- Boyle's law states that if temperature is held constant, volume varies inversely with pressure. Charles' law states that if pressure is held constant, volume varies in direct proportion with temperature. Gay-Lussac's law states that if volume is held constant, pressure and temperature vary directly. The combined gas law states that the ratio among a gas's volume, temperature, and pressure remains constant. (Chapter 5)
- A material's K-value is a measure of its thermal conductivity. It indicates how much heat will transfer through one square foot of the material one inch thick in one hour when there is a 1°F temperature difference between the two sides of the material. (Chapter 37)
- A material's thermal conductance, or C-value, is similar to its K-value, but it is not dependent on the thickness of the material. (Chapter 37)
- A material's R-value is a measure of its thermal resistance. It is the reciprocal of the material's K-value. The higher the material's R-value, the slower heat will transfer through the material. (Chapter 37)
- The U-value of a component is a measure of its thermal transmittance. It is similar to a component's C-value, but takes into account the insulating effect of boundary air films. (Chapter 37)

Introduction

The two basic types of commercial refrigeration systems are packaged (unitary) and split (site-engineered) systems. Packaged systems, such as ice machines and dispensing freezers, are delivered from the manufacturer with the refrigerated enclosure and all components preassembled. The manufacturer has chosen the correct evaporator and condensing unit and has designed the cabinet to handle a specific refrigeration job.

Split or "site engineered" refrigeration systems are units such as walk-in coolers or multiple-evaporator display cases. These units require that the service technician select the components (such as the evaporator and condensing unit) that will be used for the specific application.

To properly design and construct a split refrigeration system, the technician must understand the heat loads that the system will be required to remove. The components must be properly sized to match the system to its intended use. When selecting components, the technician must choose a condensing unit and evaporator with enough capacity to remove the heat load while still providing adequate defrosting and humidity control. Also, because refrigeration systems are not designed to operate continuously, the system must have sufficient capacity to handle the maximum heat load within its normal operating cycle.

Copyright Goodheart-Willcox Co., Inc. 2017

This chapter will explain heat loads and the thermodynamics of system operation. Chapter 51, *Commercial Refrigeration Component Selection* will explain how to use that information to properly size a system. The heat load calculations presented in this chapter are given in US Customary units (such as pounds, Btu, and feet). SI conversion factors are explained in the *Appendix*.

50.1 Heat Loads

Simply put, *heat load* is the amount of heat that must be removed from a conditioned space over a set period of time in order to maintain the desired temperature in that space. To determine the heat load, a technician must calculate the total amount of heat that must be removed every 24 hours in order to hold the temperature at its desired level. The heat load is measured in Btu (British thermal units). A Btu is the amount of heat required to raise the temperature of one pound of water one degree Fahrenheit.

When determining the total heat load, heat leakage into the cabinet and the service heat load must be considered. If the inside of the cabinet is cooler than the air outside of the cabinet, heat from the surrounding air is transferred through the materials of the cabinet to the space inside. The amount of heat that is transferred into the cabinet is referred to as the ***heat leakage load***. The amount of exposed surface, the thickness and type of insulation, and the temperature difference between the inside and outside of the cabinet all affect the amount of heat leakage that occurs.

The ***service heat load*** accounts for the temperature of articles put into the cabinet, their specific heat, any heat they generate, and any latent heat they contain. It also accounts for any additional heat brought into the cabinet due to operation. This includes air changes and the heat generated inside the cabinet by fans, lights, and other electrical devices.

The ***total heat load*** is the sum of the loads resulting from heat leakage, air changes, stored products, and miscellaneous heat sources. After determining the total heat load, a technician can determine the size of condensing unit and evaporator needed for the system.

50.1.1 Heat Leakage (Thermal Conduction) Load

The heat leakage load is the total amount of heat that leaks through the walls, windows, ceiling, and floor of the cabinet per unit of time (usually 24 hours). Research organizations, manufacturers, and refrigeration associations have determined the rate at which heat leaks through various materials. Charts and tables based on these calculations are used by engineers and technicians.

The following are five variables that affect heat leakage:

1. Time. Heat leakage is a process that occurs over time. Therefore, the total amount of heat leakage increases with time. The standard time period that is used to measure heat leakage rates in refrigeration applications is 24 hours. A one-hour period is used to measure heat leakage rates in air conditioning applications.
2. Temperature difference. The difference in temperature between the inside and outside of the cabinet is directly proportional to the rate of heat leakage. The greater the temperature difference, the more heat will transfer through the wall in a given period of time. The room temperature used to calculate heat leakage rates is the average summer temperature. In the United States, most locations have summer design temperatures ranging between 90°F and 105°F (32°C and 40°C). See **Figure 50-1**. This value can be reduced to 75°F or 80°F (25°C or 27°C) if the cabinet is located in an air-conditioned space.
3. Type of material. The rate at which heat leaks through a wall also depends on the materials the wall is made of. Expanded polystyrene (foam), for instance, will insulate approximately six times better than wood. Some insulating materials, however, are more costly than others.
4. Thickness of materials. The thicker the material, the less heat will flow through it in a given period of time. For a given length of time, nearly twice as much heat will leak through a wall with 1″ (2.5 cm) insulation than through a wall having 2″ (5 cm) of the same insulation.
5. External area of cabinet. A larger surface area allows greater heat flow. The common unit used to measure surface area in heat flow calculations is the square foot. The surface area is always calculated using the outside dimensions of the cabinet.

K-Values, C-Values, R-Values, and U-Values

As mentioned earlier, the type and thickness of the materials used to construct the cabinet are key factors in determining the rate at which heat can leak through it. In order to compare the materials, a standardized method of measuring their thermal characteristics must be used. In refrigeration work, K-values, C-values, R-values, and U-values are the measurements used to describe thermal characteristics of construction materials. However, each of these values measures thermal characteristics in

a slightly different way. Each of these values was thoroughly explained in Chapter 37, *Heating and Cooling Loads*.

K-Values (Thermal Conductivity) and C-Values (Thermal Conductance)

A material's K-value represents that material's thermal conductivity. It is a measure of how much heat can pass through one square foot of the material, one inch thick, in an hour when there is a temperature difference of 1°F (0.56°C) between one side of the material and the other. A material's K-value does not account for any boundary air film or liquid film on either side of the material. As you might expect, the symbol used to represent thermal conductivity (K-value) in formulas and equations is *K*.

Remember that a material's K-value represents the rate at which heat is transferred through a one-inch thickness of the material. If the material is thicker than 1″, it will take more time for the heat to travel through it. If the material is thinner than 1″, it will take less time for the heat to pass through it. Therefore, if the material is not exactly 1″ thick, the material's K-value must be divided by the actual thickness of the material to accurately calculate how long it takes for heat to pass through it. The resulting value is known as the material's thermal conductance, or C-value, and is measured in units of Btu/hr·ft²·°F. For materials that are exactly 1″ thick, the K-values and the C-values are equal.

$$\text{Thermal conductance } (C) = \frac{K}{X}$$

where

K = thermal conductivity (in Btu·in/hr·ft²·°F)
X = thickness of the material (in inches)

Example:

If the insulation of a cabinet box is 4″, what is the thermal conductance?

Solution:

$$C = \frac{K}{X}$$
$$= \frac{K}{4''}$$

Example:

If the insulation of a cabinet box is 1/2″, what is the thermal conductance?

$$C = \frac{K}{X}$$
$$= \frac{K}{1/2''}$$

Dividing a value by a fraction is awkward. To change the fraction into a decimal value, divide its two values. One divided by two (1 ÷ 2) equals 0.5.

$$C = \frac{K}{.5''}$$

To find the heat leakage of walls made of multiple materials (composite walls), the first step is to find the thermal conductivity of each material used in the construction. The thermal conductivity of some common materials is shown in the *Appendix*.

R-Values (Thermal Resistance)

When calculating the heat leakage rates for walls (or other components) made from multiple materials, technicians base their calculations on the thermal resistance of the materials rather than their thermal conductivity (K-value) or thermal conductance (C-value). A material's or component's resistance to heat flow is commonly known as its R-value and is represented by the letter *R* in formulas and equations. Resistance to heat flow is the inverse of thermal conductance. It is measured in units of hr·ft²·°F/Btu.

Formula:

$$\text{Thermal resistance (R)} = \frac{1}{C}$$

Total resistance to heat flow in a composite wall (or other component) is the sum of the thermal resistance of each material in the wall. The example below shows the equation for a wall constructed of two materials, but the equation can be expanded for any number of materials:

$$R_T = R_1 + R_2$$

where

R_T = total thermal resistance
R_1 = thermal resistance of material 1
R_2 = thermal resistance of material 2

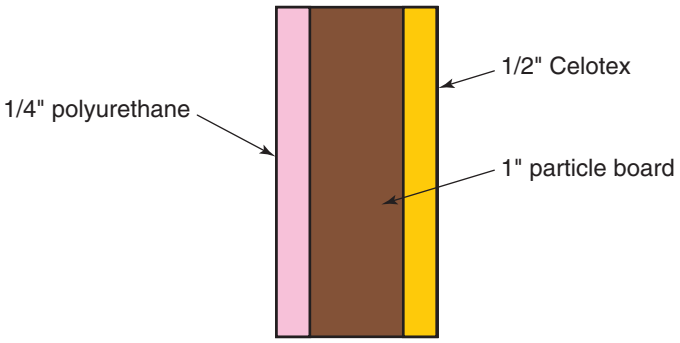
Example:

A custom-built cabinet wall is constructed of 1″ thick particle board, 1/2″ Celotex, and 1/4″ polyurethane insulation as shown in **Figure 50-2**. The K-value for the particle board is 0.94, the K-value for Celotex is 0.31, and the K-value for polyurethane is 0.16. Determine the total thermal resistance (R_T) in the composite wall.

Solution:

The K-values provided indicate how quickly heat would flow through a 1″ thickness of the materials, given a 1°F temperature difference from one side of the material to the other. However, the Celotex is only 1/2″ thick and the polyurethane is only 1/4″ thick. Each material's K-value must be divided by its thicknesses to determine the C-value (thermal conductance) of the material:

Copyright Goodheart-Willcox Co., Inc. 2017



Goodheart-Willcox Publisher

Figure 50-2. Cross section of a custom-built cooler wall.

$$C_1 = \frac{K_1}{X_1} = \frac{0.94}{1} = 0.94 \text{ Btu/hr·ft}^{2}\text{·°F}$$

$$C_2 = \frac{K_2}{X_2} = \frac{0.31}{1/2} = 0.62 \text{ Btu/ hr·ft}^{2}\text{·°F}$$

$$C_3 = \frac{K_3}{X_3} = \frac{0.16}{1/4} = 0.64 \text{ Btu/hr·ft}^{2}\text{·°F}$$

The reciprocals of the individual C-values provide the thermal resistance for each material:

$$R_1 = \frac{1}{C_1} = \frac{1}{0.94} = 1.06 \text{ hr·ft}^{2}\text{·°F/Btu}$$

$$R_2 = \frac{1}{C_2} = \frac{1}{0.62} = 1.61 \text{ hr·ft}^{2}\text{·°F/Btu}$$

$$R_3 = \frac{1}{C_3} = \frac{1}{0.64} = 1.56 \text{ hr·ft}^{2}\text{·°F/Btu}$$

The thermal resistances are then added together to calculate the total resistance in the wall:

$$R_T = R_1 + R_2 + R_3 = 1.06 + 1.61 + 1.56 = 4.23 \text{ hr·ft}^{2}\text{·°F/Btu}$$

U-Values (Thermal Transmittance)

In the above example, the R-value was calculated for a cabinet constructed of polyurethane, particle board, and Celotex. The value calculated above represents the rate at which heat leaks through the materials in the cabinet wall. But, the materials used to construct the door are not the only factors to consider when determining how quickly heat leaks through the wall. There are also thin films of stagnate air that cling to the outside and inside surfaces of the wall.

These air films are attracted to the wall surfaces and are known as inside and outside boundary air films. Because of the attraction, the air films do not move as quickly as the surrounding air. This stagnation causes the boundary air films to act like thin layers of insulation that reduce the rate at which heat is transmitted through the wall. The measurement that takes these factors into account is called thermal transmittance or U-value. A material's thermal transmittance is equal to the inverse of the sum of all thermal resistances in the material, including the thermal resistance of the boundary air films:

Formula:

$$U = \frac{1}{R_{of} + R_1 + R_{if}}$$

where

R_{of} = thermal resistance of outside boundary air film
R_1 = thermal resistance of material 1
R_{if} = thermal resistance of inside boundary air film

Example:

The wall in **Figure 50-3** includes an outside film of air with a thermal conductance (C-value) of 6.0 Btu/hr·ft²·°F and an inside film of air with a thermal conductance of 1.65 Btu/hr·ft²·°F. The K-value for the particle board is 0.94, the K-value for Celotex is 0.31, and the K-value for polyurethane is 0.16. What is the U-value of the wall?

Solution:

Begin by determining the thermal resistances of the materials and boundary air films:

Resistance of outside boundary air film:

$$R_{of} = \frac{1}{C_{of}} = \frac{1}{6.0 \text{ Btu/ hr·ft}^{2}\text{·°F}} = 0.17 \text{ hr·ft}^{2}\text{·°F /Btu}$$

Copyright Goodheart-Willcox Co., Inc. 2017

Resistance of 1/4″ polyurethane:

$$C_1 = \frac{K_1}{X_1}$$
$$= \frac{0.16}{0.25″}$$
$$= 0.64 \text{ Btu/ hr·ft}^{2\cdot}\text{°F}$$
$$R_1 = \frac{1}{C_1}$$
$$= \frac{1}{0.64 \text{ Btu/ hr·ft}^{2\cdot}\text{°F}}$$
$$= 1.56 \text{ hr·ft}^{2\cdot}\text{°F /Btu}$$

Resistance of 1″ particle board:

$$C_2 = \frac{K_2}{X_2}$$
$$= \frac{0.94}{1″}$$
$$= 0.94 \text{ Btu/hr·ft}^{2\cdot}\text{°F}$$
$$R_2 = \frac{1}{C_2}$$
$$= \frac{1}{0.94 \text{ Btu/ hr·ft}^{2\cdot}\text{°F}}$$
$$= 1.06 \text{ hr·ft}^{2\cdot}\text{°F/Btu}$$

Resistance of 1/2″ Celotex:

$$C_3 = \frac{K_3}{X_3}$$
$$= \frac{0.31}{0.5″}$$
$$= 0.62 \text{ Btu/ hr·ft}^{2\cdot}\text{°F}$$
$$R_3 = \frac{1}{C_3}$$
$$= \frac{1}{0.62 \text{ Btu/ hr·ft}^{2\cdot}\text{°F}}$$
$$= 1.61 \text{ hr·ft}^{2\cdot}\text{°F /Btu}$$

Resistance of inside boundary air film:

$$R_{if} = \frac{1}{C_{if}}$$
$$= \frac{1}{1.65 \text{ Btu/ hr·ft}^{2\cdot}\text{°F}}$$
$$= 0.61 \text{ hr·ft}^{2\cdot}\text{°F/Btu}$$

Next, the resistances of the individual materials are added together to calculate the total resistance for the wall:

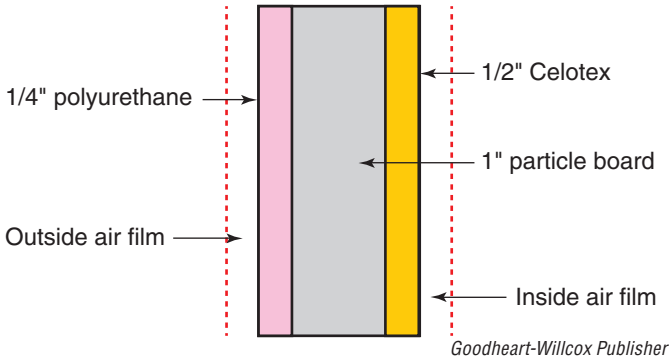


Figure 50-3. Cross section of a cooler wall, including inside and outside boundary air films.

$$R_T = R_{of} + R_1 + R_2 + R_3 + R_{if}$$
$$= 0.17 + 1.56 + 1.06 + 1.61 + 0.61$$
$$= 5.01 \text{ hr·ft}^{2\cdot}\text{°F/Btu}$$

The U-value for the composite wall is the reciprocal of the total thermal resistance of the wall:

$$U_T = \frac{1}{R_T}$$
$$= \frac{1}{5.01 \text{ hr·ft}^{2\cdot}\text{°F /Btu}}$$
$$= 0.20 \text{ Btu/ hr·ft}^{2\cdot}\text{°F}$$

Calculating Area

The area of a cabinet is measured from the outside. There are six surfaces: four walls, the ceiling, and the floor, as shown in **Figure 50-4**. Usually the floor and ceiling have the same area, as do the areas of walls opposite each other. To determine the total outside area of a typical rectangular box cabinet:

1. Multiply the width of the cabinet by the length of the cabinet. Then, multiply the result by two. This is the combined area of the floor and ceiling of the cabinet.
2. Multiply the width of the cabinet by the height of the cabinet. Then, multiply the result by two. This is combined area of the ends of the cabinet.
3. Multiply the length of the cabinet by the height of the cabinet. Then, multiply the result by two. This is the combined area of the sides of the cabinet.
4. Add these three values to determine the total external area of the cabinet.

Pro Tip

Calculating Cabinet Area

Most companies compute total area based on the outside of the cabinet. The exterior is easier to measure and the results are on the safe side.

Copyright Goodheart-Willcox Co., Inc. 2017

Calculating Heat Leakage Load

After computing the area of the cabinet's exterior, subtract the window area to obtain the area of the insulated surface. Window areas are calculated from the measurements of the outside edges of the window frame. Since the heat transfer rate through a window is different than the heat transfer rate through the insulated walls, each type of surface must be considered separately. To find the area of the cabinet's insulated walls, subtract the window area from the total area of the cabinet's exterior.

Technicians can use a table like the one shown in **Figure 50-5** to find the amount of heat leakage per 24-hour period through a square foot of a given material at a given temperature difference. Consider a wall made of steel paneling on both sides with a 4″ core of extruded polystyrene insulation in between. The table in **Figure 50-5** reveals that, at a temperature difference of 60°F (95°F – 35°F), 49.8 Btu will leak through every square foot during a 24-hour period.

The glass leakage rates listed at the bottom of the table show how much heat will leak through one square foot of glass in a 24-hour period for a given temperature difference. If the cabinet has double-pane glass, 660 Btu will leak through each square foot of glass when the temperature difference is 60°F. This rate is then multiplied by the surface area of the glass to determine the total amount of heat leakage through the glass.

Next, the heat leakage through the insulated portion of the cabinet is added to the heat leakage through the glass. The sum of the two equals the total heat leakage into the cabinet.

Example:

The walk-in cooler shown in **Figure 50-6** is 10′ × 9′ × 8′ high. It has two double-pane glass windows measuring 1 1/2′ × 2′. The box is kept at 35°F in a room with a summer design temperature of 95°F. The cabinet's wall construction consists of 4″ extruded polystyrene with metal on each side. The windows are double-pane construction. The temperature difference is 95°F – 35°F = 60°F.

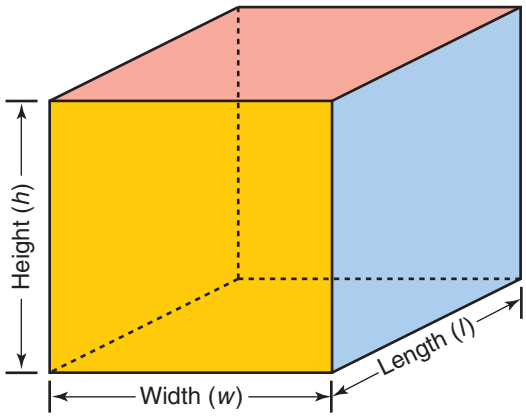
Solution:

Total area:

10′ × 9′ × 2 = 180 ft² (ceiling and floor)
9′ × 8′ × 2 = 144 ft² (ends)
10′ × 8′ × 2 = 160 ft² (sides)
Total area = 484 ft²

Area of windows:

1 1/2′ × 2′ × 2 = 6 ft² of window



Goodheart-Willcox Publisher

Figure 50-4. The area of each surface of the cabinet is calculated by multiplying the two dimensions that define the edges of that surface.

Area of insulated walls:

484 ft² – 6 ft² = 478 ft² of insulated wall

Figure 50-5 shows that 4″ thick extruded polystyrene insulation and a 60°F temperature difference will result in a transfer of 49.8 Btu of heat through each square foot of insulated wall during a 24-hour period. Multiplying this heat transfer rate by the square footage of the insulated walls calculates the total heat transferred through the walls in 24 hours:

49.8 Btu/24 hr·ft² × 478 ft² = 23,804 Btu/24 hr through the walls

Figure 50-5 also shows that 1 ft² of double-pane glass allows heat transfer of 660 Btu/24 hr when there is a 60°F temperature difference. The heat leakage rate is multiplied by the total surface area of the windows:

660 Btu/24 hr·ft² × 6 ft² = 3960 Btu/24 hr through the windows

To calculate the total heat leakage for the cabinet, the heat leakages through the insulated walls and through the glass are added together. The sum is the total amount of heat that leaks into the cabinet over a 24-hour period when there is a 60°F temperature difference between the inside and outside of the cabinet:

23,804 Btu/24 hr
\+ 3960 Btu/24 hr
27,764 Btu/24 hr

Pro Tip

Determining Cabinet Surface Area and Volume

Rather than manually calculating the exterior surface area and interior volume of cabinets, technicians can refer to a table like the one shown in **Figure 50-7**. This table lists the exterior surface area for cabinets with different dimensions. It also lists the interior volume of different size cabinets based on exterior dimensions, wall thickness, and ceiling height.

Code Alert

Federal Requirements for Walk-In Coolers and Freezers

The *Energy Independence and Security Act of 2007* requires all walk-in coolers manufactured after January 1, 2009 to have wall, ceiling, and door insulation of at least R-25. Walk-in freezers must have wall, door, and ceiling insulation of at least R-32 and floor insulation of at least R-28. The requirement does not apply to windows, glass display doors, or structural members.

Adjusting for Heat from the Sun

If part or all of the cabinet is exposed to direct sunlight, adjustments must be made to account for the solar heat load. If the cabinet is in direct sunlight and has a dark surface, add 10°F (6°C) to the ambient temperature when calculating the heat leakage load. If the cabinet is in direct sunlight and has a medium-colored surface, add 5°F (3°C) to the ambient air temperature. If the cabinet is in direct sunlight and has a light surface, add 3°F (2°C) to the ambient air temperature.

50.1.2 Service Heat Load

The service heat load, sometimes called the *usage heat load*, is the sum of the various heat loads that result from operation of the unit for a given period of time, usually 24 hours. The following are a few of the individual heat loads that typically contribute to the service heat load:

- Cooling the contents to cabinet temperature.
- Cooling of air changes.
- Removing respiration heat from fresh vegetables and meat.
- Removing the heat generated by electric lights and motors.
- Removing the heat given off by people entering or working in the cabinet.

To accurately calculate a service heat load, a technician must consider all potential heat load sources and perform the required calculations with care. The technician must know the amount of food put into the conditioned space, how many times the door is opened, the number of people working in the cabinet, the amount of time they spend in the cabinet, and the type of work they are performing.

