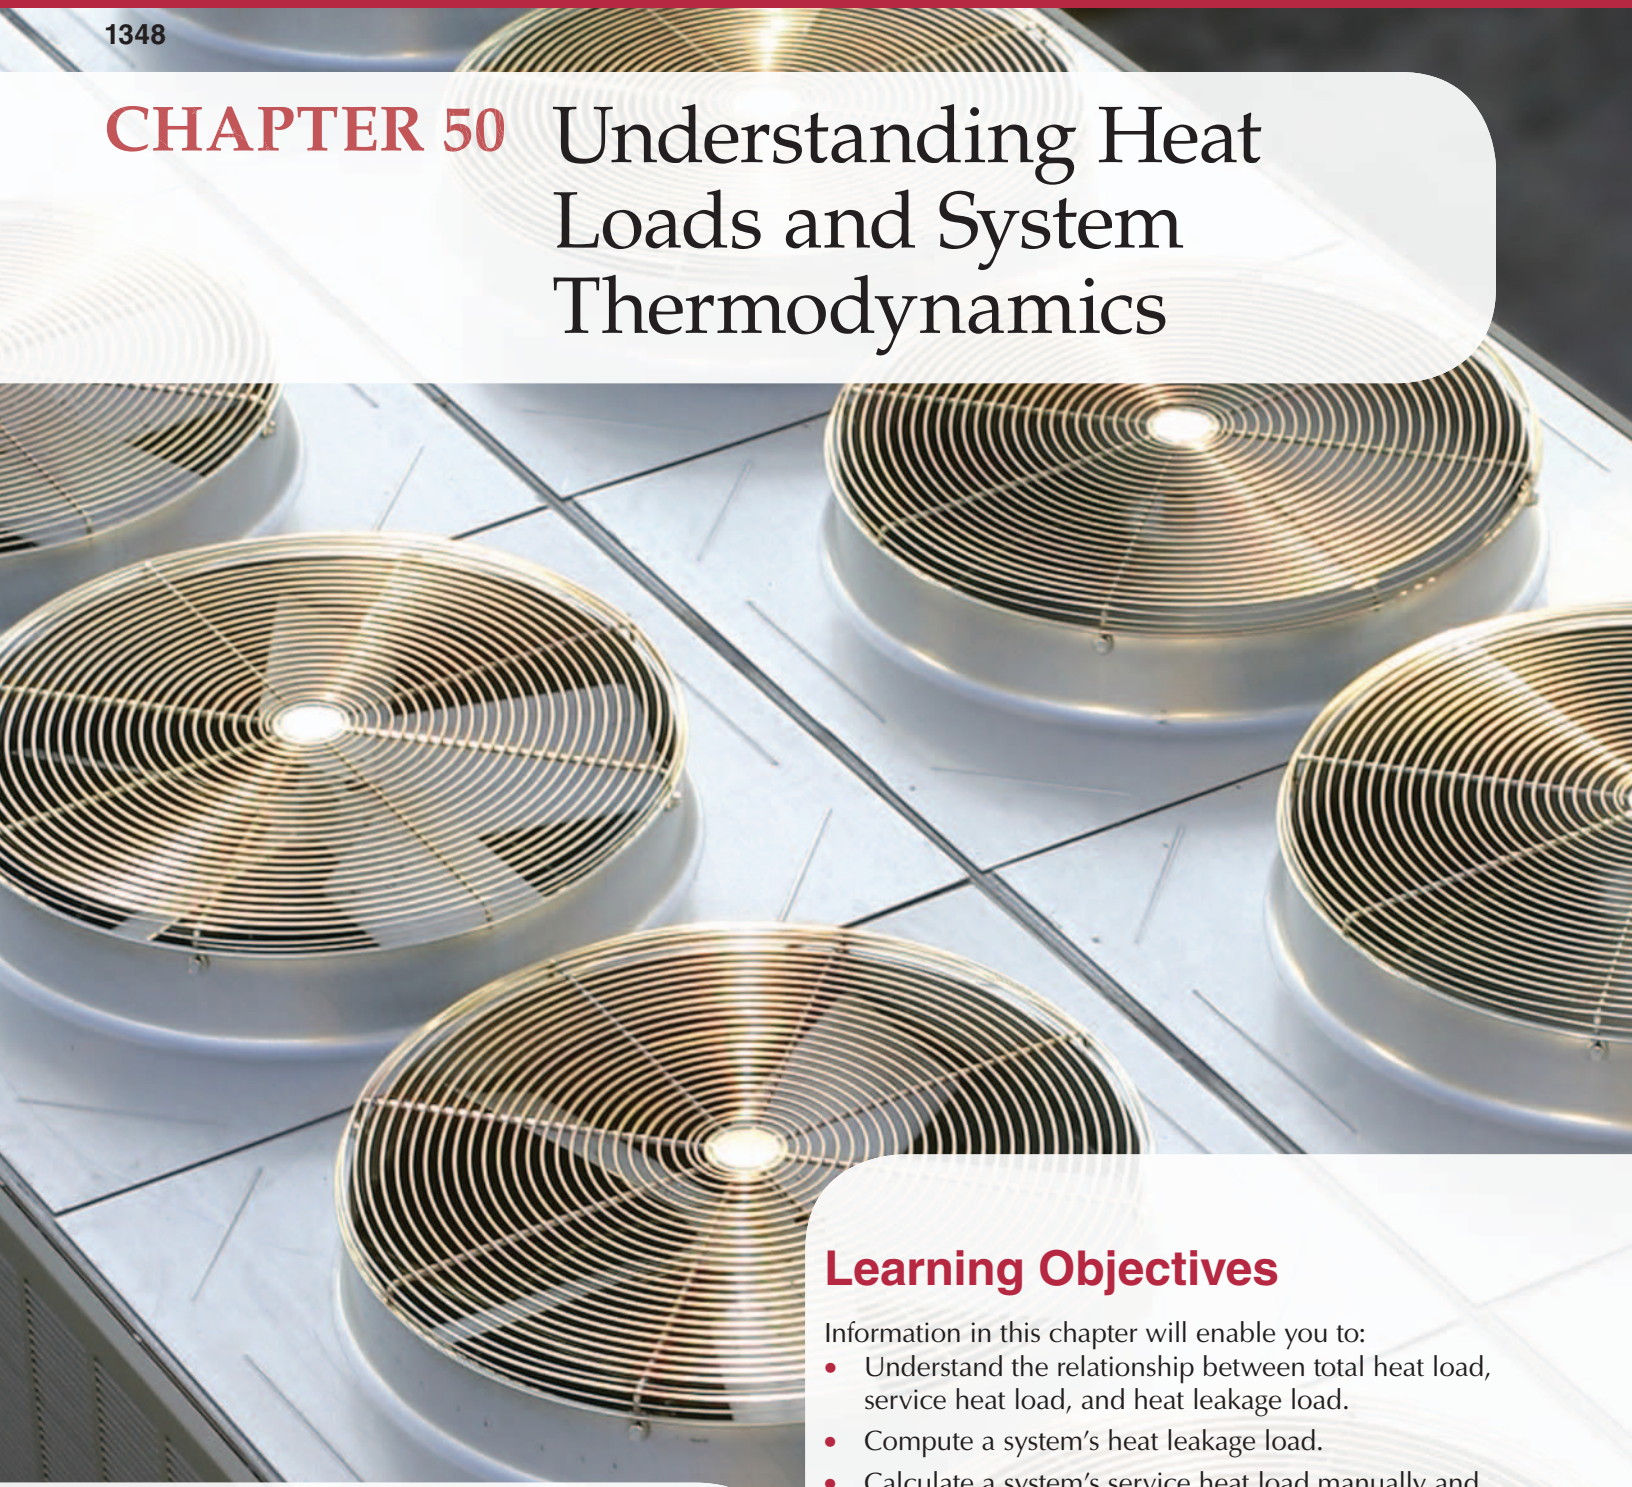
CHAPTER 50 Understanding Heat Loads and System Thermodynamics