Using Tables to Calculate Service Heat Load

Refrigeration equipment manufacturers have developed tables that help technicians estimate service heat loads accurately and more easily. In these tables, a cabinet is classified according to how it will be used. Some tables list specific classifications, such as florist's cabinets, grocery boxes, normal market coolers, fresh meat cabinets, and restaurant short-order cabinets. Other tables have more general classifications, such as average service, heavy service, and long storage. From experience, the manufacturers have found that cabinets used for the same general type of service will have roughly equivalent service heat loads when all other factors are equal.

The service heat load is affected by four basic factors:

- Temperature difference between the exterior and interior of the cabinet.
- Volume of the cabinet's interior.
- How the cabinet is used.
- Length of time for which the heat load is calculated.

Using Tables to Determine Service Heat Load

To determine the service heat load, a technician would look up vital information in a variety of tables. The following is the general procedure a technician would use to calculate service heat loads using tables:

1. Determine the type of service for which the cabinet is being used, such as average, heavy, or long storage. The type of use has a greater effect on the service heat loads of smaller cabinets than it does on the service heat loads of larger ones.
2. Find the volume of the cabinet using the cabinet's inside dimensions. Refer to the "Volume of Interior" columns in **Figure 50-7**.
3. After the total volume of the cabinet has been found, determine the usage heat gain per cubic foot of cabinet space using a table like the one in **Figure 50-8**. When looking up the usage heat gain, use the same temperature difference that was used to calculate heat leakage into the cabinet.
4. Multiply the volume of the cabinet's interior by the usage heat gain. The result is the estimated service heat load.

Example:

Use tables to find the estimated service heat load for a 9′ × 10′ × 8′ cabinet with 4″ thick walls. The cabinet will be subjected to average service. Use a temperature difference of 60°F (33°C) for the calculations.

Solution:

The volume of the cabinet is looked up in the table in **Figure 50-7** and found to be 570 ft³ (approximately 600 ft³). Next, the usage heat gain is looked up on the table in **Figure 50-8**. Since 570 ft³ is not listed on the table, the usage heat gain for a 570 ft³ must be estimated using the two closest values. The difference between the usage heat gain for a 500 ft³ cabinet and a 600 ft³ cabinet is 2.6 Btu/24 hr. Since the 570 ft³ cabinet is 30 ft³ smaller than the 600 ft³ cabinet and 70 ft³ larger than the 500 ft³ cabinet, the difference between the service loads for the 500 ft³ cabinet and the 600 ft³ cabinet is multiplied by 30% and added to the usage heat gain for the 600 ft³ cabinet:

Usage heat gain for 600 ft³ cabinet = 70 Btu/24 hr·ft³
Usage heat gain for 500 ft³ cabinet = 72.6 Btu/24 hr·ft³
Difference in cabinet volumes = 100 ft³
Difference in usage heat gain = 2.6 Btu/24 hr·ft³

Usage heat gain for 570 ft³ cabinet
= 70 Btu/24 hr·ft³
+ (0.30 × 2.6 Btu/24 hr·ft³)
= 70.8 Btu/24 hr·ft³

Multiply this value by the total volume in cubic feet to calculate an accurate estimate of the cabinet's service heat load:

Service heat load = usage heat gain per cubic foot × volume.
= 70.8 Btu/24 hr·ft³ × 570 ft³
= 40,356 Btu/24 hr

Manually Calculating Service Load

The preceding section explained how to use tables to quickly estimate the service load for a cabinet with a fair amount of accuracy. Occasionally, a technician may need to manually calculate the service load for a commercial refrigeration system. The total service load includes the air change heat load, the product heat load, and miscellaneous heat loads. The following sections explain how those individual heat loads are determined and then added together to calculate the service heat load.

Calculating Cabinet Volume

The first step in manually calculating a service heat load is to determine the cabinet volume. Cabinet volume is based on the inside dimensions of the cabinet. For standard size cabinets, the volume can be looked up in a table like the one shown in **Figure 50-7**. If a table is not available, the volume of the cabinet can be calculated manually.

The volume of the cabinet interior is calculated using the exterior dimensions minus the wall thickness, as shown in **Figure 50-9**. This volume is used to calculate the number of air changes that the cabinet is likely to undergo in a day. The volume of a rectangular box or a cube is found simply by multiplying the length of the box by the width of the box and the height of the box.

Formula for Calculating the Volume of Rectangular Boxes:

$$V = l \times w \times h$$

Example:

In the sample cabinet, which is 10′ long × 9′ wide × 8′ high, the walls are 4″ thick. Find the volume of the cabinet.

Solution:

Inside dimension = outside dimension – (wall thickness × 2)
Inside length = 10′ – 8″ = 9′-4″ or 9 1/3′

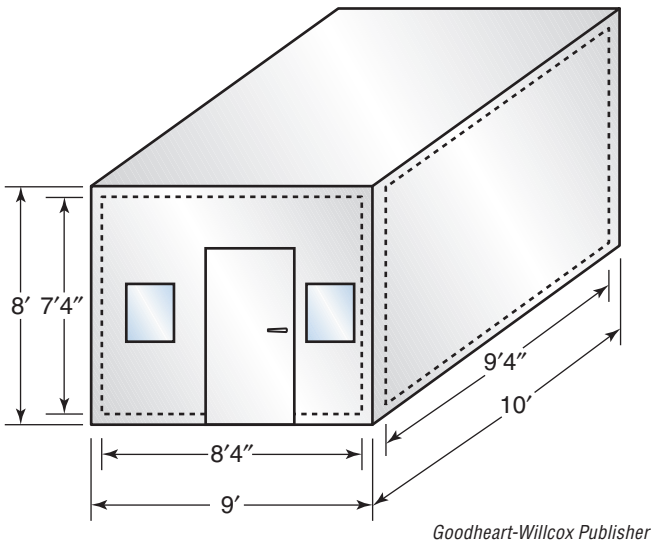
*For average and heavy service, product load is based on product entering at 10°F above the refrigerator temperature. For long storage, the entering temperature is approximately equal to the refrigerator temperature. Where the product load is unusual, do not use this table.

Goodheart-Willcox Publisher

Figure 50-8. Continued.



Goodheart-Willcox Publisher

Figure 50-9. To calculate the volume of a cabinet, the interior dimensions of the refrigerated space are multiplied together. Typically, an interior dimension is equal to the corresponding exterior dimension minus two times the thickness of the walls.

Inside width = 9′ – 8″ = 8′-4″ or 8 1/3′
Inside height = 8′ – 8″ = 7′-4″ or 7 1/3′
Inside volume = 9 1/3′ × 8 1/3′ × 7 1/3′
= 28/3′ × 25/3′ × 22/3′
= 15400/27 ft³
= 570.4 ft³

Air Change Heat Load

Each time a service door or a walk-in door is opened, the cold air inside the refrigerated space, being heavier, spills out through the bottom of the opening. This allows the warmer room air to move into the refrigerated space. This air movement is sometimes called *infiltration*.

The air that enters a refrigerated space must be cooled. According to Charles' law, the air entering the cabinet is reduced in pressure as it cools. This creates a pressure difference between the outside of the cabinet and the inside. If the cabinet is not airtight, air will continue to leak in due to the pressure difference. This infiltration of warm air continues until the pressure inside the cabinet equalizes with pressure outside the cabinet.

Figure 50-10 lists the approximate number of air changes that can be expected to occur in cabinets of various volumes. **Figure 50-11** shows the rate at which heat (sensible heat + latent heat) must be removed from infiltrating air in order to cool it to the same temperature as the refrigerated space. The amount of heat that must be removed depends on outside conditions and refrigerator temperatures. To calculate the total heat load due to air changes, the required heat removal rate must be multiplied by the number of air changes, and the volume of the cabinet, in cubic feet.

Formula:
Air change heat load = heat removal rate × volume of cabinet × number of air changes

Product Heat Load

Any substance that is warmer than its surroundings will lose heat. This will continue until the substance cools to the ambient temperature. ***Product heat load***

Figure 50-10. Table listing the average number of storage room air changes per 24 hours. The values listed are based on volume and take into account door openings and air filtration.

refers to the heat contained in products that are placed in a refrigerated space. Some of the product's heat must be removed in order to cool the product to the desired temperature. This heat is transferred to the air surrounding the product. If this heat is not transferred outside of the cabinet by the refrigeration system, the temperature inside the cabinet will gradually rise.

When product heat loads are being discussed, three different types of heat must be considered: sensible heat, latent heat, and respiration heat.

Sensible Heat

Sensible heat is heat that results in a temperature change in the product. To lower the temperature of the product, sensible heat must be transferred to the air surrounding the product and rejected from the cabinet by the refrigeration system.

To calculate the amount of sensible heat that must be removed to bring the product down to cabinet temperature, the weight of the product is multiplied by the specific heat capacity of the product and the temperature difference between the product temperature and the cabinet temperature. The *specific heat capacity* of a substance is the amount of heat needed to raise the temperature of one pound of that substance by 1°F. The specific heat of various products can be looked up on a table like the one shown in **Figure 50-12**.

Formula for Sensible Heat Load:

$$Q = W \times sp\ ht \times (T_1 - T_2)$$

where

Q = sensible heat to be removed
W = weight of the product
$sp\ ht$ = specific heat capacity of the product
T_1 = temperature of the product
T_2 = cabinet temperature

When a material changes its physical state (such as changing from liquid to solid, solid to gas, or vice-versa) the specific heat of the material also changes. It is important to use the correct specific heat in the load calculations.

If the product is going to be cooled below its freezing point, two separate sensible heat calculations are performed. The first calculation determines the sensible heat that must be removed to cool the product from its initial temperature to its freezing point. This calculation requires the technician to use the specific heat value for above-freezing temperatures. The second calculation determines how much sensible heat must be removed after the product is frozen to cool it to its final temperature. For this calculation, the below-freezing specific heat value is used.

Pro Tip

Specific Heat of Vapors

Every substance has four different values for its specific heat, one value for the solid state, one for the liquid state, and two for the vapor state. The following are the two different values for specific heat of a vapor:

- Specific heat when under a *constant pressure.*
- Specific heat when confined to a *constant volume.*

A vapor under constant pressure has a greater specific heat value than the same vapor under constant volume. The vapor heated with a constant pressure upon it will expand and do external work, such as increasing the size of a balloon. This external work naturally requires an additional quantity of heat.

Latent Heat

Latent heat is the heat that results in a phase change in the product. For example, if a bowl of soup is put in a freezer, sensible heat is removed to bring the soup down to its freezing temperature, and then latent heat must be transferred out of the soup to freeze it solid. If the soup were steaming when it was put into the freezer, additional latent heat would need to be removed from the steam in order to condense it.

Figure 50-11. Table listing the heat that must be removed, per cubic foot, to cool replacement air to cabinet temperature. The values are given in Btu/ft³.

To calculate the latent heat that must be removed from a product in order to freeze it, multiply the weight of the product by its latent heat of fusion. The latent heat of fusion of most food products is equal to the percentage of water in the food times the latent heat of fusion for water, which is 144 Btu/lb. The latent heat of fusion for various products can be looked up in a table like the one shown in **Figure 50-12**.

Formula for Latent Heat Load

$$Q = W \times L_f$$

where

Q = total heat released during freezing
W = weight of the product
L_f = the product's latent heat of fusion

Respiration Heat

When fruits and vegetables are put into cold storage, their biological processes continue. As produce ripens and ages, it absorbs oxygen and releases carbon dioxide, ethylene gas, and heat. This heat is called ***respiration heat*** and must be removed by the refrigeration system to prevent the cabinet from warming. The respiration heat of various products can be looked up on a table similar to the one shown in **Figure 50-12**.

Total Product Heat Load

The total product heat load is the sum of the sensible heat loads, latent heat loads, and respiration heat loads for every item in a refrigerated space. **Figure 50-12** shows the specific heat and latent heat of various refrigerated products. In addition, it recommends temperatures and relative humidity for storing various items.

Miscellaneous Heat Load

All sources of heat not covered by heat leakage, product cooling, and respiration heat loads are usually categorized as ***miscellaneous heat loads***. Some of the more common miscellaneous heat loads are lights, electric motors, people, and defrosting heat sources.

Heat from Lights

Lights located in the refrigerated space will release heat. Light emitting diodes (LED) and compact fluorescent (CFL) lights use about 1/4 of the energy of traditional incandescent lights and produce much less heat. A typical 100 W incandescent lightbulb can be replaced with a 20 W LED or CFL light and emit the same amount of light, while emitting far less heat. For example, a 100 W lamp will give off 341 Btu in one hour:

1 W = 3.41 Btu/hr
100 W = 341 Btu/hr

If the same 100 W incandescent light is replaced with a 20 W LED light, it will give off only 68 Btu/hr.

To find the amount of heat released by a light source, multiply the number of Btu released in one hour by the number of hours per day the light is on. For example, if a 100 W incandescent bulb runs continuously, the heat load would be:

341 Btu/hr × 24 hr/24 hr = 8184 Btu/24 hr

If the workday is eight hours (only time light is on), the heat load would be:

341 Btu/hr × 8 hr/24 hr = 2728 Btu/24 hr

Thinking Green

High-Efficiency Lighting

Use of high-efficiency lighting in a walk-in freezer or cooler can improve the overall energy efficiency of a system by as much as 10%.

Heat from Electric Motors

The heat released by any electric motors operating in the conditioned space must also be determined. On the average, electric motors release heat at a rate of approximately 2550 Btu/hp·hr. The exact amount of heat released depends on motor efficiency. The larger the motor, the more efficient it is. **Figure 50-13** shows the heat given off by motors and the devices they drive. Forced-draft evaporators usually have motors and fans. Heat is released at a rate of 4600 Btu/hp·hr for motor sizes ranging from 1/8 hp to 1/3 hp. To calculate the total heat released by a particular motor, the horsepower rating of the motor and the number of hours the motor operates in a 24-hour period are multiplied by the heat release rate. For example, the following calculates the heat released by a continuously operating 1/8 hp fan motor in one day:

Total heat released in 24 hr
= heat release rate × horsepower of motor × hours of operation
Q = 4600 Btu/hp·hr × 1/8 hp × 24 hr
= 13,800 Btu

Heat Equivalent of Electric Motors

Motor Size (hp)	Connected Load in Refrigerated Space[a]	Motor Losses Outside Refrigerated Space[b]	Connected Load Outside Refrigerated Space[c]
	Btu/hp·hr	Btu/hp·hr	Btu/hp·hr
1/8 to 1/3	4600	2550	2100
1/2 to 3	3800	2550	1300
5 to 20	3300	2550	800

[a] For use when both useful output and motor losses are dissipated within refrigerated space; motors driving fans for forced circulation unit coolers.

[b] For use when motor losses are dissipated outside refrigerated space and useful motor work is expended within refrigerated space; pump on a circulating brine or chilled water system; fan motor outside refrigerated space driving fan circulating air within refrigerated space.

[c] For use when motor heat losses are dissipated within refrigerated space and useful work expended outside of refrigerated space; motor in refrigerated space driving pump or fan located outside of space.

Thinking Green

High-Efficiency Motors

Use of high-efficiency compressors in a walk-in cooler or freezer can increase system efficiency by up to 10%. Use of high-efficiency evaporator fan motors can further improve energy efficiency up to an additional 10%. Use of high-efficiency condenser fan motors can boost energy efficiency another 5%.

Heat from People

People inside a refrigerated space release heat at varying rates. This depends on what they are wearing (insulation), the temperature of the cabinet, and on how hard they are working. **Figure 50-14** shows that occupants add 720 Btu/hr of heat load per person at 50°F (10°C) and 1400 Btu/hr heat load per person at –10°F (–23°C).

To find the heat load resulting from people working in the refrigerated space, use the table to find the heat equivalent of occupancy based on the temperature inside the refrigerated space. Next determine the total number of hours worked. For example, if three people work in a space for four hours and then two people work in the space for an additional two hours, the total number of hours worked would be 16. The next step in determining the heat load from occupants is to multiply the heat equivalent of occupancy by the total number of hours worked. For example, if one person worked in a 30°F (–l°C) refrigerator for eight hours, the heat load would be:

950 Btu/hr × 8 hr = 7600 Btu

Heat Equivalent of Occupancy

Refrigerated Space Temperature (°F)	Heat Equivalent per Person (Btu/hr)
50	720
40	840
30	950
20	1050
10	1200
0	1300
–10	1400

Note: Heat equivalent may be estimated by $q_p = 1295 - 11.5t$ (°F)

Reprinted by permission of the American Society of Heating, Refrigerating, and Air-Conditioning Engineers, Atlanta, Georgia, from the 1993 ASHRAE Handbook—Fundamentals

Figure 50-14. Table indicating the approximate amount of heat released each hour by a person in a refrigerated space, based on the temperature of the space.

Heat from Defrosting Heat Sources

Many refrigerating units have defrosting heat sources, especially if the operating temperature is 32°F (0°C) or lower. Whether the defrost heat source is electric, hot gas, or water, the defrosting operation adds heat to the interior of the refrigerator. The amount of heat is difficult to determine because most of the defrosting heat is removed in the defrost drain water. Add approximately 10% of the defrosting heat input as part of the service heat load.

50.1.3 Calculating the Total Heat Load

Total heat load is the sum of the heat leakage load and all of the individual heat loads that make up the service heat load. The information presented in the previous sections of this chapter can be used to find the total heat load in the following example:

Example:

A metal-sheathed walk-in cabinet is 10′ long × 9′ wide × 8′ high. The wall construction consists of 4″ extruded polystyrene with metal on each side. The cabinet has two double-pane glass windows measuring 1 1/2′ × 2′ each. It is in a room with a temperature of 95°F and a relative humidity of 60%. It cools 2000 lb of fresh lean beef from 60°F to 35°F each day. The evaporator has two 1/8-hp motors and the cabinet has two 40-watt lamps that operate 8 hours each day. One person works in the cabinet 8 hours each day.

Solution, Step 1: Calculate the Heat Leakage Load

The first step in calculating the total heat load is to calculate the total heat leaking through the cabinet. To find this, the surface area of the entire cabinet is calculated. Then, the surface area of the windows is subtracted from the total surface area to determine the surface area of the insulated walls.

Next, the heat leakage rates through the various materials of the cabinet are determined, based on the temperature difference between the inside and outside of the cabinet. The heat leakage rates can be determined using the material's R- or U-values or by looking them up on a table similar to the one shown in **Figure 50-5**.

Next, the heat leakage rate for the insulated walls of the cabinet is multiplied by the surface area of the walls, and the heat leakage rate through the windows is multiplied by the surface area of the windows. Finally, the heat leakage through the walls is added to the heat leakage through the windows. The result is the total heat leakage into the cabinet. The total heat leakage for the cabinet described in the example is 28,063 Btu/24 hr.

Solution, Step 2: Calculating the Air Change Heat Load Portion of the Service Heat Load

The next step in calculating total heat load for the cabinet is to find the heat load that results from air

Copyright Goodheart-Willcox Co., Inc. 2017

changes inside the cabinet. The volume of the cabinet can be calculated manually or can be looked up on a table like the one shown in **Figure 50-7**. The volume of the cabinet in the example is 570 ft^3. The number of air changes, based on the volume of the cabinet, can be looked up on a table like the one shown in **Figure 50-10**. The cabinet in the example will undergo roughly 24 air changes per day. The volume of air exchanged each day equals the volume of the cabinet times the number of air changes per day, or 13,680 ft^3 in the case of the example.

Next, the amount of heat that must be removed in order to cool the replacement air to the cabinet temperature can be calculated manually using the specific heat of air and the latent heat of vaporization of water vapor, or it can be looked up on a table similar to the one shown in **Figure 50-11**. For the cabinet in the example, 2.25 Btu must be removed for every cubic foot of replacement air.

The last step in determining the air change load is to multiply the heat removal rate by the volume of the cabinet. For the cabinet described in the example, this equals 30,780 Btu/24 hr.

Solution, Step 3: Calculating the Product Heat Load Portion of the Service Heat Load

The first step in calculating the product heat load is to determine the amount and weights of products that will be stored in the cabinet. Next, the specific heat of each produce must be looked up on a table like the one shown in **Figure 50-12**. Then, the temperature difference between the inside of the cabinet and the product entering the cabinet is multiplied by the product's specific heat and the weight of the product.

In the case of the 2000 lb of beef in the example, the specific heat is 0.77 Btu/lb and the temperature difference is 25°F. Therefore, the product heat load is 38,500 Btu per day. The beef does not freeze and there is no respiration heat associated with its storage, so no further product heat load calculations are required.

Solution, Step 4: Calculating the Miscellaneous Heat Load Portion of the Service Heat Load

The miscellaneous heat load is the sum of all the heat generated from electric motors, lights, people inside the refrigerated space, and heat added during defrosting cycles. The heat from electric motors can be looked up on a table like the one shown in **Figure 50-13**. The two 1/8 hp motors described in the example produce 27,600 Btu of heat every 24 hours.

To calculate the load from lights inside the refrigerated space, the wattage of each bulb is multiplied by the time of operation and a conversion factor of 3.41 Btu/watt. The two bulbs in the example generate a heat load of 2182 Btu per day.

An estimate of the amount of heat that is added by a person working in the refrigerated space can be looked up in a table like the one shown in **Figure 50-14**. The heat equivalent found on the table is then multiplied by the total number of hours worked by all occupants. The cabinet temperature in the example is 35°F, which is halfway between the 30°F and 40°F values listed on the table. The heat equivalent of occupancy is found by averaging the heat equivalents for 30°F and 40°F, which result in a heat equivalent of 895 Btu/hr. Since the worker is in the cabinet 8 hours a day, the total heat load due to occupants is 7160 Btu per day.

Solution, Step 5: Combining the Various Heat Loads

Once the heat leakage load and all of the individual heat loads that make up the service heat load are calculated, they are added together to find the total heat load. Since the loads are being added together, it is important that each load be expressed in the same terms, typically Btu/24 hr. The following shows how the various heat loads are added to arrive at the total heat load for the cabinet described in the example:

Total heat load =		28,063 Btu/24 hr
		30,780 Btu/24 hr
		38,500 Btu/24 hr
		27,600 Btu/24 hr
		2182 Btu/24 hr
	+	7160 Btu/24 hr
Total heat load (daily) =		134,285 Btu/24 hr
	or	5,595 Btu/hr

50.1.4 Heat Loads for Water Coolers

So far, the discussion of heat loads has been limited to coolers, walk-in freezers, and similar systems. The same principles can be applied to refrigeration systems that are used to cool water rather than to cool air. Finding the total heat load of a water-cooling system is a combination of a specific heat and a heat leakage problem:

1. Water is cooled to temperatures that vary upward from 35°F. Calculating the amount of heat removed from the water to cool it to a certain temperature is a specific heat–related problem.
2. Because the water in the system is stored at a low temperature, heat from the room leaks into the stored water. The rate of heat leakage in a water cooler is calculated in essentially the same way that heat leakage into a refrigerated cabinet is calculated.

The first step in installing a water cooling system is to determine what the cooling capacity of the system must be in order to effectively and efficiently handle

Copyright Goodheart-Willcox Co., Inc. 2017

the total heat load. As with total heat load for a walk-in cooler, the total heat load for a water cooler is a combination of the heat leakage load and the service heat load.

Calculating the Service Heat Load for a Water Cooler

For a water cooler, the service heat load is simply the heat that must be removed to cool the water. The service heat load that can be expected depends on the way the system will be used. The following are the common variables that will affect the service heat load:

- The rate at which water from the system will be consumed. The rate at which water will be consumed varies greatly depending on the types of activities the consumers will be performing. For example, a worker in a machine shop or factory can be expected to drink about twice the amount of water that a worker in an office building would drink. The number of people that are expected to use the system must also be known.
- The temperature of the water leaving the cooler. Drinking water temperatures should be regulated based on the type of work the consumers are doing. The heavier the work, or the warmer the room temperature, the warmer the drinking water must be.
- The temperature of the water entering the cooler. In order to calculate the amount of heat that must be removed to cool the water, the temperature difference between the incoming and outgoing water must be known.

The table in **Figure 50-15** lists different types of water cooler applications, the rates of consumption that can be expected for those applications, and the temperature of water that should be supplied for each application. These values, in combination with the temperature of the supply water and the number of people expected to use the system, can be used to quickly calculate the service heat load for a water cooling system.

Example:

The "heavy manufacturing" usage listing on the table in **Figure 50-15** indicates that drinking water should be kept at a temperature between 50°F and 55°F. Also, 1/4 gallon of water per hour per person will be consumed.

A production foundry can be classified as heavy manufacturing. If the foundry employs 50 workers for a period of eight hours, the water load per day would be 50 people × 8 hours × 1/4 gal/hr·person, or 100 gal of water. In other words, the system must be capable of cooling 100 gallons of water during the 8-hour workday.

Water Requirements

Usage	Final Temp. Required (°F)	Total Amount of Water Used and Wasted
Office building—employees	50	1/8 gallon per hour per person
Office building—transients	50	1/2 gallon per hour for each 250 persons per day
Light manufacturing	50–55	1/5 gallon per hour per person
Heavy manufacturing	50–55	1/4 gallon per hour per person
Restaurant	45–50	1/10 gallon per hour per person
Cafeteria	45–50	1/12 gallon per hour per person
Hotels	50	1/2 gallon per room (14 hr. day)
Theaters	50	1 gallon per hour per 75 seats
Stores	50	1 gallon per hour per 100 customers per hour
Schools	50–55	1/8 gallon per hour per student
Hospitals	45–50	1/12 gallon per day per bed

Note: The total amount of water used and wasted varies with the type of installation and kind of service. This table will serve as a basis for determining the cooler capacity required.

Copyright Goodheart-Willcox Co., Inc. 2017

If the incoming water in the supply pipe is 75°F, the cooler must reduce its temperature 20°F in order to provide water that is 55°F. Since there are 8.34 lb of water in 1 gallon, and the specific heat for water is 1 Btu/lb·°F, the service heat load can be computed as follows:

Formula:

Service heat load = specific heat × weight × temp. difference

Solution:

Service heat load = 1 Btu/lb·°F × (100 gal × 8.34 lb/gal) × 20°F
= 16,680 Btu

Calculating the Heat Leakage Load for a Water Cooler

The amount of heat leakage is determined by the materials used to construct the insulated water-storage parts of the system, the thickness of the materials, and their exterior surface area. Insulation 1″ to 3″ thick is common for water-cooling insulations. Ice water insulation is typically 1 1/2″ thick. The heat leakage load for standalone water-cooling systems is calculated the same way as the heat leakage load for cabinets.

50.2 Thermodynamics of the Basic Refrigeration Cycle

Thermodynamics is the science that describes the relationships between heat and mechanical action. The compression refrigeration cycle is a good example of the interaction of heat and mechanical action in a closed system. Pressurized refrigerant that is in the liquid state and near room temperature passes through a metering device, which reduces the pressure on the refrigerant. The temperature of the refrigerant also decreases. However, because the boiling point of the refrigerant decreases along with the pressure, the latent heat in the refrigerant increases as sensible heat decreases. As a result, the enthalpy remains constant. The metering device does not remove or add heat. It only converts some sensible heat to latent heat. This process results in a large pressure and temperature drop without gaining or losing heat (Btu) and is known as ***adiabatic expansion***.

The drop in pressure and corresponding drop in boiling point causes some of the refrigerant to immediately vaporize as it passes through the metering device. When this refrigerant vaporizes, it absorbs heat from the remaining refrigerant. The refrigerant that immediately vaporizes as it passes through the metering device is referred to as flash gas.

The remainder of the refrigerant absorbs heat from the evaporator and, therefore, from the cabinet, until that refrigerant also vaporizes. The rate at which heat is absorbed by the refrigerant as it vaporizes is known as the *latent heat of vaporization*. The amount of heat absorbed from the cabinet and evaporator is the ***effective latent heat***.

When the refrigerant vapor leaves the evaporator, it travels along the suction line. During this movement, the pressure of the vapor decreases slightly (usually 2 psi [14 kPa]). It increases in temperature by about 10°F (6°C). The term "superheat" refers to heat added to the refrigerant after it has vaporized. The amount of superheat is all sensible heat and amounts to the difference between the refrigerant's evaporating temperature and the temperature of the vapor at the compressor's inlet.

The compressor then takes the slightly superheated vapor and compresses it. It is compressed to a high-temperature, high-pressure vapor. Because of the pressure applied to the refrigerant, the condensing temperature of the refrigerant can rise to as high as 250°F (121°C), depending on the type of refrigerant and the pressure generated in the compressor.

Pro Tip

Refrigerant Compression

The term *adiabatic compression* refers to compressing a vapor without adding or removing heat energy from the vapor. When a compressor compresses refrigerant vapor, it decreases the volume of the vapor, which in turn increases the temperature and pressure of the vapor. Because this process is done relatively quickly, only a small amount of heat from the compressor is added to the vapor. As a result, the process is nearly adiabatic.

The superheated and compressed vapor passes to the condenser. If the refrigerant's temperature is higher than ambient temperature, it loses some of its heat to the air or water surrounding the condenser. This lowers the vapor temperature of the refrigerant. Eventually the refrigerant in a condenser loses enough sensible heat to completely desuperheat the refrigerant. At this point, it is at its condensing temperature. If the refrigerant loses any more heat, it will begin to condense from a vapor into a liquid.

Since a high-side refrigerant's condensing temperature is higher than the temperature of any water or air surrounding the condenser, the refrigerant vapor starts losing some of its latent heat of vaporization and begins condensing. The amount of heat the vapor loses determines how much of it condenses into a liquid. After the refrigerant condenses into a liquid, it may

Copyright Goodheart-Willcox Co., Inc. 2017

continue to lose heat to the condenser. This additional heat loss is in the form of sensible heat, meaning the liquid refrigerant's temperature will drop. This is known as subcooling.

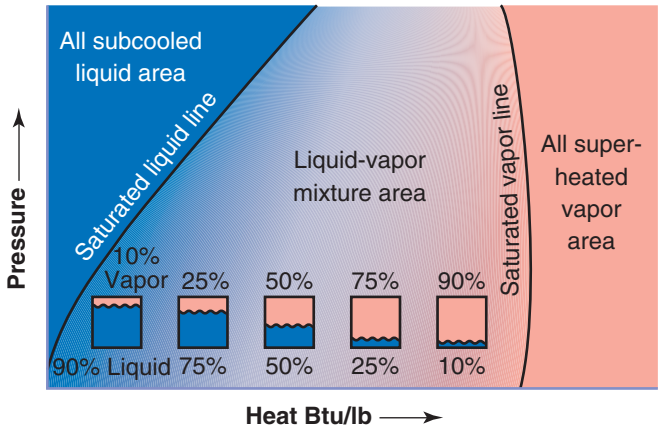
The liquid refrigerant returns to the metering device, where the refrigeration cycle is repeated. **Figure 50-16** shows this cycle taking place. It also indicates the temperatures in various parts of the refrigerating system.

50.2.1 Reading a Pressure-Enthalpy Diagram

A graph that plots refrigerant properties against pressure and heat conditions is commonly known as a *pressure-enthalpy diagram*, or *pressure-heat diagram*. Detailed instructions for reading pressure-enthalpy diagrams were presented in Chapter 9, *Introduction to Refrigerants*. The following is a brief overview.

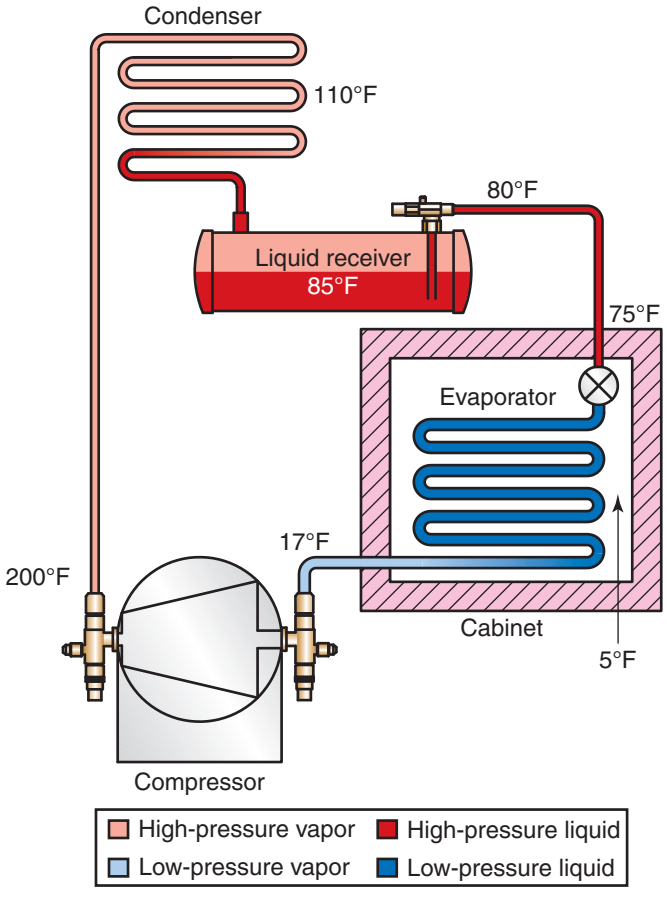
A pressure-enthalpy diagram can be divided into three main areas, **Figure 50-17**. Graph points that fall between the saturated liquid line and the saturated vapor line represent refrigerant that is a mixture of saturated liquid and saturated vapor. Graph points to the left of the saturated liquid line indicate that the refrigerant is all subcooled liquid. Graph points to the right of the saturated vapor line indicate the refrigerant is all superheated vapor.

Many facts can be determined from the simplified pressure-enthalpy diagram in **Figure 50-18**.



Goodheart-Willcox Publisher

Figure 50-17. The saturated liquid line and saturated vapor line divide a pressure-enthalpy diagram into three distinct areas. Note that, as heat is removed from saturated refrigerant, more of it becomes liquid. As heat is added to saturated refrigerant, more of it becomes vapor.



Goodheart-Willcox Publisher

Goodheart-Willcox Publisher

Figure 50-18. Simplified pressure-enthalpy diagram showing the different types of lines included in a pressure-enthalpy diagram. Line A indicates constant heat condition with pressure change. Line B shows constant pressure and condition of refrigerant with changing heat content. Line C indicates constant temperature with changing pressure and heat.

Copyright Goodheart-Willcox Co., Inc. 2017

Along any vertical line, such as A, the heat in one pound of refrigerant is constant. Along any horizontal line, such as B, the refrigerant has a constant pressure. Along stepped lines, like C, the temperature reading is constant. Note that the constant temperature line is vertical in the subcooled liquid area. It is horizontal in the liquid-and-vapor area. It slopes down and slightly to the right in the superheated vapor area.

Refrigerant quality refers to how much of the mass of a refrigerant is in the liquid state and how much is in the vapor state. A 10% quality means that the refrigerant is 10% vapor and 90% liquid. Line D is a line of constant quality.

Saturated Vapor

A *saturated vapor* is a refrigerant vapor under conditions that would cause some of the vapor to condense if any amount of heat were removed from it or if pressure was increased on it. Often saturated vapor is in the presence of some of its own liquid. For example, the vapor in a refrigerant cylinder that is half-full of liquid refrigerant would be a saturated vapor.

Superheated Vapor

A *superheated vapor* is a vapor whose temperature has increased above its 100% saturated condition for the pressure that it is under. When additional heat is added to a 100% saturated vapor, a superheated vapor is created, and its temperature increases above its saturation temperature. A superheated vapor will abide by Charles' and Boyle's gas laws. Superheat is the sensible heat (as measured in degrees) above the vapor's saturation temperature.

When refrigerant vaporizes in an evaporator, it is a saturated vapor at first. However, as this vapor leaves the evaporator and passes through the suction line to the compressor, it usually becomes warmer by 5°F to 15°F (3°C to 8°C). This increase in temperature is called "superheating the low-side vapor."

In a compressor, the low-pressure, superheated vapor gets compressed. Most of the mechanical energy of compression is used to reduce the volume of the refrigerant vapor, which increases its temperature and pressure. Some of the mechanical energy of compression is converted to heat energy due to friction. The heat from friction is absorbed by the refrigerant, further increasing its superheat.

Excessive superheating of refrigerant vapor lowers the efficiency of the system. The less superheating that takes place, the more efficient the system will be. As mentioned earlier, the amount of heat added by a refrigeration compressor is relatively small. On a pressure-enthalpy diagram, like the one shown in **Figure 50-19**, the superheat added by the compressor causes the compression line (B to C) to slant to the right.

There are three general places in the refrigeration system where refrigerant is a superheated vapor:

- In the suction line.
- In the compressor.
- In the discharge line.

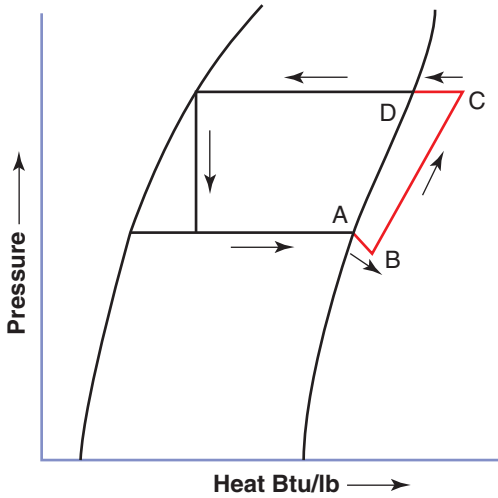
In **Figure 50-19**, the portions of the refrigeration cycle where the refrigerant is a superheated vapor are shown in red. When heat is removed from a superheated vapor, its volume and/or pressure decreases without condensation until the refrigerant's temperature reaches its condensation point. In **Figure 50-19**, this cool down is denoted by line from C to D.

Saturated Liquid

The term ***saturated liquid*** refers to a refrigerant in liquid form under conditions that would cause some of the liquid to vaporize if any amount of heat were added or if pressure was decreased. A refrigerant with a quality of 99% is composed of 1% saturated liquid and 99% saturated vapor. As the percentage of saturated vapor decreases, the percentage of saturated liquid increases.

Subcooled Liquid

If a refrigerant consists of 100% saturated liquid and additional heat is removed, the refrigerant is referred to as a *subcooled liquid*. Refrigerant is



Goodheart-Willcox Publisher

Figure 50-19. The superheated vapor portions of the refrigeration cycle are shown in red. From A to B, superheat is added to refrigerant vapor as it travels through suction line from evaporator to intake valve of compressor. From B to C, superheat is added as the vapor is compressed. From C to D, superheat is removed in the top portion of the condenser.

Copyright Goodheart-Willcox Co., Inc. 2017

subcooled before it enters the refrigerant metering device. Subcooling the refrigerant before it enters the metering device increases the refrigerant's effective latent heat (heat-absorbing capacity).

Effective Latent Heat

The amount of latent heat contained in vaporizing and in condensing refrigerant changes at different pressures. At a lower pressure, more latent heat must be added to a saturated liquid at any given temperature in order to vaporize it.

In a refrigeration system, the high-pressure liquid refrigerant leaving the condenser is throttled down to a low-pressure, low-temperature liquid by the metering device. Some of the liquid forms flash gas as it passes through the metering device, cooling the remaining liquid.

The formation of the flash gas causes the refrigerant to become a mixture of liquid and vapor refrigerant as it enters the evaporator. The refrigerant that has been converted to flash gas can no longer cool effectively. Therefore, the latent heat absorbed to form the flash gas must be subtracted from the total latent heat when determining the cooling ability of the refrigerant at a given pressure. In **Figure 50-20**, the latent heat absorbed to create the flash gas is indicated by the dotted green line. Only the latent heat to the right of the dotted green line contributes to the cooling effect of the system, and it is therefore referred to as the effective latent heat.

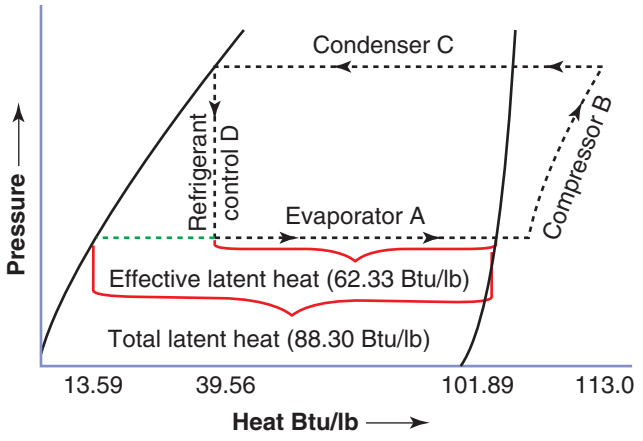
The effective latent heat is an average value because low-side pressure and high-side pressure vary somewhat during the operation of the system. Conditions such as oil in the system and system efficiencies can cause variations from the ideal cycle.

For R-134a, the total latent heat of vaporization at 5°F (–15°C) is 88.30 Btu/lb. However, after accounting for the latent heat used to form flash gas in the refrigerant, its actual heat-absorbing ability, or effective latent heat, is only about 62.33 Btu/lb, as shown in **Figure 50-20**. These values are based on the standard evaporating temperature of 5°F (–15°C) and standard condensing temperature of 86°F (30°C).

50.2.2 Practical Pressure-Enthalpy Cycles

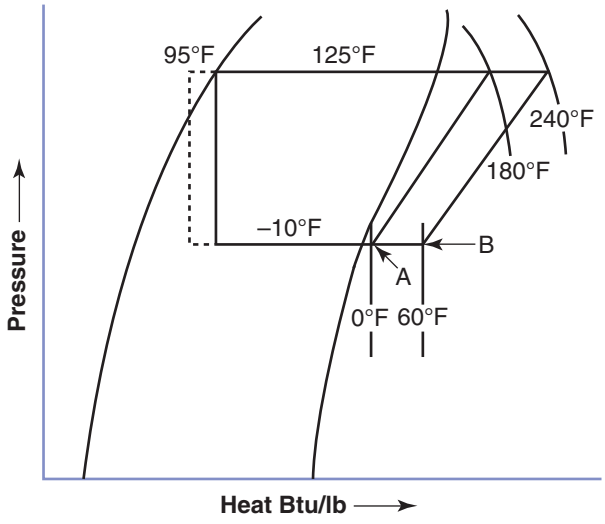
The refrigeration cycles for different systems vary depending on applications and conditions. A graph showing two different refrigeration cycles used in freezers is shown in **Figure 50-21**. The cabinet is kept at 0°F (–17.8°C). The refrigerant in the evaporator is at –10°F (–23.3°C). The air surrounding the condenser is 95°F (35°C).

With insulation on the suction line, superheat can be minimized for efficient operation. See the compression/superheat line beginning at point A in **Figure 50-21**. With only 10°F (6°C) of superheat, refrigerant enters the condenser at 180°F (82°C). The condenser must remove 55°F (30°C) of superheat before refrigerant can begin condensing.



Goodheart-Willcox Publisher

Figure 50-20. Pressure-enthalpy diagram plotting the operation of R-134a system. The total latent heat in 1 lb of refrigerant entering the compressor is 88.30 Btu/lb (101.89 Btu/lb – 13.59 Btu/lb). However, 25.97 Btu/lb (39.56 Btu/lb – 13.59 Btu/lb) of the total latent heat was used to create flash gas, and does not contribute to cooling the cabinet. As a result, the effective latent heat is only 62.33 Btu/lb (88.30 Btu/lb – 25.97 Btu/lb).



Goodheart-Willcox Publisher

Figure 50-21. Pressure-enthalpy diagram showing the typical refrigeration cycles of an air-cooled system for storing frozen foods.

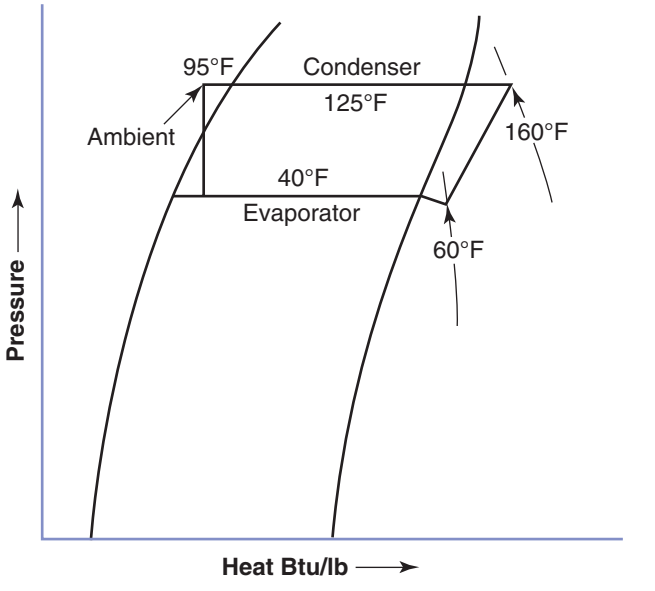
Copyright Goodheart-Willcox Co., Inc. 2017

If the suction line was not insulated, the cool suction line would continue to absorb heat along its entire length. This would increase the amount of superheat. See the compression/superheat line that begins at point B in **Figure 50-21**. With 60°F (33°C) of superheat, the compressor would pump the refrigerant vapor to the proper pressure at 240°F (116°C) at the condenser inlet. The condenser would need to remove 115°F (64°C) of superheat before the refrigerant could begin condensing.

Not insulating a suction line results in unnecessarily high superheat. As shown in this example, increasing superheat by 60°F (33°C) means that the condenser has to remove 60°F (34°C) more superheat than if the suction line had been insulated properly. Minimizing superheat results in the condenser providing the best possible subcooling. The better the system subcooling, the better the effective latent heat for the evaporator. A typical air conditioning (comfort cooling) cycle is shown in **Figure 50-22** for comparison.