Chapter Outline

50.1 Heat Loads
- 50.1.1 Heat Leakage (Thermal Conduction) Load
- 50.1.2 Service Heat Load
- 50.1.3 Calculating the Total Heat Load
- 50.1.4 Heat Loads for Water Coolers

50.2 Thermodynamics of the Basic Refrigeration Cycle
- 50.2.1 Reading a Pressure-Enthalpy Diagram
- 50.2.2 Practical Pressure-Enthalpy Cycles

Learning Objectives

Information in this chapter will enable you to:

- Understand the relationship between total heat load, service heat load, and heat leakage load.
- Compute a system's heat leakage load.
- Calculate a system's service heat load manually and by using manufacturer's tables.
- Use heat leakage load, service heat load, and all applicable miscellaneous heat loads to calculate a system's total heat load.
- Compute the total heat load for a water cooler.
- Summarize the thermodynamic principles at work in the basic refrigeration cycle.
- Identify the various lines on a pressure-enthalpy diagram.
- Interpret the graphs of different refrigeration cycles on pressure-enthalpy diagrams.

Copyright Goodheart-Willcox Co., Inc. 2017

Technical Terms

adiabatic expansion
effective latent heat
heat leakage load
miscellaneous heat loads
product heat load
refrigerant quality
respiration heat
saturated liquid
service heat load
total heat load

Review of Key Concepts

Reviewing these concepts from earlier chapters will help you understand new concepts presented in this chapter:

- The amount of heat energy required to raise the temperature of one pound of a substance by 1° Fahrenheit or one kilogram of a substance by 1 Kelvin is the substance's specific heat capacity. (Chapter 4)
- The specific heat capacity of a substance is the amount of heat added or released to change the temperature of one pound of a substance by 1°F. In the SI system, specific heat capacity is the amount of heat needed to change one kilogram of a substance by one degree Kelvin. (Chapter 4)
- Enthalpy is the total heat energy a substance contains, measured from an accepted reference temperature. (Chapter 4)
- Sensible heat is the heat energy absorbed or released to change the temperature of a substance. Latent heat has no effect on the temperature of a substance, because it is heat absorbed or released as a substance changes state. For example, the latent heat added to a liquid to change it into a gas or the latent heat removed from a gas to change it into a liquid is the latent heat of vaporization. (Chapter 4)
- Adiabatic compression is the compressing of a gas without gaining heat from or losing heat to its surroundings. This occurs in the cylinder of reciprocating compressors. (Chapter 5)