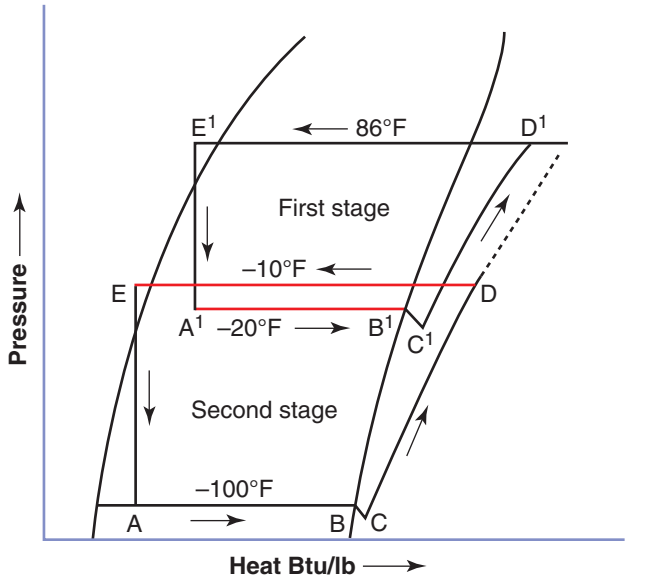
Cascade System

To produce extremely low temperatures efficiently, two refrigeration systems with separate refrigerant circuits may be used instead of one. The two systems are connected by a shared heat exchanger that transfers the heat of one circuit's condenser into the evaporator of the other circuit. The resulting arrangement is called a cascade system.



Goodheart-Willcox Publisher

Figure 50-22. Pressure-enthalpy diagram showing the typical cycle of a comfort cooling system with an evaporator temperature of 40°F (4.4°C) operating in an ambient temperature of 95°F (35°C).



Goodheart-Willcox Publisher

Figure 50-23. Pressure-enthalpy diagram showing the operation of cascade system used to obtain ultralow temperatures. Refrigerant passing through the first-stage evaporator (A^1 to B^1) removes heat from the second-stage condenser (D to E).

In a cascade system, the evaporator of the higher-pressure subsystem (first stage) removes the heat from the condenser of the lower-pressure subsystem (second stage). **Figure 50-23** shows the principle of this type system on a pressure-enthalpy diagram. Many cascade systems use a different refrigerant for the lower pressure subsystem than the refrigerant used in the higher pressure subsystem.

Compound Systems

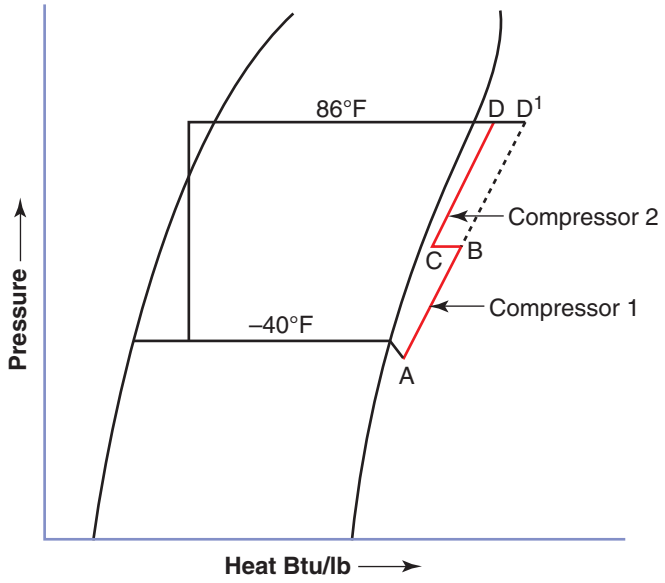
Some refrigeration systems, especially ultralow-temperature systems, use two compressors connected in series. They pump the very low-pressure suction line vapor up to the condensing pressure and temperature condition. In the first stage, a compressor pumps the vapor up to a midpoint on the compression curve. Then, the compressed vapor is cooled (desuperheated) but remains in vapor form. The second compressor further compresses the cooled intermediate vapor to the final pressure-temperature condition. **Figure 50-24** shows the operation of a compound refrigeration system graphed on a pressure-enthalpy diagram.

Hot-Gas Cycles

A compressor's discharge hot gas may be used for any of the following purposes:

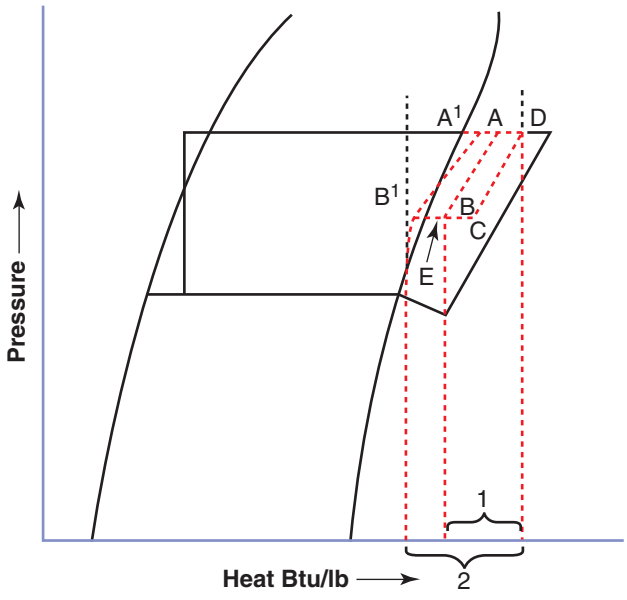
- Defrosting evaporators.
- Preventing suction pressure from dropping too low (when cooling load decreases).

Copyright Goodheart-Willcox Co., Inc. 2017



Goodheart-Willcox Publisher

Figure 50-24. Pressure-enthalpy diagram showing the typical cycle of a compound refrigeration system. Compressor 1 (first stage) compresses the vapor partway to its final pressure (A to B). The vapor passes through a heat exchanger, where it is desuperheated (B to C). Compressor 2 (second stage) then compresses the vapor to its condensing pressure (C to D). Using a heat exchanger to cool the refrigerant between compressor stages reduces the amount of heat of compression at the final stage (D^1 to D) and reduces the temperature at the second-stage compressor's exhaust valve but still allows for a high compression ratio needed for low-temperature operation.



Goodheart-Willcox Publisher

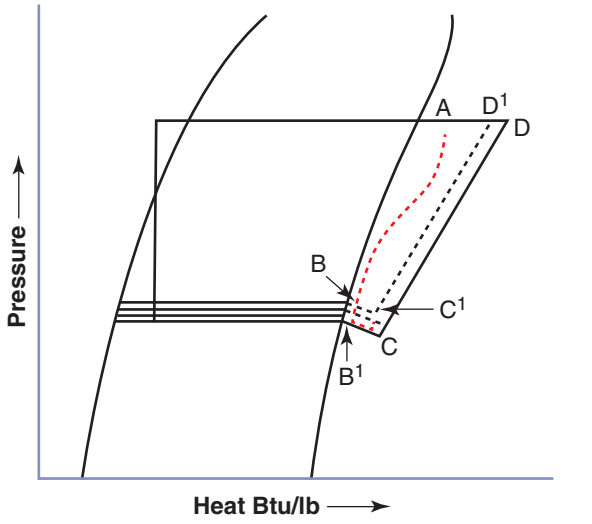
Figure 50-25. Pressure-enthalpy diagram plotting a hot-gas defrosting cycle. The heat lost from A to B, as shown at 1, is the heat used to defrost the evaporator.

- Keeping liquid refrigerant from entering compressor.

Many refrigeration systems use an automatic bypass system. A graph of hot-gas bypass being used to defrost an evaporator is shown in **Figure 50-25**. The refrigerant is compressed normally. The hot gas is then bypassed through the evaporator, as shown by the lines from A to B to C to D.

If the hot gas used for defrosting is cooled too much (as indicated by the line from A to B^1), it will become partly liquid. This could cause liquid to enter the compressor. To prevent this, an accumulator is installed on the suction line to ensure that only vapor can reach compressor. The maximum heat for defrosting is shown at 2, unless bypass gas is allowed to condense and is then vaporized (in another evaporator of a multiple system or in a special defrost evaporator).

The cycle for hot-gas bypass for low-pressure control is shown in **Figure 50-26**. The bypass line (controlled by a solenoid valve and a pressure-responsive valve) is piped from the discharge line into the suction line. The bypass circuit is controlled by a sensor or sensing bulb connected to the suction line. The bypass action will return the compression line to approximately C^1 to D^1. The four horizontal evaporator lines represent how the low-pressure side changes from cut-in pressure to cut-out pressure.



Goodheart-Willcox Publisher

Figure 50-26. A hot-gas bypass system helps maintain a normal low-side pressure in the low side of the system. If the low-side pressure drops to point B^1, the bypass circuit A to B opens and brings low-side pressure up to normal, at C^1. Without the bypassed hot gas, the low-side would operate at a lower pressure.

Chapter Review

Summary

- A heat load is the amount of heat that must be removed from the conditioned space over a set period of time in order to maintain the desired temperature in the conditioned space.
- Heat leakage load is the amount of heat that leaks through the cabinet over a specific period of time, usually 24 hours.
- The five variables that affect heat leakage load are the length of time through which leakage is measured, the difference between outside temperature and the temperature inside the cabinet, the thickness of the materials used to construct the cabinet, the type of materials used to construct the cabinet, and the surface area of the cabinet.
- A material's thermal conductivity, or K-value, represents the rate at which heat is transferred through a 1" thickness of the material. A material's thermal conductance, or C-value, is the material's thermal conductivity (K-value) divided by its thickness. A material's thermal resistance is equal to the inverse of its thermal conductivity, or C-value. A material's thermal transmittance, or U-value, is equal to the inverse of the sum of thermal resistances in the material, including boundary air films.
- Heat leakage load is calculated by multiplying the surface area of each material in the cabinet by the thermal transmittance, or U-value, of that material and then adding the results together.
- The service heat load, or usage heat load, is the sum of the various heat loads that result from operation of the unit for a given period of time, usually 24 hours. The individual heat loads that make up the service heat load include cooling the products in the cabinet, cooling air changes in the cabinet, removing respiration heat from the products, removing heat from lights and motors, and removing heat generated by people working in the conditioned space.
- The service heat load is affected by the temperature difference between the interior and exterior of the cabinet, the volume of the cabinet's interior, how the cabinet is used, and the length of time through which the load is measured. Service heat load can be calculated manually or estimated using manufacturer's tables.
- A system's total heat load is the sum of its heat leakage load and its service heat load. A properly sized system will remove the total heat load during the appropriate operating cycle.
- Calculating the total heat load for a water cooler is similar to calculating the total heat load for a refrigerated cabinet. The service heat load is determined by the temperature difference between the incoming water and the cooled water and the rate at which water is consumed. The heat leakage load for a standalone water-cooling system is calculated the same way as for a refrigerated cabinet.
- Thermodynamics is the science that describes the relationship between heat and mechanical action. The compression and expansion of fluids in a closed system, such as a refrigeration system, shows thermodynamic principles in action.
- A pressure-enthalpy diagram graphs the physical properties of refrigerant at different points in the refrigeration cycle. The graph can be divided into three distinct areas: subcooled liquid only, saturated liquid and vapor, and superheated vapor only. A refrigerant's heat content, pressure, and temperature throughout a refrigeration cycle are shown on a pressure-enthalpy diagram.

Review Questions

Answer the following questions using the information in this chapter.

1. A refrigeration system's heat leakage load is determined by the materials the cabinet is made of, the surface area of the cabinet's exterior, and _____.
   A. the number of air changes per hour
   B. the products stored in the cabinet
   C. the temperature difference between the inside and outside of the cabinet
   D. All of the above.
2. Which of the following measurements accounts for the boundary air films inside and outside of a cabinet?
   A. C-value.
   B. K-value.
   C. R-value.
   D. U-value.

Copyright Goodheart-Willcox Co., Inc. 2017

3. Which of the following variables does *not* affect the service heat load of a refrigeration system?
   A. The number of people working inside the cabinet.
   B. The number and size of electric motors operating inside the cabinet.
   C. The quantity and types of products stored in the cabinet.
   D. The thermal conductance of the cabinet's walls.
4. The three types of heat that must be considered when calculating the product heat load are _____.
   A. latent heat, sensible heat, and superheat
   B. latent heat, respiration heat, and subheat
   C. latent heat, respiration heat, and sensible heat
   D. respiration heat, sensible heat, and superheat
5. Which of the following variables are used to calculate the sensible heat load of a product?
   A. Latent heat, product weight, and respiration heat.
   B. Latent heat, product weight, and temperature change.
   C. Product weight, specific heat, and temperature change.
   D. Respiration heat, specific heat, and temperature change.
6. A refrigerant quality of 30% means that the refrigerant is _____.
   A. 30% liquid and 70% vapor
   B. 70% liquid and 30% vapor
   C. subcooled by 30°F
   D. superheated by 30°F
7. When a refrigeration system's suction line that is cooler than ambient temperature is not insulated, heat absorbed into the suction line _____.
   A. does not affect the system at all
   B increases superheat
   C. increases system efficiency
   D. All of the above.
8. A line that is completely vertical in a pressure-enthalpy diagram shows constant _____.
   A. heat (enthalpy)
   B. pressure
   C. refrigerant quality
   D. temperature
9. A line that is completely horizontal in a pressure-enthalpy diagram shows constant _____.
   A. heat (enthalpy)
   B. pressure
   C. refrigerant quality
   D. temperature
10. On a pressure-enthalpy diagram, a line that is vertical in the liquid-only portion, horizontal in the liquid-vapor portion, and slants slightly to the right from vertical in the gas-only portion shows constant _____.
    A. heat (enthalpy)
    B. pressure
    C. refrigerant quality
    D. temperature

CHAPTER 51 Commercial Refrigeration Component Selection

Chapter Outline

51.1 Sizing Compressors, Condensers, and Evaporators
- 51.1.1 Selecting a Compressor
- 51.1.2 Selecting a Condenser
- 51.1.3 Selecting an Evaporator
- 51.1.4 Liquid Receiver Sizing

51.2 Calculating Theoretical Compressor Volume
- 51.2.1 Volumetric Efficiency
- 51.2.2 Factors Affecting Volumetric Efficiency

51.3 Designing Piping
- 51.3.1 Pressure Drop
- 51.3.2 Refrigerant Velocity
- 51.3.3 Oil Circulation
- 51.3.4 Condenser Condensate Line
- 51.3.5 Liquid Line
- 51.3.6 Suction Line
- 51.3.7 Compressor Discharge Line

Learning Objectives

Information in this chapter will enable you to:

- Identify the factors that affect compressor sizing.
- Calculate a compressor's required capacity based on its total heat load and operating cycle.
- Summarize the factors that affect the heat transfer rates of evaporators and condensers.
- Use tables from manufacturers to size compressors, condensers, and evaporators.
- Calculate a compressor's theoretical volume and volumetric efficiency.
- List the basic criteria that must be considered when sizing refrigerant lines.

Technical Terms

bore
condenser condensate line
operating cycle
static loss
stroke
total equivalent length
total heat of rejection (THR)
volumetric efficiency

Review of Key Concepts

Reviewing these concepts from earlier chapters will help you understand new concepts presented in this chapter:

- A commercial refrigeration system's heat load is the amount of heat that it must remove from a conditioned space over a set period of time in order to maintain the desired temperature in the space. (Chapter 50)
- Relative humidity is the amount of moisture in an air sample compared to the total amount of moisture the same sample would hold if it were completely saturated at the same temperature. Relative humidity is stated as a percentage. (Chapter 27)
- A saturated vapor produces condensate (liquid) if it loses heat (Btu) or applied pressure increases. A saturated vapor's temperature is equal to its boiling point at the given pressure. (Chapter 5)
- Air-cooling evaporators, such as natural-draft and forced-draft evaporators, are evaporators that are designed to directly cool the air in a conditioned space. Liquid-cooling evaporators are designed to cool a liquid rather than air. (Chapter 21)
- A modulating refrigeration system is able to adjust its capacity to more closely match a variable heat load. Modulating systems may use two or more compressors operating in parallel, one single compressor capable of varying its speed or output, or hot-gas bypass for capacity control. (Chapter 49)

Introduction

Commercial refrigeration often requires the installation of custom systems that are designed for a specific application. For instance, the existing space available in a building may dictate the size of a walk-in cabinet. The first step in sizing a custom refrigeration system is to determine the purpose of the system. The product to be refrigerated determines the type of refrigerant and the size of equipment to be used.

Low-temperature applications, such as freezers that operate from 0°F to –60°F (–18°C to –51°C), may use R-404A or R-508B with multiple compressors in a cascade system to achieve low temperatures. Mid-temperature applications, such as grocery display cases that operate from 35°F to 45°F (2°C to 7°C), may use a secondary loop refrigeration system circulating a non-phase changing refrigerant that absorbs heat but does not vaporize. Higher-temperature applications, such as florist cabinets, may use R-134a with a hermetic compressor and require high humidity. Since each application is unique, the condensing and evaporating units must be matched to the specific refrigeration requirements of the conditioned space.

51.1 Sizing Compressors, Condensers, and Evaporators

A preliminary step in designing a commercial refrigeration system is estimating anticipated total heat loads. The total heat load determines how much cooling capacity the system must have in order to function effectively and efficiently. The total heat load represents the total amount of heat added to the conditioned space in a 24-hour period.

The selection and installation of commercial refrigeration equipment requires a technical understanding of the variables involved. The capacity of the metering device, type of temperature control, method of air circulation, and specific duty of the system affect the selection of the compressor, condenser, and evaporator. These variables can have a profound effect on the system's operation.

Selecting Components for a Commercial Refrigeration System

Commercial refrigeration components are selected based on the total heat load for the system. Many methods are used to select these components. The following is a basic overview of one method:

1. Select the compressor and condenser using capacity tables provided by manufacturers.
2. Select the evaporator to match the compressor capacity.
3. Select other system components based on compressor, evaporator, and system characteristics.

Pro Tip

Component Sizing

The refrigeration component sizing and selection information in this chapter provides a simplified overview of the process. The type of refrigerant, compressor, condenser, and evaporator are unique to each application. Refer to manufacturers' information and advanced technical manuals for additional information.

51.1.1 Selecting a Compressor

One of the first components selected for a system is the compressor. The compressor is the heart of a refrigeration system, using mechanical energy produced by an electric motor to pump refrigerant through the system. The refrigerant picks up heat in one place and releases it in another place.

Basically, a compressor must remove vapor from the evaporator fast enough to enable the refrigerant to vaporize at the correct low pressure. Refrigerant vapor must be removed from the evaporator as fast as heat enters the evaporator in order to vaporize the refrigerant.

A compressor is selected based on manufacturers' tables of compressor capacities. The compressor's capacity must be sufficient to move enough refrigerant through the system to remove the total heat load within the operating cycle. The capacity of a compressor varies based on the suction line temperature and the condensing temperature. The compressor selection also determines the refrigerant to be used to operate the system at maximum efficiency.

Suction Line Temperature

The suction line temperature is determined based on the design temperature of the conditioned space and the temperature difference (TD) between the design temperature and the refrigerant in the evaporator. Other system conditions affecting compressor sizing include the desired relative humidity in the conditioned space and the defrost method used in the system.

Relative humidity in a refrigerated storage space must be controlled. High relative humidity can promote the growth of mold and mildew in some products. Low relative humidity can cause some products to lose moisture and become too dry. Every product has an ideal relative humidity for refrigerated storage. When designing a refrigeration system, a technician determines the relative humidity based on the product to be stored in the space, **Figure 51-1**.

Storage Relative Humidity for Select Products

Product	Relative Humidity (%)
Onions	70–75
Ham	80
Grapes	80–85
Mushrooms	80–85
Beef	84–85
Apples	85–88
Broccoli	90–95
Turnips	95–98

Goodheart-Willcox Publisher

Figure 51-1. A refrigerated storage space must maintain the relative humidity appropriate for the product being stored.

Copyright Goodheart-Willcox Co., Inc. 2017

Once the relative humidity is selected based on the product to be stored, the temperature difference (TD) can be determined. When the TD and the design temperature of the conditioned space are known, you can calculate the saturated suction line temperature. To do so, simply subtract the TD from the design temperature. For example, a 45°F (7°C) refrigerated storage space with a 10°F (5°C) TD would have a suction line temperature of 35°F (2°C). A table showing TDs and relative humidity levels is shown in **Figure 51-2**.

Operating Cycle

The capacity of a compressor is determined in part by its ***operating cycle***, which is the number of hours that it operates per day. A smaller compressor with a longer operating cycle can be as effective as a larger compressor with a shorter operating cycle.

The operating cycle is partly based on the evaporator defrosting requirements. See **Figure 51-3**. Once the operating cycle is determined, the compressor capacity can be calculated by dividing the total heat load (which is based on 24 hours) by the number of hours in the operating cycle.

Temperature Difference and Relative Humidity

Relative Humidity (%)	Temperature Difference (°F)
90–95	8
80–90	10–12
65–80	12–15
50–65	17–22

Goodheart-Willcox Publisher

Figure 51-2. Relationship between relative humidity and temperature difference (TD) in the conditioned space.

Formula for required compressor capacity:

$$\text{Required capacity (Btu/hr)} = \frac{\text{Total heat load (Btu/day)}}{\text{Operating cycle (hr/day)}}$$

Example:

A particular walk-in cabinet used to store lean beef at 35°F (2°C) requires 160,524 Btu/day. The system has a TD of 10°F (5°C) and, thus, a suction line temperature of 25°F (–4°C). Based on the cabinet and suction line temperatures, warm air defrost can be used for the system. For a system with warm air defrost, the operating cycle is 16 hours. Determine the required compressor capacity.

Solution:

$$\text{Required capacity (Btu/hr)} = \frac{\text{Total heat load (Btu/day)}}{\text{Operating cycle (hr/day)}}$$

$$= \frac{160{,}524 \text{ Btu/day}}{16 \text{ hr/day}}$$

$$= 10{,}033 \text{ Btu/hr}$$

The required system capacity can also be expressed in tons of refrigeration effect.

Example:

Given a system load of 10,033 Btu/hr, determine the equivalent load in tons.

Solution:

One ton is equal to 12,000 Btu/hr. Therefore, divide the load by the number of Btu per hour in 1 ton of refrigeration as follows:

$$\text{Required capacity (tons)} = 10{,}033 \text{ Btu/hr} \div 12{,}000 \frac{\text{Btu/hr}}{\text{ton}}$$

$$= 0.84 \text{ tons}$$

Operating Cycle Based on Defrost Requirements

System Temperatures	Comment	Operating Cycle (hours per day)
Suction line temperature 30°F or higher.	No defrost cycle needed.	20–22
Suction line temperature below 30°F and cabinet temperature 35°F or higher.	Warm air defrost. Compressor stops and evaporator fans run to defrost the evaporator. One hour of Off cycle for every two hours compressor is run.	16
Suction line temperature below 30°F and cabinet temperature below 35°F.	Dedicated defrost system required.	18–22

Goodheart-Willcox Publisher

Thinking Green

Compressor Loads

After calculating the compressor load based on the system operating cycle, some HVACR technicians in the past would add 5% to 10% to the load as a "safety factor" to ensure the system components would not be undersized. Generally, this extra safety factor is unnecessary. The resulting oversized components are an inefficient use of energy. Determining the load based on the operating cycle typically provides a sufficient safety factor. In addition, heat loads are calculated based on the most unfavorable ambient temperature conditions. This provides an additional safety factor for most days of the year.

Condensing Temperature

Compressor capacity is affected by both the suction line temperature and the condensing temperature. The condensing temperature is determined from the characteristics of the condenser, including the condenser type and the ambient design temperature.

Condensers can be air cooled or water cooled. For commercial refrigeration systems, air-cooled condensers are commonly used. Air-cooled condensers in commercial systems generally have a temperature difference (TD) of 10°F to 30°F (5°C to 17°C). The condensing temperature is the ambient design temperature plus the TD.

Example:

A rooftop air-cooled condenser has a TD of 20°F (11°C). The ambient design temperature is 100°F (38°C). Determine the condensing temperature.

Solution:

Condensing temp = Ambient temp + TD
= 100°F + 20°F
= 120°F

Compressor Capacity Tables

Compressor manufacturers provide tables listing compressor capacities. The capacity of a compressor is determined by three factors:

- Refrigerant type.
- Suction line temperature.
- Condensing temperature.

To select a compressor for a given load and conditions, first locate tables for available compressors. Then check the compressor capacities based on the refrigerant type, suction line temperature, and condensing temperature. See **Figure 51-4**.

51.1.2 Selecting a Condenser

A condenser is selected with the compressor. Sometimes, a single condensing unit (consisting of a compressor, condenser, and liquid receiver) is selected. In other cases, the compressor and condenser are selected as separate units.

A condenser is selected based on the ***total heat of rejection (THR)***. THR comprises the total heat load for the system and the energy added to the refrigerant by the compressor. As a result, the required capacity for the condenser is greater than the required capacity for the compressor or the evaporator.

An estimation is often used to determine the energy added to the refrigerant by the compressor.

Average Compressor Capacities (Btu/hr)

Compressor hp	Suction Line Temperatures (°F)							
	–30		–15		+20		+40	
	Condensing Temperatures (°F)							
	110	120	110	120	110	120	110	120
2	5,200	4,500	9,100	8,200	18,000	16,800	22,800	21,200
5	14,200	12,500	24,800	22,400	41,700	39,300	62,400	58,500
10	31,000	26,000	44,800	43,600	81,000	75,000	120,000	112,000
25	70,000	56,000	96,000	85,000	188,000	174,000	283,000	263,000
50	122,000	100,000	188,500	159,500	375,000	350,000	585,000	550,000

Goodheart-Willcox Publisher

Figure 51-4. Compressor capacities for a given refrigerant at various suction line temperatures and at two different condensing temperatures. These capacities are only examples. Always refer to the capacity values provided by the compressor manufacturer.

Copyright Goodheart-Willcox Co., Inc. 2017

One estimating method multiplies the nominal horsepower of the compressor by 3,000 Btu/hr·hp. A second method of estimating the THR multiplies the compressor capacity by a factor to account for the added energy. The factor used in the calculation depends on the compressor type:

For an open-drive compressor:

$$THR = \text{Compressor capacity} \times 1.25$$

For a hermetic compressor:

$$THR = \text{Compressor capacity} \times 1.30$$

Once the THR is estimated, the condenser is selected based on capacities provided in manufacturers' tables. The design of the condenser is also important. The refrigerant tubes at the core of the condenser reject heat to the surrounding air by convection through the condenser fins attached to the tubes. Condensers are categorized by size and the number of fins per inch (FPI) attached to the refrigerant tubes. See **Figure 51-5**.

The following are some of the factors affecting a condenser's ability to transfer heat:

- Surface area. The greater the number of fins per inch (FPI), the greater the surface area of the condenser and the greater the heat transfer.
- Temperature difference (TD). The greater the TD between the condenser and the cooling medium (air or water), the greater the heat transfer.
- Air/water velocity. The greater the velocity of the cooling medium, the greater the heat transfer.

Condensers are categorized by their cooling medium. Air-cooled condensers are commonly used for commercial refrigeration systems. Water-cooled condensers are also used.

Water-cooled condensers have a much greater capacity than air-cooled condensers. The heat transfer rate for air-cooled condensers varies between 1 Btu/hr·ft^2·°F and 4 Btu/hr·ft^2·°F. The heat transfer rate for water-cooled condensers varies between 100 Btu/hr·ft^2·°F and 500 Btu/hr·ft^2·°F. The capacity of a water-cooled condenser requires the good thermal contact between the shared heat exchanger surface area of the cooling medium and the refrigerant. The flow rate of the water also has a significant impact on the condenser's capacity. See **Figure 51-6**.

Condenser Heat Transfer Rates (Btu/hr·°TD)

Model	R-22 and R-410A				R-404A			
	8 FPI	10 FPI	12 FPI	14 FPI	8 FPI	10 FPI	12 FPI	14 FPI
A	9,400	10,300	10,800	11,800	9,200	10,100	10,600	11,600
B	21,600	22,900	23,800	24,500	21,200	22,400	23,300	24,000
C	32,400	34,400	35,700	36,800	31,800	33,700	35,000	36,100

Goodheart-Willcox Publisher

Figure 51-5. Table of heat transfer rates for three different condenser models. A condenser's ability to transfer heat varies based on the number of fins per inch (FPI) on the condenser and the type of refrigerant used in the system. Heat transfer rates are listed per degree of TD, so the values in the table must be multiplied by the condenser TD to determine the condenser capacity in Btu/hr.

Condenser Capacity (Btu/hr)

Water Flow Rate (gpm)	Temperature Difference (°F)					
	15	20	25	30	35	40
2	11,000	14,500	17,900	21,300	24,500	27,600
6	23,800	31,500	38,900	46,100	53,100	59,900
10	31,500	41,700	51,500	61,200	70,600	79,700

51.1.3 Selecting an Evaporator

An evaporator removes heat from the conditioned space only when the compressor is running. Therefore, the heat-removing capacity of the evaporator is calculated on the same operating cycle as that of the compressor. Evaporators are selected using capacity data provided by the manufacturer. See **Figure 51-7**.

The capacity of the evaporator should be matched to the capacity of the compressor. When balancing the capacity of the compressor and the evaporator, a technician must make calculations for each based on the same suction line temperature. As the suction line temperature decreases, the capacity of the evaporator increases to remove an increased amount of heat (greater TD).

Factors Affecting Evaporator Capacity

When calculating the capacity of evaporators, a technician should rely on manufacturer specifications. Manufacturers obtain their heat capacity values from actual experiments. Such factors as poor circulation, frosted fins, air turbulence around the evaporator, and even the amount of moisture in the air can affect the capacity of the evaporator.

One of the laws of thermodynamics is that heat always flows from an object at a higher temperature to an object at a lower temperature. The ability of an evaporator to absorb heat from the conditioned space depends on many variables, including the following:

- Surface area. The greater the number of fins per inch (FPI), the greater the surface area of the evaporator and the greater the amount of heat transfer.
- Temperature difference (TD). The greater the TD, the greater the amount of heat transfer.
- Heat conductivity of the material. The greater the conductivity of the material, the greater the heat transfer.
- Thickness of material. The thinner the material, the greater the heat transfer.
- Time. The greater the amount of time the compressor is running, the greater the heat transfer.

Evaporators are made of materials that are good conductors of heat. For air-cooling evaporators, the heat must pass through an air film on the evaporator tubing. Then, the heat travels through the evaporator tubing and the oil or liquid refrigerant film on the inside of the tubing to the refrigerant. Heat is also absorbed by the metal fins of the evaporator and transferred by conduction to the tubing, **Figure 51-8**.

If the air is moved rapidly, heat flow to the evaporator tubing is greater. More air contacts the tubing per unit of time, and the air film is thinner. If the oil or refrigerant film inside the tubing is moved faster, the film will be thinner. Generally, the denser the fluid is, the greater the heat flow. Likewise, the faster the fluid motion is, the greater the heat flow.

Heat transfer rates for the three primary types of evaporators vary significantly:

Performance Data for Evaporator Models

Model	No. of Fans	Airflow (cfm)	Motor Heat (Btu/hr)	Capacity (Btu/hr)			
				Suction Line Temperature (°F)			
				–20	–10	+20	
				Temperature Difference (°F)			
				10	10	10	15
EV-1	1	825	220	4,100	4,300	4,700	7,100
EV-2	2	1,565	440	5,600	5,900	6,400	9,700
EV-3	3	2,340	660	12,200	12,800	14,000	21,000

Goodheart-Willcox Publisher

Figure 51-8. Heat transfer from conditioned space to refrigerant through evaporator tubing. Heat passes through an air film, the tubing wall, and an oil or liquid refrigerant film.

- Natural-draft evaporators—approximate rate of 1 Btu/hr·ft^2·°F.
- Forced-draft evaporators—approximate rate of 3 Btu/hr·ft^2·°F.
- Liquid-cooling evaporators—approximate rate of 15 Btu/hr·ft^2·°F to 150 Btu/hr·ft^2·°F.

The heat transfer rate of a specific evaporator may vary from these approximations, but the approximate value may be helpful for general estimates and comparison purposes. Always refer to the manufacturer's data for the specific unit.

Example:

What is the approximate capacity of a natural-draft evaporator (a simple cold plate that absorbs heat from the surrounding area) with a surface area of 15 ft^2, a refrigerant temperature of 22°F (–6°C), and an average cabinet temperature of 42°F (6°C)?

Solution:

To find the evaporator capacity, multiply the heat transfer rate for a natural-draft evaporator (1 Btu/hr·ft^2·°F) by the surface area (15 ft^2) and the temperature difference (20°F):

Evaporator capacity = 1 Btu/hr·ft^2·°F × 15 ft^2 × 20°F

Evaporator capacity = 300 Btu/hr

Forced-Draft Evaporator Capacities

A forced-draft evaporator is an evaporator with an electric fan mounted near it to increase airflow. The evaporator fan is rated in size by how much air it is able to move in a given time. The common rating is cubic feet per minute (cfm). In a forced-draft evaporator, a large quantity of air flows over the evaporator. This airflow increases the capacity of the evaporator because a greater volume of air comes in contact with the evaporator over time. The table in **Figure 51-9** shows a sample of typical forced-draft evaporator performance data.

Liquid-Cooling Evaporator Capacities

The heat transfer rate of liquid-cooling evaporators can range from 15 Btu/hr·ft^2·°F to 150 Btu/hr·ft^2·°F. The heat transfer rate is affected by the cooled liquid velocity, evaporator construction, and temperature difference. Liquid velocity is usually measured in feet per minute (fpm). The table in **Figure 51-10** illustrates the significant effect that water velocity and TD can

Forced-Draft Evaporator Performance Data					
Model	Fan Size (in)	Airflow (cfm)	Total Surface Area—Fins and Tubes (in^2)	Cooling Capacity (Btu/hr)	
				15°F TD	25°F TD
EV-12	12	620	35	2,200	4,500
EV-15	15	1,200	78	5,200	9,000
EV-17	17	2,020	98	6,500	10,500

Goodheart-Willcox Publisher

Liquid-Cooling Evaporator Heat Transfer Rates (Btu/hr·ft²·°F)					
Water Velocity (fpm)	Temperature Difference (°F)				
	6	8	10	12	15
150	67	76	83	90	97
200	83	95	103	110	118
250	97	109	115	122	129
300	103	115	123	130	138

Goodheart-Willcox Publisher

Figure 51-10. As water velocity and temperature difference increase, the heat transfer rate also increases. For this particular evaporator, if the water velocity is reduced from 250 fpm to 150 fpm, the cooling capacity of the evaporator is reduced by about 30%.

have on the evaporator's heat transfer rate and, subsequently, on the evaporator's cooling capacity.

51.1.4 Liquid Receiver Sizing

Liquid receivers for a commercial system should be selected to be 15% larger than the total liquid volume in the system. This practice is a safety measure in the event the refrigerant circuit becomes restricted. The restriction could be a clogged filter or frozen moisture stuck in a metering device's valve opening. **Figure 51-11** shows liquid capacity for various models. Note that the capacity of a liquid receiver varies for different refrigerants.

51.2 Calculating Theoretical Compressor Volume

In the previous section, compressor capacity was determined based on manufacturer information. The volume of refrigerant vapor moved through a compressor can also be calculated mathematically. For a reciprocating compressor, the volume of vapor is determined by the ***bore*** (cylinder diameter), ***stroke*** (distance traveled by a piston), number of cylinders, speed of the compressor (rpm), and volumetric efficiency. Using this information, a technician can calculate the heat-removing capacity of the compressor.

As the crankshaft of the compressor completes one revolution, the piston moves from the lowest point of its travel (bottom dead center) to the highest point (top dead center) and back to the lowest point again. On the downstroke, low-pressure refrigerant vapor is drawn into the cylinder. The vapor fills the space between the top of the piston and the head of the cylinder. The piston compresses this vapor on the upstroke. It pushes the vapor through the exhaust valve into the high-pressure side of the system. The volume displaced by the piston on each stroke (movement from bottom dead center to top dead center) is the volume of refrigerant vapor moved through the compressor. See **Figure 51-12**.

Liquid Receiver Data					
Model	Diameter (in)	Length (in)	Inlet/Outlet Size	Capacity (lb)	
				R-134a, R-22	R-404A, R-507
LR-A	4	10	1/4	4.0	3.6
LR-B	5	10	1/4	6.0	5.4
LR-C	5	10	3/8	6.0	5.4
LR-D	6	12	3/8	10.0	9.0
LR-E	6	18	1/2	16.0	14.4

Goodheart-Willcox Publisher

Figure 51-11. Liquid receiver capacities. Capacity depends on the type of refrigerant in the system.

Goodheart-Willcox Publisher

Figure 51-12. Stroke is the distance a piston travels from bottom dead center to top dead center. The volume of vapor displaced by the piston can be calculated by multiplying the stroke by the surface area of the piston head.

Formula for volume of vapor moved per minute through a compressor:

$$V = \frac{\pi D^2}{4} \times S \times N \times R$$

where

V = volume (in^3) pumped per minute
D = diameter of cylinder (inches)
S = length of stroke (inches)
N = number of cylinders
R = revolutions per minute (rpm)

This formula for volume simply calculates the surface area of the piston head, $\pi D^2/4$, and multiplies it by the length of the stroke (S). The resulting product is the displacement volume. Next, this value is multiplied by the number of cylinders (N). Then it is multiplied by the revolutions per minute of the compressor (R). This gives the total volume in cubic inches pumped per minute.

The formula presented in this section calculates the theoretical compressor volume. The actual volume of vapor moved through a compressor is always less than this theoretical volume as a result of manufacturing tolerances and friction losses.

Example:

How much vapor will a two-cylinder compressor pump at 400 rpm if it has a 2″ bore and a 2″ stroke?

Solution:

$$V = \frac{\pi D^2}{4} \times S \times N \times R$$
$$= \frac{3.1416 \times (2'')^2}{4} \times 2'' \times 2 \times 400 \text{ rpm}$$
$$= 3.1416 \text{ in}^2 \times 2'' \times 2 \times 400 \text{ rpm}$$
$$= 5{,}027 \text{ in}^3/\text{min}$$

This volume can be converted into cubic feet per minute (1,728 in^3 = 1 ft^3):

$$V = 5{,}027 \text{ in}^3/\text{min} \times \frac{1 \text{ ft}^3}{1{,}728 \text{ in}^3}$$
$$= 2.91 \text{ ft}^3/\text{min}$$

51.2.1 Volumetric Efficiency

The actual volume of vapor pumped through a compressor is always less than the calculated theoretical volume. A compressor's ***volumetric efficiency*** is the actual volume of vapor pumped divided by the theoretical volume of the compressor cylinder. This value is then multiplied by 100 to obtain a percentage.

Formula for volumetric efficiency:

$$\text{Volumetric efficiency} = \frac{\text{Actual volume}}{\text{Theoretical volume}} \times 100$$

Example:

A compressor is designed to pump 10 in^3 of vapor each revolution. If it pumps only 6 in^3 each revolution, what is the volumetric efficiency of the compressor?

Solution:

$$\text{Volumetric efficiency} = \frac{\text{Actual volume}}{\text{Theoretical volume}} \times 100$$
$$= \frac{6 \text{ in}^3}{10 \text{ in}^3} \times 100$$
$$= 60\%$$

51.2.2 Factors Affecting Volumetric Efficiency

For efficient compressor operation, the volumetric efficiency must be as high as possible. Several conditions affect volumetric efficiency:

- Head pressure. The greater the head (high-side) pressure, the lower the volumetric efficiency. The compressed vapor in the clearance space (space

Copyright Goodheart-Willcox Co., Inc. 2017

within the cylinder when the piston is at top dead center) expands on the piston downstroke. The greater the head pressure, the greater the amount of vapor remaining in the cylinder and not being discharged.

- Low-side pressure. As low-side pressure decreases, so does volumetric efficiency. The lower pressure results in a lower amount of vapor in the cylinder for each stroke.
- Clearance space. The larger the clearance space, the lower the volumetric efficiency. A larger clearance space allows a greater amount of compressed vapor to remain in the cylinder.
- Valve openings. The size and condition of valve openings affect volumetric efficiency. The intake and exhaust valves offer restrictions to the vapor flow. If the intake valve reduces low-side vapor flow into the cylinder, the cylinder will not be completely filled and the efficiency will be lowered. If the exhaust valve sticks, the extra pressure generated in the cylinder will reduce the compressor's efficiency. A reduction in efficiency also occurs if the line from the compressor to the condenser is pinched or otherwise restricted.
- Compressor speed. The compressor piston travels so fast that it prevents the vapor from filling the cylinder chamber completely. Therefore, there are losses in efficiency. The pressure in the cylinder never gets as high as the pressure in the suction line during the suction stroke. The greater the speed of the compressor, the less vapor pumped per stroke.
- Compressor heat. The compressor runs at a warm temperature. Some of this heat warms the vapor as it enters the cylinder, causing the vapor to expand. This reduces the amount of vapor pulled into the cylinder.
- Leaking vapor. Some vapor may leak past the piston into the crankcase, resulting in a reduction in the amount of vapor being discharged by the compressor.

Small compressors used in domestic refrigeration have a bore and stroke of about 1 1/2″ (4 cm). Their volumetric efficiency varies between 40% and 75%, with 60% being an average value. Larger commercial compressors have volumetric efficiencies from 50% to 80%. The average value is 70%. A volumetric efficiency of 60% to 65% is common in air-cooled units.

51.3 Designing Piping

When designing piping for commercial refrigeration systems, technicians must take into account practical considerations. For example, refrigerant lines should be arranged so that they do not interfere with normal inspection or service. Do not run lines that obstruct the view of sight glasses or interfere with the removal of compressor components, such as cylinder heads and end bells. There should also be adequate clearance between refrigerant lines and walls for installing support hangers or insulation. Before sealing insulation around a refrigerant line, test the line's joints and fittings for leaks.

Commercial refrigeration systems have several different types of refrigerant lines, including the compressor discharge line, hot-gas bypass line, condenser condensate line, liquid line, and suction line. While these different lines are sized in a similar manner, the key sizing criteria vary based on the purpose of the line and the state of the refrigerant in it. The basic criteria that must be considered when sizing refrigerant lines include the following:

- Pressure drop.
- Refrigerant velocity.
- Oil circulation.

51.3.1 Pressure Drop

As fluid travels through a pipe, the pressure of the fluid decreases due to friction between the fluid and the walls of the pipe. This pressure drop occurs in refrigerant piping, in airflow through duct systems, and in water flow through plumbing systems.

In refrigeration systems, pressure drop in refrigerant lines should be kept to a minimum. This means that lines should be short and direct with as few fittings as possible. For most lines, the maximum allowable pressure drop is equal to a saturation temperature drop of 2°F (1°C). The actual amount of pressure drop (in psi or kPa) that is equal to a 2°F drop in saturation temperature varies based on the type of refrigerant.

For example, two different refrigeration systems operate at an evaporator saturation temperature of 20°F (–7°C), but one uses R-134a as a refrigerant and the other uses R-404A. The pressure of R-134a at 20°F is 18.4 psi (127 kPa), and its pressure at 18°F (–8°C) is 17.0 psi (117 kPa). Thus, a 2°F drop in saturation temperature from 20°F to 18°F is equal to a pressure drop of 1.4 psi (10 kPa) for R-134a. For R-404A, however, the pressure at 20°F is 56.8 psi (392 kPa), and the pressure at 18°F is 54.2 psi (374 kPa). This means that R-404A can have a 2.6 psi (18 kPa) pressure drop for the same 2°F drop in saturation temperature.

Pressure drop is affected by refrigerant line diameter, line length, and number and types of fittings used. Smaller lines have a greater pressure drop. If refrigerant lines are too small, they create excessive

Copyright Goodheart-Willcox Co., Inc. 2017

pressure drop and cause a reduction in system efficiency. Increasing the line size decreases the pressure drop.

The length of the refrigerant line also affects pressure drop. As the length of the line increases, the pressure drop increases. Each bend, fitting, and valve in the line causes additional pressure drop. Pressure drop due to fittings is usually expressed as an equivalent length of line. See **Figure 51-13**.

The equivalent length for each fitting and valve is added to the length of the line itself to find the line's ***total equivalent length***. When determining pressure drops by looking up line lengths in a sizing table, remember to determine the line's total equivalent length, not just the length of the line itself. Neglecting the values of the valves and fittings can result in improper refrigerant line sizing.

51.3.2 Refrigerant Velocity

The velocity of the refrigerant in the refrigerant lines is a significant concern when determining line sizes. The refrigerant velocity must be sufficient to ensure that oil is properly circulated throughout the system. If the refrigerant velocity is too low, excessive amounts of oil can be trapped in certain parts of the system.

The required minimum velocity for a refrigerant line depends on the size of the line, the type of refrigerant, and the temperature of the refrigerant. Some manufacturers provide a chart for determining refrigerant velocity based on these three variables. This chart can be used to find the refrigerant velocity in different types of refrigerant lines, such as the suction line, liquid line, and compressor discharge line, **Figure 51-14**.

For example, to use the chart in **Figure 51-14** to determine suction line velocity, start by finding the system's capacity at the top of the chart, which is 5.5 tons. Next, draw a vertical line down from 5.5 tons until it intersects with the line that corresponds with the system's evaporator temperature, which is –40°F (–40°C) in this example.

At the intersection of those two lines, draw a horizontal line across to the different tubing sizes on the left-hand side of the chart. After choosing one of the tubing sizes (5 1/8″ for example), draw a vertical line down from where the horizontal line and tubing size intersect. At the bottom of the chart, the vertical line intersects with a line indicating the refrigerant velocity for that tubing size. Thus, the chart shows that a 5 1/8″ suction line with an evaporator temperature of –40°F has a velocity of 730 fpm (feet per minute). If the velocity is too low or too high for a certain application, choose a different tubing size and draw a new line down to find the velocity for that size.

There is a tradeoff between pressure drop and refrigerant velocity. Larger lines cause less pressure drop, but they require a higher velocity to ensure that oil flows with the refrigerant. Likewise, low-temperature lines require higher velocities than high-temperature lines because oil is more viscous and flows less easily at lower temperatures. In general, commercial refrigeration systems should be designed with low refrigerant velocities to ensure efficient compressor performance and low operating costs.

Equivalent Length for Fittings and Valves (feet)

Nominal Size	Fittings				Valves		
	90° Std Elbow	45° Std Elbow	Tee (Branch Flow)	Tee (Through Flow)	Globe or Solenoid	Angle	Gate
1/2	1.4	0.7	2.7	0.9	17	6	0.6
7/8	2.0	0.9	4.0	1.4	22	9	0.9
1 5/8	4.0	2.1	8.0	2.6	43	18	1.8
2 1/8	5.0	2.6	10.0	3.3	84	35	3.2
3 1/8	7.5	4.0	15.0	5.0	84	35	3.2
4 1/8	10.0	5.2	21.0	6.7	120	47	4.5
6 1/8	16.0	7.9	30.0	10.0	170	70	7.0

Figure 51-14. Chart for systems using R-134a that can be used to find the refrigerant velocity in the liquid line, discharge line, and suction line based on different line sizes.

Copyright Goodheart-Willcox Co., Inc. 2017

The refrigerant velocity in both the suction line and the compressor discharge line ranges from 500 fpm to 3,000 fpm. Velocities greater than 3,000 fpm may cause noise problems or excessive pressure drop. Although refrigerant velocity varies widely based on the type of refrigerant, most suction lines and compressor discharge lines have a velocity around 700 fpm for horizontal runs and 1,500 fpm for vertical risers. In the liquid line, the refrigerant velocity ranges from 100 fpm to 300 fpm. The condenser condensate line should be sized for 100 fpm or less.

51.3.3 Oil Circulation

As a compressor operates, most of the lubricating oil remains in the compressor, but some oil mixes with the refrigerant and travels through the system. Since the oil in a refrigeration system serves no purpose other than to lubricate the compressor, an adequate refrigerant velocity is necessary to ensure that oil is returning to the compressor. If not enough oil is returned to the compressor, the following problems can occur:

- Seized or badly worn bearings due to overheating from a lack of lubrication.
- Broken valves, pistons, or connecting rods in the compressor.
- Compressor failure or destruction.

In addition to possibly destroying the compressor, inadequate oil return also reduces system capacity. Instead of returning to the compressor, lubricating oil becomes trapped in other parts of the system, such as in the evaporator and condenser coils. Excess oil in either the evaporator or condenser can coat the interior of the coil, acting as insulation and reducing the coil's ability to transfer heat. As a result of poor heat transfer, the temperature in the evaporator increases, which can cause the metering device to feed more liquid refrigerant into the evaporator. This can lead to liquid refrigerant entering the compressor, causing slugging and eventual compressor failure.

51.3.4 Condenser Condensate Line

In a commercial refrigeration system equipped with a liquid receiver, the ***condenser condensate line*** runs from the outlet of the condenser to the inlet of the liquid receiver. The condensate line should be kept as short as possible. The condenser condensate line should have a pressure drop of 0 psi and a velocity of 100 fpm or less. These two factors make it almost impossible to oversize the condenser condensate line. See **Figure 51-15**.

If the condenser condensate line is undersized or excessively long, it can restrict the flow of refrigerant into the receiver, causing some liquid refrigerant to be held in the condenser. Liquid refrigerant in the condenser reduces the condenser's available surface area for heat transfer. This leads to a decrease in condenser capacity, an increase in head pressure, and a reduction in the overall system capacity. In addition, the increased head pressure also forces the compressor to use more electrical power, which increases operating costs.

Condenser Condensate Line Sizes (R-410A)

System Capacity		Equivalent Line Length (ft)	
Btu/hr	Tons/hr	25	50
18,000	1.5	1/2	1/2
30,000	2.5	1/2	1/2
42,000	3.5	1/2	5/8
60,000	5.0	5/8	5/8
120,000	10.0	5/8	3/4
240,000	20.0	7/8	7/8
420,000	35.0	1 1/8	1 3/8
600,000	50.0	1 3/8	1 3/8

51.3.5 Liquid Line

The liquid line connects the liquid receiver to the metering device or the condenser to the metering device in a system without a liquid receiver. The most important factor in sizing the liquid line is minimizing the amount of pressure drop. Excessive pressure drop can cause insufficient liquid pressure at the metering device and flash gas formation in the liquid line, reducing system efficiency.

The refrigerant velocity in the liquid line is less important because oil and liquid refrigerant mix easily, which means lower velocities will not inhibit proper oil flow. Typically, the refrigerant velocity in the liquid line is between 100 fpm and 300 fpm.

The liquid line should be sized so that the pressure drop does not exceed a corresponding drop of 1°F to 2°F in saturation temperature. Excessive pressure

Copyright Goodheart-Willcox Co., Inc. 2017

drop in the liquid line can be caused by a line that is too small, is too long, or has too many fittings and valves, **Figure 51-16**.

In addition, vertical risers are also a source of pressure drop. In a riser, the liquid refrigerant at the top of the riser exerts force on the liquid refrigerant at the bottom of the riser. ***Static loss*** is the pressure drop that occurs from the bottom of a riser to the top due to the weight of liquid refrigerant in the line. In general, the static loss in a riser is approximately 0.5 psi per foot although the actual value varies based on the type of refrigerant. See **Figure 51-17**.

Liquid Line Sizes for Low-Temperature Systems (R-410A)

System Capacity		Equivalent Line Length (ft)	
Btu/hr	Tons/hr	25	50
18,000	1.5	5/8	3/4
30,000	2.5	3/4	7/8
42,000	3.5	7/8	1 1/8
60,000	5.0	1 1/8	1 1/8
120,000	10.0	1 3/8	1 5/8
240,000	20.0	1 5/8	2 1/8
420,000	35.0	2 1/8	2 5/8
600,000	50.0	2 5/8	2 5/8

Goodheart-Willcox Publisher

Figure 51-16. Example of a liquid line sizing chart. A technician must know the system capacity and the liquid line's total equivalent length to find the correct liquid line size. The sizes in the chart are valid for only the refrigerant listed.

To counteract excessive pressure drop in the liquid line, a technician should keep the liquid line as short as possible and avoid using vertical risers. If this cannot be avoided, a suction line-liquid line heat exchanger can be used to subcool refrigerant in the liquid line. Although a riser or an excessively long line causes pressure drop and decreases the refrigerant's saturation temperature, the additional subcooling provided by a heat exchanger helps keep the temperature of the liquid refrigerant below the saturation temperature, preventing the formation of flash gas. Subcooling is the only way to reduce the effect of excessive pressure drop.

Pro Tip

Liquid Line Insulation

The liquid line is usually not insulated unless it is exposed to extreme heat, such as in an attic or on a hot, metal roof. In these cases, insulating the liquid line helps prevent the high ambient temperature around the liquid line from transferring heat to refrigerant in the line. If the line absorbs too much heat, it can raise the temperature of the liquid refrigerant, causing it to evaporate and form flash gas.

51.3.6 Suction Line

The suction line runs from the evaporator outlet to the compressor inlet. A technician must consider both pressure drop and refrigerant velocity when sizing the suction line.

An excessive pressure drop in the suction line increases the refrigerant vapor volume and causes the compressor to operate at a lower suction pressure. This reduces the compressor's capacity and increases its power usage by forcing it to pump a higher volume of refrigerant vapor to maintain the desired temperature in the evaporator. As with the liquid line, the suction line should be

Pressure Drop in Risers

Refrigerant	Liquid Line Rise (ft)									
	10		20		30		50		100	
	psig	°F	psig	°F	psig	°F	psig	°F	psig	°F
R-22	4.8	1.6	9.7	3.1	14.5	4.7	24.2	8.0	48.4	16.5
R-134a	4.9	2.0	9.8	4.1	14.7	6.3	24.6	11.0	49.1	23.7
R-507, R-404A	4.1	1.1	8.2	2.1	12.2	3.3	20.4	5.6	40.8	11.8

Goodheart-Willcox Publisher

Copyright Goodheart-Willcox Co., Inc. 2017

sized so that the maximum pressure drop is equal to a saturation temperature drop of 2°F. See **Figure 51-18**.

Whereas liquid refrigerant mixes with lubricating oil and transports it with ease, refrigerant vapor is a poor carrier of oil. In addition, oil in the suction line is at a lower temperature than in the liquid line, making it more viscous. As a result, maintaining the proper refrigerant velocity in the suction line is critical to ensuring that oil is returned to the compressor.

For horizontal suction lines, the refrigerant velocity is normally between 500 fpm and 700 fpm, but for vertical risers, the velocity is about double (between 1,000 fpm and 1,500 fpm). These values, however, vary by refrigerant, so always follow equipment or refrigerant manufacturer recommendations. If there is ever a conflict between the suction line size needed to minimize pressure drop and the suction line size needed to ensure adequate velocity for oil return, use the suction line size that achieves the required minimum velocity.

The suction line should slope downward to the compressor about 1/4″ for every 10′ (6 mm for every 3 m). This permits oil drainage down the suction line to the compressor. If the suction line has any vertical risers, install traps at the base of each riser. An inverted trap can be installed at the top of the riser as well to prevent oil from flowing back down the riser when the system is not operating. These traps prevent a large slug of oil from returning to the compressor during system start-up, **Figure 51-19**.

In addition, a vertical riser should have a smaller diameter than a horizontal suction line. Since the required velocity for a vertical riser is greater, the smaller diameter helps maintain the minimum velocity required for oil return.

Some commercial refrigeration systems vary capacity by using multiple compressors or a single compressor with an internal unloader. In these types of systems, called modulating refrigeration systems, a single suction line may cause unacceptably high pressure drop or low refrigerant velocity. For example, if the suction line is sized for a light heat load, the line may produce excessive pressure drop at maximum load.

On the other hand, if the suction line is sized for the system's maximum heat load, the system may not produce enough vapor as the heat load decreases to maintain an adequate velocity for sufficient oil return. This occurs because as the heat load decreases, either one or more compressors stop pumping in a multiple-compressor system, or one or more cylinders stop pumping in a compressor capable of unloading cylinders.

One solution to suction line problems in a modulating refrigeration system is to use a double suction line. The two lines should be sized so that together they provide an acceptable refrigerant velocity and pressure drop at maximum load. One line should be larger than the other and be equipped with an oil trap. See **Figure 51-20**.

When the system is at full capacity, both suction lines carry the refrigerant vapor at an adequate velocity.

Suction Line Sizes for Low-Temperature Systems (R-410A)

System Capacity		Equivalent Line Length (ft)	
Btu/hr	Tons/hr	25	50
18,000	1.5	5/8	3/4
30,000	2.5	3/4	7/8
42,000	3.5	7/8	1 1/8
60,000	5.0	1 1/8	1 1/8
120,000	10.0	1 3/8	1 5/8
240,000	20.0	1 5/8	2 1/8

Goodheart-Willcox Publisher

Figure 51-20. A double suction line used in a modulating refrigeration system to prevent high pressure drop or low refrigerant velocity.

As the load decreases and the compressor capacity is reduced (or one compressor stops pumping in a multiple-compressor system), the vapor velocity slows. The oil trap in the larger suction line fills with oil, preventing refrigerant from flowing through that line.

As a result, the refrigerant vapor flows through the smaller suction line, which should be sized to provide adequate velocity to carry oil back to the compressor under light load conditions. When the system returns to operating at full capacity, the increased vapor velocity pushes the oil in the larger suction line back to the compressor, allowing refrigerant to flow through both suction lines again.

51.3.7 Compressor Discharge Line

The compressor discharge line carries high-pressure vapor refrigerant from the compressor outlet to the condenser inlet. This line is also called the hot gas line. A hot-gas bypass line may also be connected to the compressor discharge line. The hot-gas bypass line connects the compressor discharge line to the suction line or the evaporator (if for defrosting). High-temperature refrigerant vapor from the discharge line is fed into the evaporator through the hot-gas bypass line to defrost the evaporator. Hot gas can also be fed into the suction line for low-load capacity control.

Refrigerant velocities in the compressor discharge line are similar to the velocities in the suction line. Velocities of 500 fpm to 700 fpm in horizontal runs and 1,000 fpm to 1,500 fpm in risers are common. Refrigerant velocity in the hot-gas bypass line is generally greater, in the range of 1,000 fpm to 2,000 fpm.

Pressure drop is generally not a primary concern in the compressor discharge line. However, maintaining a 2°F maximum pressure drop is still recommended. An example of a chart used for selecting compressor discharge size is shown in **Figure 51-21**.

When compressor discharge vapor is piped to a remote condenser, the condenser may become warmer than the compressor during the Off cycle. When this happens, the temperature difference can create a pressure difference that causes refrigerant vapor to move

Compressor Discharge Line Sizes (R-410A)

System Capacity		Equivalent Line Length (ft)	
Btu/hr	Tons/hr	25	50
18,000	1.5	1/2	1/2
30,000	2.5	1/2	5/8
42,000	3.5	5/8	5/8

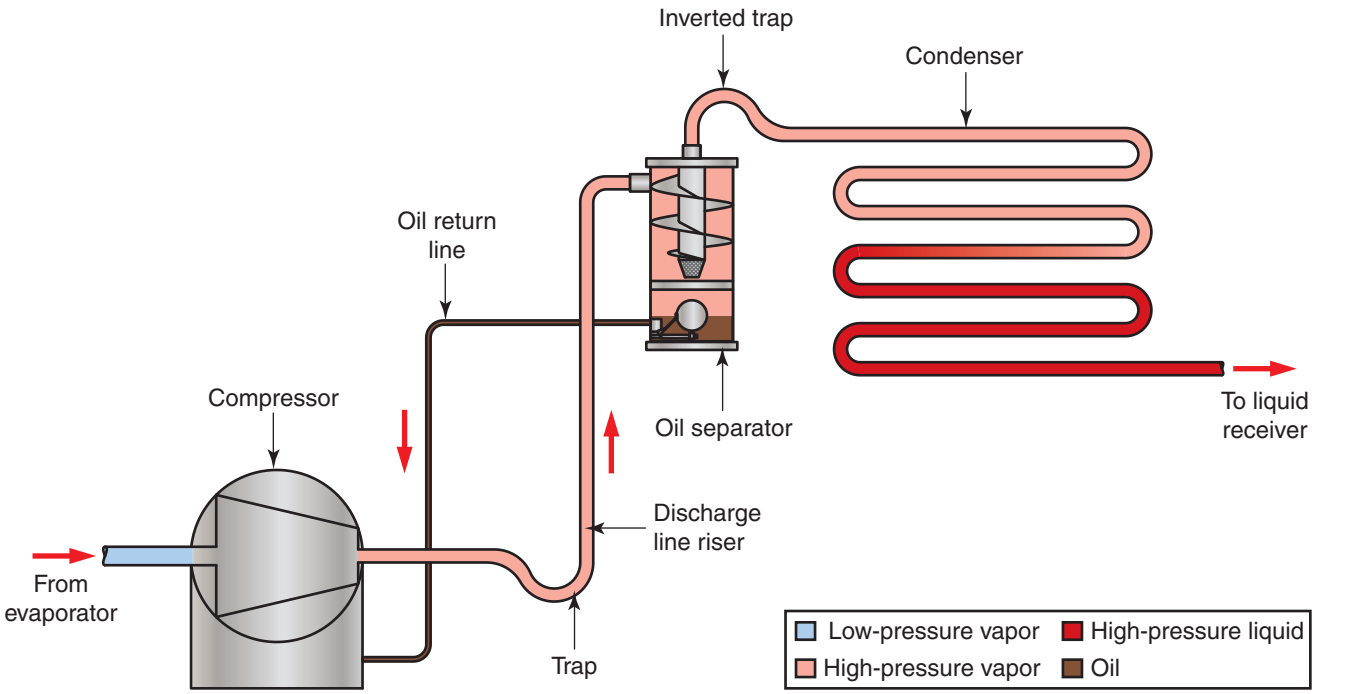
back from the condenser and condense in the head of a reciprocating compressor.

If the compressor discharge valves leak, liquid refrigerant will collect in the cylinders. This could cause the compressor to pump liquid refrigerant on start-up, which would reduce lubrication of the pistons and valves and could even break them. If the compressor valves do not leak, the collection of liquid refrigerant in the cylinder head may still cause damage when the compressor starts up. This is due to the dynamic hydraulic pressure on the compressor head and piping.

A primary concern of compressor discharge line design and installation is ensuring that liquid refrigerant and oil do not flow back into the compressor during the Off cycle. The compressor discharge line should be sloped toward the condenser a minimum of 1/4″ per 10′ of run. This slope ensures that any liquid in the line will flow away from the compressor. In some systems, a check valve is installed in the discharge line near the condenser to protect the compressor by preventing Off-cycle backflow.

Discharge lines rising from compressors to remote condensers must also have an oil trap. The trap keeps oil from returning by gravity to fill the space above the discharge valves of the compressor during the Off cycle.

Some systems include an oil separator in the compressor discharge line. An oil separator removes much of the oil from the vapor refrigerant. The collected oil flows back into the compressor crankcase. Oil separators are commonly used when the compressor discharge line includes a riser. See **Figure 51-22**.



Goodheart-Willcox Publisher

Chapter Review

Summary

- A commercial refrigeration system's total heat load determines how much cooling capacity the system must have. The compressor's capacity must be sufficient to move enough refrigerant through the system to remove the total heat load within its operating cycle.
- A compressor's operating cycle is the number of hours that it operates per day. The operating cycle is partly based on evaporator defrosting requirements. Once the operating cycle is determined, the compressor's required capacity can be calculated by dividing the total heat load (Btu/day) by the operating cycle (hr/day).
- Factors that affect compressor sizing include suction line temperature, condensing temperature, and the relative humidity of the conditioned space. The relative humidity is selected based on the product being refrigerated. After calculating the suction line temperature and condensing temperature, a technician uses tables from compressor manufacturers to find a compressor with the right capacity.
- A condenser is sized based on the total heat of rejection (THR). THR comprises the total heat load for the system and the energy added to the refrigerant by the compressor. Once the THR is estimated, the condenser is selected based on capacities provided in manufacturer tables.
- Manufacturer tables are used to match the capacity of the evaporator to the capacity of the compressor. Factors that affect heat transfer in both the evaporator and condenser include surface area and temperature difference (TD).
- A compressor's theoretical volume is calculated by multiplying the surface area of the piston head ($\pi D^2/4$) by the length of stroke, number of cylinders, and revolutions per minute. A compressor's volumetric efficiency is the actual volume of vapor pumped divided by the theoretical volume and multiplied by 100 to obtain a percentage.
- The basic criteria that must be considered when sizing refrigerant lines are pressure drop, refrigerant velocity, and oil circulation. Pressure drop is affected by refrigerant line diameter, line length, and fittings. A line's total equivalent length is the length of the line itself plus the equivalent length for each fitting and valve in the line.
- The type of refrigerant line determines which sizing criteria are more important. In the condenser condensate line and liquid line, minimizing pressure drop is the most important factor because excessive pressure drop causes flash gas formation. In the suction line, refrigerant velocity is the most important factor because the proper velocity is critical to ensuring that oil is returned to the compressor.

Review Questions

Answer the following questions using the information in this chapter.

1. Total heat load represents the amount of heat that a commercial refrigeration system must remove in a _____ period.
   A. 1-hour
   B. 6-hour
   C. 12-hour
   D. 24-hour
2. Once the relative humidity of a conditioned space is selected based on the product being refrigerated, the _____ can be determined.
   A. condensing temperature
   B. temperature difference
   C. theoretical compressor volume
   D. volumetric efficiency
3. If a commercial refrigeration system's total heat load is 200,000 Btu/day and its operating cycle is 18 hours, what is the required compressor capacity in tons?
   A. 0.93 tons
   B. 16.7 tons
   C. 300 tons
   D. 11,111 tons
4. What is the condensing temperature of an air-cooled condenser with a TD of 25°F (14°C) and an ambient temperature of 85°F (29°C)?
   A. 60°F (16°C)
   B. 100°F (38°C)
   C. 110°F (43°C)
   D. 120°F (49°C)
5. If a hermetic compressor has a capacity of 18,000 Btu/hr, what is the estimated total heat of rejection (THR)?
   A. 13,846 Btu/hr
   B. 14,400 Btu/hr
   C. 22,500 Btu/hr
   D. 23,400 Btu/hr

Copyright Goodheart-Willcox Co., Inc. 2017

6. Which of the following factors affects an evaporator's ability to absorb heat?
   A. Surface area
   B. Thickness of material
   C. Temperature difference (TD)
   D. All of the above.
7. The heat transfer rate for a forced-draft evaporator is approximately _____.
   A. 3 Btu/hr·ft^2·°F
   B. 8 Btu/hr·ft^2·°F
   C. 15 Btu/hr·ft^2·°F
   D. 25 Btu/hr·ft^2·°F
8. Liquid receivers should be 15% larger than the system's _____.
   A. accumulator volume
   B. condenser volume
   C. evaporator volume
   D. total liquid volume
9. What is the theoretical compressor volume in cubic feet per minute of a four-cylinder compressor with a 3″ bore, a 2″ stroke, and a speed of 1,200 rpm?
   A. 39.26 ft^3/min
   B. 42.39 ft^3/min
   C. 69.80 ft^3/min
   D. 67,824 ft^3/min
10. As high-side pressure increases, volumetric efficiency _____.
    A. decreases
    B. doubles
    C. increases
    D. stays the same
11. For most refrigerant lines, the maximum allowable pressure drop is equal to a saturation temperature drop of _____.
    A. 2°F (1°C)
    B. 4°F (2°C)
    C. 6°F (3°C)
    D. 8°F (4°C)
12. The required minimum velocity for a refrigerant line depends on the _____.
    A. line size
    B. type of refrigerant
    C. temperature of the refrigerant
    D. All of the above.
13. The refrigerant velocity in the liquid line is typically _____.
    A. less than 100 fpm
    B. between 100 fpm and 300 fpm
    C. between 300 fpm and 500 fpm
    D. greater than 500 fpm
14. If a suction line has any vertical risers, a(n) _____ should be installed at the base of each riser.
    A. double suction line
    B. filter-drier
    C. oil separator
    D. trap
15. The compressor discharge line should slope toward the condenser a minimum of _____ per 10′.
    A. 1/4″
    B. 1/2″
    C. 6″
    D. 12″

Learning Objectives

Information in this chapter will enable you to:

- Summarize some of the basic regulations found in most codes.
- Identify procedures for locating and mounting condensing units and evaporators.
- Determine where to mount thermostatic expansion valve sensing bulbs based on suction line tubing size.
- Install various components, such as valves, filter-driers, and sight glasses, along refrigerant lines.
- Properly mount and install open-drive compressor motors and also hermetic compressors.
- Test a refrigeration installation for leaks by using leak detection devices, a standing pressure test, and a standing vacuum test.
- Charge a system with refrigerant using either the low-side method or the high-side method.
- Start a multiple-evaporator system under a full heat load without overloading the compressor.

low-side charging

Review of Key Concepts

Reviewing these concepts from earlier chapters will help you understand new concepts presented in this chapter:

- There are two basic types of commercial systems: packaged and split. Packaged systems arrive ready for installation fully wired, charged, and tested. The components of split systems are purchased separately and assembled at the jobsite. (Chapter 49)
- Motor specifications (such as rated voltage, full-load amperage, frequency, and phase) can be found on the motor nameplate, which is mounted on the outside of the motor frame. (Chapter 15)
- There are two primary methods for pressurizing a refrigeration system to test for leaks. One method involves charging the system with an inert gas. The second method, used if the leak cannot be found with just an inert gas, involves evacuating the system and charging it with an inert gas and a trace amount of the system's specified refrigerant. (Chapter 11)
- Refrigerant can be charged into a system in either vapor or liquid form. Liquid charging is quicker, but it presents some serious risks because liquid refrigerant can cause slugging in the compressor. (Chapter 11)
- A pressure motor control is used to regulate the compressor motor based on pressure in the evaporator. It is mounted on the suction side of the compressor to monitor evaporator suction pressure. (Chapter 16)
- A hot pull down is when a system cycles on with the conditioned space temperature being pulled down to normal operating temperature from much higher starting temperature (generally ambient temperature). A refrigeration system needs time for the compressor to remove the bulk of the heat load and drop temperature and pressure to normal levels. (Chapter 19)

Introduction

Installing commercial refrigeration equipment is a major part of the HVACR industry. Regulating bodies and authorities inspect and examine installations for proper workmanship, safety concerns, and code-required practices. Commercial installation codes are very strict to ensure the safety of the building occupants at all times. Improper installations can lead to equipment failure, which can result in companies losing valuable work time and refrigerated or frozen products.

Copyright Goodheart-Willcox Co., Inc. 2017

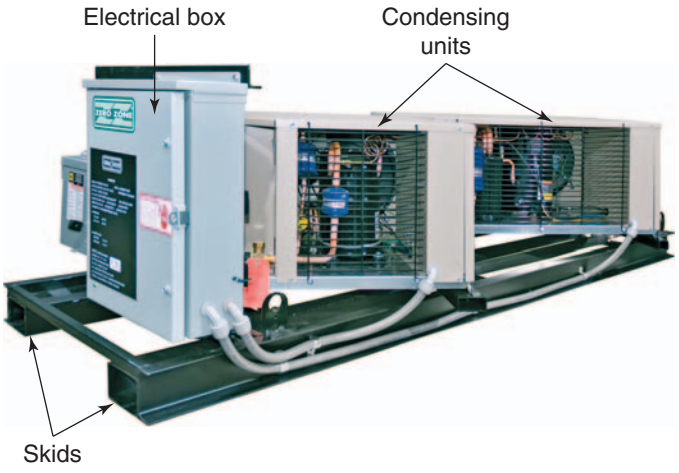
52.1 Types of Commercial Installations

Commercial refrigeration installations vary considerably—from a small refrigerated vending machine found in a convenience store to multiple refrigerated display cases found in a large grocery store. Installations are broadly classified in one of two groups: packaged systems and split systems. Sometimes split systems are referred to as field-erected systems. Split systems can have a single refrigerated cabinet or multiple cabinets at different temperatures.

Commercial refrigeration systems must be installed properly to handle the refrigeration load efficiently. Always take into consideration the products being refrigerated and the duty cycle of the system. Although some jobs may simply be the installation of a replacement cooler or a new refrigerated display case, a technician should make sure that the location of the new unit is correct and that the new unit is large enough to handle the heat load.

Commercial operations, such as restaurants and grocers, often change the layout of their refrigerated space without considering if the old system can satisfy the demand of the new layout. For example, a heat source, such as a stove or range, may have been installed next to the condensing unit. Walls may have been added that restrict condenser airflow, or a window may have been installed directly in front of a refrigerated display case, resulting in an increased solar load.

An installation must also be done in such a way as to eliminate hazardous conditions that might lead to accidents. Electrical conduit and refrigerant lines should be routed to ensure they are not damaged by employees moving stock. Condensate drain lines must be secure and leakproof to prevent tripping hazards. Two guiding principles of installation are durability and neatness, which help to minimize future dangers.



Zero Zone, Inc.

Figure 52-1. Some commercial refrigeration condensing units come mounted on skids, making it easier to move them to the installation location.

Commercial Refrigeration Installations

Commercial refrigeration installations typically progress in the following order:

1. Position and secure the refrigerated cabinets. Heavy and large pieces of equipment may be delivered by truck to the jobsite, **Figure 52-1**. Dollies or other moving devices may be needed to locate the equipment.
2. Identify the best place for the condensing unit and install it.
3. Install the evaporators in the refrigerated cabinets.
4. Install all the valves and controls.
5. Install refrigerant lines and any other tubing, such as condensate drain lines.
6. Pressurize the system with dry nitrogen and check for leaks using a bubble solution or an ultrasonic leak detector.
7. If no leak is found, perform a standing pressure test by leaving the nitrogen under pressure in the system for 24 hours. If the pressure in the system drops, the system has a leak.
8. If the leak cannot be found with a bubble solution or an ultrasonic leak detector, evacuate the system and charge it with a small amount of refrigerant (to 10 psig) and then finish pressurizing the system with nitrogen.
9. Leak test using an electronic leak detector. Once the leak is found, vent the refrigerant-nitrogen mixture and evacuate the system. (This venting is allowed per EPA Section 608 regulations.)
10. Repair the leak and then pressurize the system with dry nitrogen to check for leaks again.
11. If the system is free of leaks, evacuate it to the proper level before charging it with refrigerant.
12. Start the system.
13. Check the operation of the system and get a 24-hour temperature and pressure record of the system in operation.

Copyright Goodheart-Willcox Co., Inc. 2017

52.2 Codes and Standards

Most refrigeration equipment manufacturers provide guidelines for installing their equipment. Furthermore, many municipalities have laws and codes covering the installation of certain refrigeration systems. Domestic systems and some other small-capacity, self-contained systems are usually not included. This is because these systems are inspected and certified by the manufacturer prior to shipping to the customer. Some cities and rural communities, however, are not restricted by any codes. Where there is no local code, the code of the nearest city should be followed.

Compared to domestic systems, commercial refrigeration systems typically require a significant amount of custom work when delivered to the jobsite. For instance, the condensing unit may be mounted on the roof or placed in a remote area of the building. In addition, refrigerant lines need to be run between the condensing unit and the evaporator unit, and electrical connections need to be made to power and control the units. The system then needs to be charged with refrigerant and tested for proper operation. Codes help ensure uniform performance and safe installations. Codes also protect the customer from careless installations.

The local codes in most cities, towns, or counties are established to ensure conformity to national codes and standards. Local codes regarding commercial refrigeration installations are typically adopted from the standards developed by the American Society of Heating, Refrigerating and Air-Conditioning Engineers (ASHRAE). In addition, nearly all local codes adopt the National Electrical Code® (NEC), which is applicable to the installation of any wiring and electrical equipment for a commercial refrigeration system. Other codes often referenced include the International Mechanical Code (IMC) and the International Plumbing Code (IPC) for systems using water.

In many instances, municipalities adopt only some international codes and ASHRAE standards or modify them based on local conditions. For example, a county in California may establish a code requiring specific mounting of refrigerant lines to protect against earthquakes, which is not applicable in Florida.

An HVACR technician must be knowledgeable of all applicable national and local codes. The following are some points found in most codes:

- Only licensed refrigeration contractors may install commercial equipment.
- A permit must be obtained for each installation.
- Each installation must be inspected by local authorities.
- Lines must be labeled to identify the refrigerant used.
- Certain safety devices must be installed in the system.
- The condensing unit must be installed in a safe place.
- Electrical and plumbing work must conform to code and be done by licensed electricians and plumbers.
- Systems must be tested under pressure on both the high side and the low side and be free of leaks.

Codes should be carefully followed in order to ensure safety for the installer, owner, user, and public. Most municipalities require that permits be obtained before an installation can be made. They may also require that the company performing work show proof of insurance prior to granting a permit to work on a job. A code enforcement officer issues the permit prior to the installation and conducts an inspection upon completion of the job.

Oftentimes, a permit is also needed before performing a major service operation on a commercial system. Specifications of the proposed job must be presented, and permits are not issued unless the specifications presented meet code requirements. Failure to secure proper permits and inspections for an installation may result in fines and possible loss of the technician's license.

52.3 Installing Condensing Units

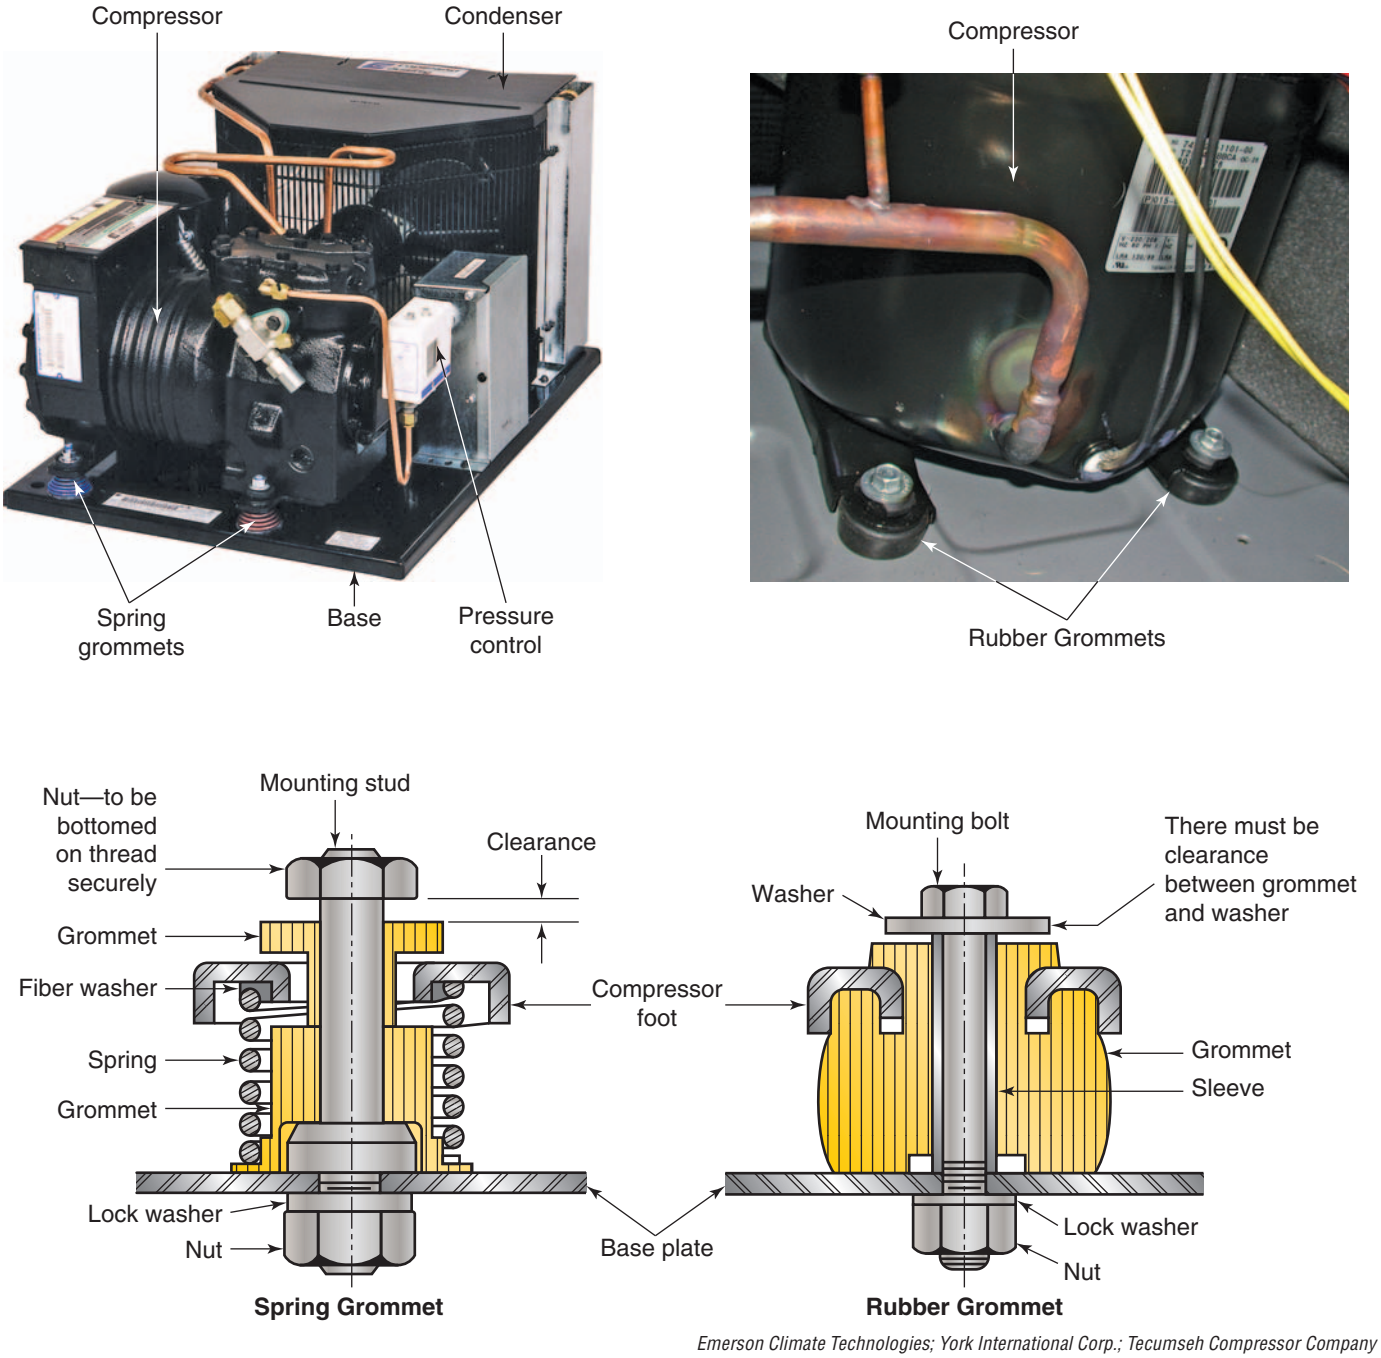
The first step in installing a condensing unit is determining where it should be placed. Ideally, the condensing unit is located as close to the conditioned space as possible. A central location is best, such as in a basement or on the roof, just above the conditioned space. The condensing unit may also be placed in a separate, well-ventilated room next to the room containing the conditioned space. If possible, avoid placing the condensing unit where it can be exposed to heat sources (such as near steam pipes, hot air grilles, and in the sun) or to low or freezing temperatures. Locating a condensing unit in the same room as the conditioned space is not recommended because of the heat and noise produced by the condensing unit.

When placed indoors, the temperature of the room containing the condensing unit should be monitored during warm ambient conditions to ensure that the compressor does not overheat. A high ambient temperature produces higher head pressure and less efficient operation. Often, a fresh air intake must be installed to obtain optimum

Copyright Goodheart-Willcox Co., Inc. 2017

room temperature in a condensing unit room. This intake also permits refrigerant to escape to outdoors in case the unit develops a leak. If the room has no ventilation, refrigerant accumulation can create a life-threatening hazard by displacing oxygen in the room. Screens should be secured over any ventilation openings to prevent insects, rodents, and other objects from entering.

Running compressors may produce some vibration. **Figure 52-2** shows two common types of compressor mounting grommets used to absorb vibrations. Condensing units must be electrically grounded, and there should be proper floor drainage in the event of a flood. A technician should also install a valve and accessory board on a wall just above the condensing unit. This board can be used



Emerson Climate Technologies; York International Corp.; Tecumseh Compressor Company

Figure 52-2. Both rubber grommets and spring grommets physically isolate the compressor from the rest of the condensing unit, preventing vibrations from being transferred to other system components.

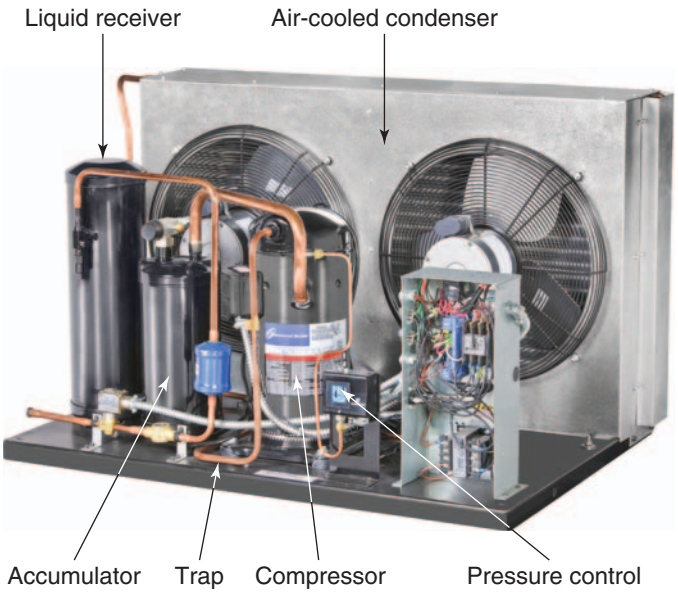
Copyright Goodheart-Willcox Co., Inc. 2017

to mount valves, filter-driers, motor controls, electrical boxes, and service instruction cards.

If required, a protective cage should be placed around condensing units. The cage ensures that only service technicians have access to the condensing equipment. It also establishes a safe area around the condensing unit so that regular employees cannot come in contact with the unit. Larger units must also be protected from fire damage with fire-resistant, self-closing doors. Locks should be placed on all doors to a condensing unit room, and instructions for proper entry should be posted near the lock.

In some cases, a system's condensing unit is installed away from the compressor. In these instances, traps are used in the compressor discharge line. The traps keep the oil in the condenser and away from the compressor's discharge valve, **Figure 52-3**. Discharge lines should also be slanted downward away from the compressor and toward the condenser.

Most municipal codes include restrictions on the condensing unit's noise level and requirements for placing the condensing unit a certain distance from property lines. Some 1 hp to 5 hp condensing units can be converted from indoor to outdoor installations by adding a shroud from the manufacturer. These condensing units can be used with most coolers and freezers regardless of the refrigerated cabinet's location. Conversion for outside installation may also require the addition of crankcase heaters and insulation for cold climates.



Emerson Climate Technologies

Figure 52-3. Even though the compressor and condenser are mounted together on this condensing unit, a trap is used to prevent oil from flowing backward into the compressor.

To prevent damage to the condensing unit or an explosion due to excessive pressure, most codes require the installation of the following safety devices:

- Pressure control—stops compressor motor operation under excessively high pressure.
- Spring-loaded relief valve or rupture disc—dissipates refrigerant under excessively high pressure.
- Fusible plug—used where the unit may become overheated due to fire.

All refrigerant lines should have labels identifying the refrigerant in the system. Install the condensing unit so that all parts are accessible for maintenance and service. Water lines connected to a condensing unit are either soft copper tubing or flexible plastic pipe. Allow enough piping to permit some movement of the condensing unit.

New condensing units use shipping blocks to protect various components during transport. The shipping blocks must be removed before the unit can be installed. Spin any fan or other moving parts by hand to make sure they can move freely prior to turning on.

52.3.1 Installing Air-Cooled Condensers

When installing air-cooled condensers, always protect the condenser fins and condenser tubing, including return bends. Mount the condenser securely in its frame and install it as level as possible. Connect the condenser to the compressor and the liquid receiver, if used.

Flared fittings should be carefully aligned, so they are not under tension or forced in any way. If the fittings are out of line or under strain, the threads on the fittings or the flare may be damaged. Brazed connections must also be carefully aligned before brazing.

Before assembling a brazed connection, a technician should clean the surface to be brazed using a wire brush, clean steel wool, or dry sandpaper. Flux should be put on the outside of the male part only. The joint should be supported during the brazing operation. For instructions on brazing, see Chapter 8, *Working with Tubing and Piping*. Use metal sheets as shields to protect other parts of the condensing unit by blocking them from the brazing flame.

52.3.2 Installing Water-Cooled Condensers

Installation of a water-cooled condenser is similar to installation of an air-cooled unit. The condenser mounting and joint brazing should be done with the same care. All parts should be cleaned before

Copyright Goodheart-Willcox Co., Inc. 2017

assembly. Be sure to test the water lines for leaks after the unit has run for a few hours to permit the condensing temperature to reach its peak. Check that the water flow is sufficient to effectively cool the condenser. Closely monitor the head pressure to make sure the unit is operating within the manufacturer's specifications.

Code Alert

Water Connections

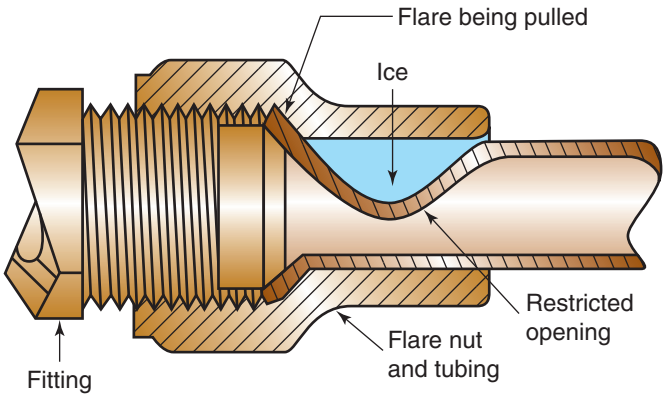
Article 1101.4 of the International Mechanical Code (IMC) states that any water supply and discharge connections associated with a refrigeration system must made in accordance with the International Plumbing Code (IPC).

52.4 Installing Expansion Valves

In commercial refrigeration installations, expansion valves are often attached to an evaporator using brazed or flared connections. The flare nut in such an installation must be sealed from moisture. Sealing is done after the installation is made and before the system starts to operate.

If a flare nut is not sealed, ice may form between the nut and the tubing. See **Figure 52-4**. In a short time, ice can cause the tube to collapse or break. This condition can also occur where the suction line fastens to the evaporator. Other methods, such as a rubber seal at the end of the flare nut, have also been devised to stop moisture from collecting between the nut and the tubing.

Although the best type of connection is a brazed connection, it may not be possible to fit a torch into all areas to be brazed, or brazing may cause adjacent components to overheat and malfunction. Flared connections are used primarily where access to the evaporator and expansion valve is limited. Short-shank flare nuts should be used in places where frosting occurs.



Goodheart-Willcox Publisher

Figure 52-4. Ice formation between the flare nut and tubing pinches the tubing and restricts the flow of refrigerant.

52.4.1 Installing Thermostatic Expansion Valves in Multiple-Evaporator Systems

In multiple-evaporator systems, install thermostatic expansion valves (TXVs) along with individual solenoid valves in the liquid lines to each evaporator. The solenoid valves allow each evaporator to be isolated from the rest of the system. When demand for a specific evaporator is low, the solenoid valve closes to stop refrigerant flow to that evaporator.

The compressor is then required to provide refrigerant only to the other operating evaporators. In a system with a variable capacity compressor, the compressor may use an unloader to reduce its capacity when the heat load is low. This permits a single condensing unit to efficiently serve numerous evaporators that may be operated at various temperatures. Other methods of modulating refrigeration capacity are available.

Although adjustments to the TXVs can make slight changes to an evaporator's temperature, evaporator pressure regulators (EPRs) are installed to maintain temperature differences between evaporators. The evaporator operating at the lowest temperature does not have an EPR, but evaporators operating at higher temperatures do. The EPR closes when pressure in the suction line drops below a set level, maintain a higher pressure (and thus, temperature) in the evaporator.

52.4.2 Installing Thermostatic Expansion Valve Sensing Bulbs

The location and attachment of a TXV's sensing bulb onto a suction line influences how the sensing bulb senses the refrigerant. How a sensing bulb senses refrigerant affects how a TXV adjusts refrigerant flow from the liquid line into the evaporator. Proper sensing bulb placement is necessary for proper TXV operation. A misplaced or poorly positioned sensing bulb can cause a TXV to respond incorrectly and result in an evaporator with the wrong temperature.

The location and position of a TXV sensing bulb on the suction line depends on the tubing size. The best way of determining where to mount sensing bulbs is to imagine looking head-on at a horizontal run of suction line tubing at eye level. Next, imagine the face of a clock inside the tubing. Based on the size of the suction line tubing, sensing bulbs are mounted at positions aligning with different hour hand positions, **Figure 52-5**.

Copyright Goodheart-Willcox Co., Inc. 2017

Mounting TXV Sensing Bulbs

Tubing Size	Sensing Bulb Position	
< 3/4"	Eleven o'clock	One o'clock
3/4"–7/8"	Ten o'clock 	Two o'clock > 7/8"	Eight o'clock 	Four o'clock 
Goodheart-Willcox Publisher

Figure 52-5. For tubing smaller than 3/4″, sensing bulbs are mounted at eleven o'clock or one o'clock. For tubing between 3/4″ and 7/8″, sensing bulbs are mounted at ten o'clock or two o'clock. For tubing over 7/8″, sensing bulbs are mounted at eight o'clock or four o'clock.

Pro Tip

Sensing Bulb Placement

Never mount a sensing bulb on the bottom of a tube or near a bend or turn of tubing. Collected oil at the bottom of the tubing may cause the sensing bulb to function incorrectly. Always clean the part of the suction line tubing where the sensing bulb is being placed by using a fine grit emery cloth. Make sure the entire length of the sensing bulb is in contact with the tubing.

Sensing bulb mounting straps should be made of some type of material that conducts heat well, so heat will be transferred across the surface of the entire sensing bulb and not just the part that is in direct contact with the tubing. The sensing bulb needs to react to the refrigerant in the system and not to hot or cold ambient air.

In many cases, ambient air may offset the reaction of a sensing bulb. To avoid this problem, wrap the sensing bulb in self-adhesive elastomeric foam tape. In areas where the ambient air may dip below freezing, the foam tape prevents ice or frost from forming between the sensing bulb and the tubing. Any ice or frost can insulate the sensing bulb from the tubing, inhibiting heat transfer and further offsetting the reaction of the TXV.

Caution

Sensing Bulb Mounting Straps

Do not use plastic straps to mount a sensing bulb to tubing. The temperature changes and wear will eventually break the straps. Using the proper strap will avoid needless system downtime and service calls.

52.5 Installing Evaporators

Evaporators for commercial refrigeration systems should be carefully mounted, delicately leveled, and firmly fastened. HVACR technicians should know the principles of air circulation and the proper direction of evaporator airflow. For more information on evaporators and their airflow, see Chapter 21, *Heat Exchangers* and Chapter 47, *Overview of Commercial Refrigeration Systems*.

Pro Tip

Moving Cabinets

Refrigerated cabinets are bulky and sometimes difficult to handle. A dolly is handy for cabinet moving. Moving equipment may also be useful when moving condensing units.

52.5.1 Evaporator Mounting

Different evaporators use different mounting methods. Evaporators in refrigerated display cases are usually mounted on stands or brackets. These stands or brackets are adjustable to allow the technician to level the evaporator in all directions. Evaporators in florist cabinets and walk-in cabinets are typically fastened with hangers to the ceiling, **Figure 52-6**.

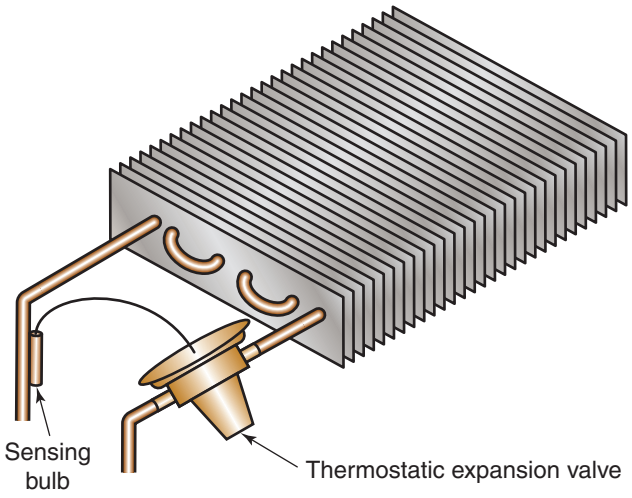
U.S. Cooler Company

Figure 52-6. Forced-draft evaporators mounted to the ceiling of a walk-in cabinet in a grocery store.

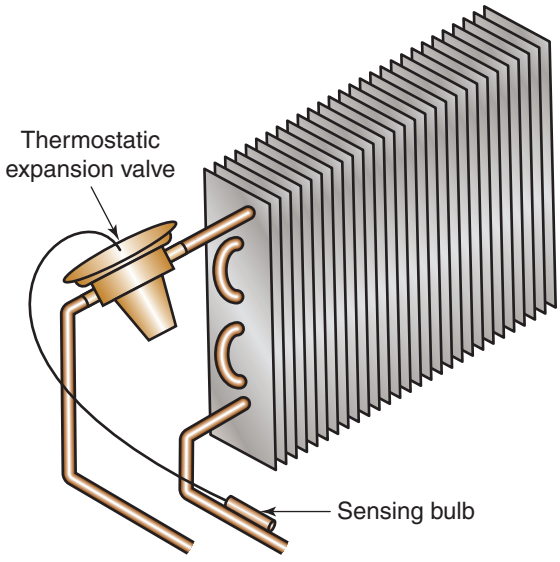
Copyright Goodheart-Willcox Co., Inc. 2017

To attach the hangers to the ceiling of the cabinet, use a cardboard template and a plumb line to accurately align and mark the placement of the hangers. Hydraulic or pneumatic platforms can be used to lift the evaporator into place and hold it until it can be fastened. Each evaporator should be carefully checked after mounting to make sure it is level.

If an evaporator is mounted vertically, the evaporator outlet should always be below the inlet. This allows for proper oil return to the compressor. It also means that the coldest fins will be at the top where they contact the warmest air, which improves the rate of heat transfer. Sometimes, an evaporator is mounted horizontally. In either case, be mindful of how the TXV and sensing bulb are installed, **Figure 52-7**.



Horizontal Evaporator



Vertical Evaporator

Goodheart-Willcox Publisher

Figure 52-7. Recommended expansion valve and sensing bulb mounting locations for two different evaporator installations.

Caution

Evaporator Grounding

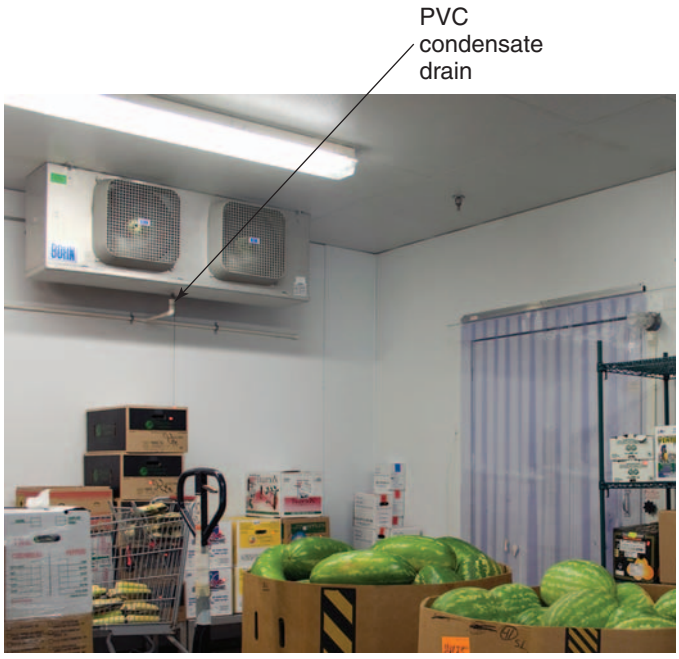
Evaporators must be electrically grounded if they have a motor and fan.

52.5.2 Installing Evaporator Condensate Tubing

Commercial evaporators produce large amounts of condensate. Use straight tubing runs and tubing with an adequate diameter (as recommended by the manufacturer) to provide for sufficient condensate flow from the evaporator drain pan. Flexible plastic tubing may be used on low-volume condensate drains. Hard PVC is often used on larger commercial evaporators, which produce greater volumes of condensate flow, **Figure 52-8**.

52.5.3 Installing Evaporator Pressure Regulators

Evaporator pressure regulators (EPRs) should be installed at the outlets of warmer-temperature evaporators in multiple-evaporator systems. EPR operation is usually not affected by the distance from the evaporator. However, an EPR should be connected between an evaporator's outlet and the suction line manifold.



U.S. Cooler Company

Figure 52-8. A large forced-air evaporator with a PVC drain connection in a refrigerated grocery storage room.

Copyright Goodheart-Willcox Co., Inc. 2017

A multiple-evaporator installation should also have a check valve, not an EPR, between the outlet of the coldest evaporator and the suction line. This prevents higher pressure gases from backflowing into the coldest evaporator during the Off cycle and warming it. Also, an accumulator should be mounted in or near the condensing unit between the main suction line and the compressor. This cuts down on low-side pressure fluctuations.

52.6 Installing Refrigerant Lines

For commercial refrigeration installations, most local codes require the refrigerant lines to be made of hard-drawn air conditioning and refrigeration (ACR) tubing. Hard-drawn ACR tubing is required to ensure that runs are straight and stable. Although soft ACR tubing is permissible at the condenser end of the lines, even these short lengths should be eliminated wherever possible. This reduces the potential for leaks since soft ACR tubing flexes at flared joints.

Hard-drawn ACR tubing used in commercial refrigeration is usually Type K (heavy wall) although Type L (medium wall) can be used in some applications. Some codes recommend a wall thickness of at least 0.065" where the tubing is exposed. Hard-drawn ACR tubing comes in straight lengths of 10' or 20' rather than in coils. In smaller commercial installations, 1/4" tubing is used for the liquid line, and 1/2" tubing is used for the suction line. Larger commercial refrigeration systems may have lines as large as 6". For more information on how to size refrigerant lines correctly, see Chapter 51, *Commercial Refrigeration Component Selection*.

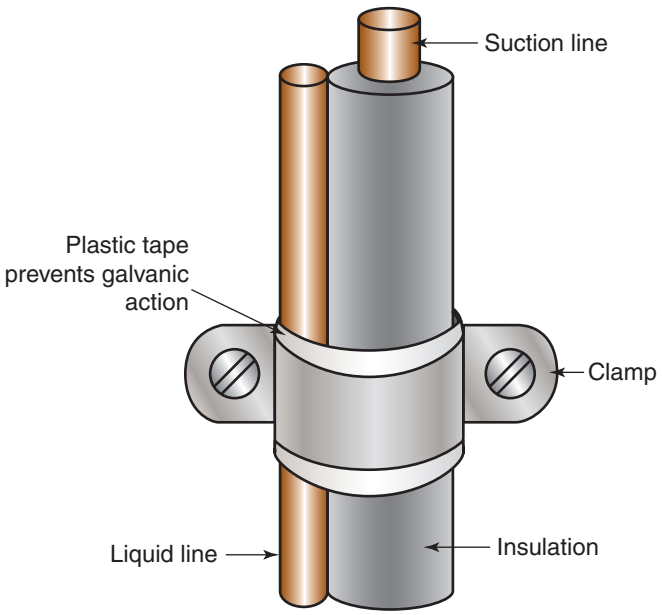
Unlike soft ACR tubing, hard-drawn tubing is not pliable enough to be flared, which means joints must be brazed. Joints and fittings must be placed so that they can be easily inspected. Since leaks may result from poorly brazed joints, the brazing of hard-drawn ACR tubing joints must be expertly done. Always use the fluxes and brazing alloys recommended by the manufacturer. The surfaces to be joined should be clean, and the ends of the tubing should be cut square. This allows proper flow of the brazing alloy into the joint.

When installing a system, plan your work so that all connections are completed in one day. Leaving tubing exposed for long periods may introduce moisture and debris into the system. To keep unused tubing clean, place caps or plugs in the ends of the tubing to seal out dirt and moisture. Never put tubing aside with ends open unless it will be used immediately.

The appearance of an installation is important. Therefore, the tubing should be put in as neatly as possible with minimal bends and adequate supports for straight runs. Supports are used at intervals frequent enough to keep the tubing straight and to prevent the tubing from pinching or crimping. Being easily bent, soft ACR tubing must be supported by clamps or brackets every four to six feet. Hard-drawn tubing should be supported every six to eight feet.

Copper tubing clamps are used to support the tubing by fastening it to the building structure. Other clamps, such as galvanized electrical conduit clamps, can also be used in most situations. Tubing should be insulated or protected from these clamps with short wrappings of plastic tape, **Figure 52-9**. The tape helps to prevent chafing and galvanic action. ***Galvanic action*** is the corrosion of metal that occurs when two different metals are in contact in moist air.

Copper Tubing Clamp



Galvanized Tubing Clamp

Mueller Refrigeration Company, Inc.; Goodheart-Willcox Publisher

Figure 52-9. Tubing clamps are used to fasten refrigerant tubing to walls and other flat surfaces for support. When using a galvanized conduit clamp, wrap plastic tape around the tubing before attaching the clamp to the wall with screws.

Copyright Goodheart-Willcox Co., Inc. 2017

Code Alert

Refrigerant Piping Height Requirements

Article 1107.2 of the International Mechanical Code (IMC) states that refrigerant piping across an open space that provides passageway in a building must be at least 7′-3″ (2210 mm) above the floor, unless the piping is located against the ceiling.

Tubing installations are usually run along ceilings and walls. Many technicians use a rubber covering over the tubing that serves both as protection and as insulation. This covering must be placed on the tubing before assembly unless the insulation is split. When tubing must be run through a floor or wall, use short runs of conduit or flexible metal tubing (FMT) to protect the tubing. The ends of the conduit should be sealed on the outside with a sealing compound to prevent chafing and water intrusion.

Code Alert

Refrigerant Piping Penetrations

Article 1107.2.2 of the International Mechanical Code (IMC) prohibits the penetration of a building's floors, ceilings, and roofs by refrigerant piping. However, this article also lists the exceptions in which refrigerant piping penetration is allowed.

A system's suction line should be mounted with a slight slope toward the compressor. This slope allows oil to flow by gravity back to the compressor during the Off cycle. If the suction line has low spots, oil can accumulate and may eventually form a liquid slug in the tubing. Such a slug carried to the compressor can produce a disturbance in the crankcase and may cause temporary oil pumping. Suction lines that cannot be sloped may require the installation of an accumulator to ensure proper oil circulation to the compressor. The liquid line presents no difficulties regarding slope and position.

Pro Tip

Heat Sources and Refrigerant Tubing

Never run refrigerant tubing near sources of heat, such as hot-water lines, steam lines, or furnaces. The heat can reduce system efficiency by causing flash gas formation in the liquid line or condensation on the suction line.

Copper tubing normally comes with no special finish on the inside or the outside. This means the tubing will corrode if it is placed in contact with the ground, liquid, or air saturated with acid fumes or corrosive elements. If the refrigerant tubing must be installed in a harsh environment, tubing with a plastic coating may be used, **Figure 52-10**.

Code Alert

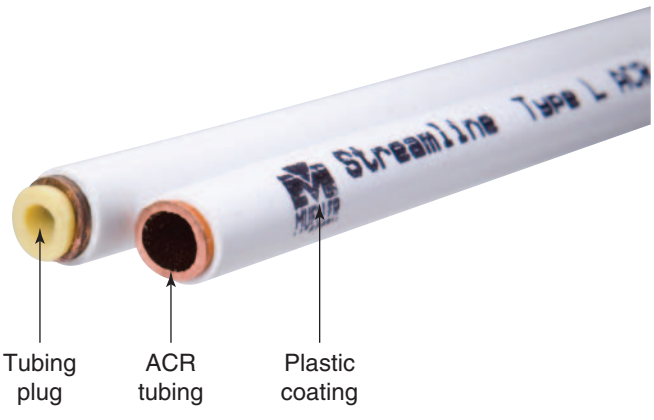
Prohibited Refrigerant Piping Locations

Article 1107.2 of the International Mechanical Code (IMC) states that refrigerant piping must not be installed in any elevator, dumbwaiter, or other shaft containing a moving object or any shaft with openings to living quarters or to a means of egress. Refrigerant piping cannot be installed in an enclosed public stairway, stair landing, or means of egress.

52.6.1 Installing Refrigerant Lines in Multiple-Evaporator Systems

There are two common methods of installing refrigerant lines for multiple-evaporator systems. In one method, there is a common liquid line and common suction line. The various evaporators in the system use T-fittings to tap into these common lines at the most convenient points.

In the other method, manifolds are used to bring the various lines to a centralized point. See **Figure 52-11**. Each line is connected through a shutoff valve to the manifolds. The suction line manifold connects the smaller suction lines from each evaporator to a single, larger suction line that runs to the compressor. The liquid line manifold, which may be located on a wall near the condensing unit, distributes refrigerant from a single liquid line to separate metering devices and their corresponding evaporators. This method, however, is not always practical, especially when one evaporator is isolated by a long distance because a duplication of long runs to and from each manifold is required.



Mueller Refrigeration Company, Inc.

Figure 52-11. Isometric drawing showing the layout of refrigerant lines in a multiple-evaporator system with a suction line manifold and a liquid line manifold. Each manifold connects to six refrigerant lines.

Copyright Goodheart-Willcox Co., Inc. 2017

Pro Tip

Reducing Pressure Drop

Each bend and valve placed in a refrigerant line increases the line's pressure drop. This is a result of the friction caused by the bend or valve. To keep pressure drop in refrigerant lines to a minimum, use as few bends and valves as possible.

52.6.2 Installing Valves

Most codes require large commercial systems to have shutoff valves so that parts of the system can be isolated from occupied areas in the event of a leak. These shutoff valves must be constructed so that anyone may shut them off. This means that there must not be any need for special tools to operate the valve. As a result, shutoff valves have handwheels, so they can be operated by hand. These valves are also provided with brackets so they can be firmly attached to a panel or wall.

Other valves installed in refrigerant lines, such as refrigerant line valves and service valves, are commonly covered with insulating tape or specially formed pieces of insulation. See **Figure 52-12**. The connections for most valves in commercial systems are brazed, except where soft copper is used and flared connections can be made. Valves, driers, and other heavy objects should not be supported only by the tubing. These components should be mounted on a wall or some other support.

Pro Tip

Brazing Valves

If possible, remove the inner parts of valves (such as the Schrader valve cores in service valves) while brazing them to refrigerant tubing. This protects the inner parts from excessive heat that can be transferred through the tubing during brazing. Another method for protecting against heat transfer involves wrapping the valve in a wet cloth to absorb the heat conducted by the tubing. However, do not allow moisture from the wet cloth to enter the valve.

Code Alert

Locking Access Port Caps

Article 1101.10 of the International Mechanical Code (IMC) states that refrigerant circuit access ports that are located outdoors must have locking caps or be secured in another manner to prevent unauthorized access.

Valve and Insulation

Insulated Refrigerant Line Valve

Mueller Refrigeration Company, Inc.

Figure 52-12. Special cuts of insulation may be used to cover line components, such as this refrigerant line valve.

52.6.3 Installing Vibration Absorbers

To prevent leaks caused by compressor vibrations and to minimize vibration noise, install a vibration absorber in both the refrigerant lines connected to the compressor. Vibration absorbers are also installed in lines that experience expansion and contraction as a result of temperature changes, such as hot-gas defrost lines. Always follow the installation and service procedures provided by the vibration absorber's manufacturer. See **Figure 52-13**.

If a suitable vibration absorber is not available, an alternate method may be used to reduce the spread and effect of vibration. This method is to make one horizontal loop of soft copper tubing in the suction line and another horizontal loop of tubing in the liquid line. These vibration loops help to keep movement

Goodheart-Willcox Publisher

Figure 52-13. Vibration absorbers should be secured to the building structure using clamps. Allow a space of 1 1/4″ at *X* for each 100′ per 100°F (55°C) temperature change.

from crystallizing the copper, making it crack or break. However, only put loops and unsupported bends in the tubing at the condensing unit.

52.6.4 Installing Filter-Driers

In commercial refrigeration systems, filter-driers are a standard part of the installation. Filter-driers help to protect the compressor from contamination and moisture, both of which can cause compressor burnout. Filter-drier size is typically based on the following criteria:

- Compressor horsepower.
- Compressor operating cycle (hours of operation per day).
- Type and quantity of refrigerant.

If additional tubing must be run during an installation, the technician must account for the added volume of refrigerant and oil in the system. Always consult manufacturer specifications when sizing filter-driers. If specifications indicate that the refrigeration system falls between two different filter-drier sizes, choose the larger filter-drier.

Filter-driers hold more moisture at lower temperatures. As a result, a liquid line filter-drier should be installed as close to the metering device as possible to keep the filter-drier away from the hot condenser. If a filter-drier heats up (often due to a shortage of refrigerant or due to high ambient temperature), it may release some of its absorbed moisture. Keep a filter-drier sealed until just before it is installed to prevent it from absorbing moisture from the air.

52.6.5 Installing Sight Glasses

The one component that should be located between a filter-drier and a refrigerant metering device is a sight glass. Most sight glasses have a moisture indicator, which is a color-changing element used to indicate a system's moisture content. If the sight glass is installed prior to the filter-drier, the moisture indicator may show moisture that will be trapped by the filter-drier. Most sight glasses have brazed connections and are sized based on the diameter of the liquid line.

Caution

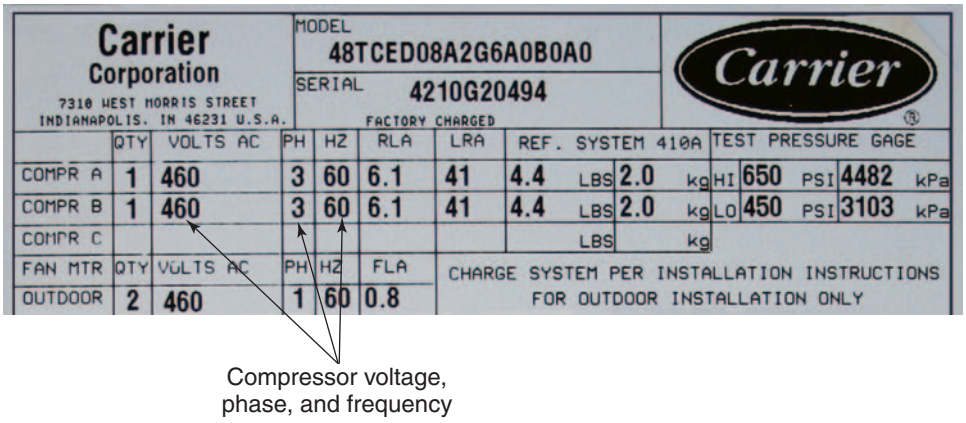
Brazing Moisture Indicators

Most sight glass moisture indicators have a removable moisture indicator core. The core may be removed when brazing the indicator into the refrigerant line and replaced when installation is complete. When installing a sight glass that does not have a removable core, avoid overheating the moisture indicator by putting a cold pack on it. A temperature of 275°F (135°C) or higher can affect the color-changing element. Also, avoid getting flux inside the sight glass because flux chemicals can affect the color-changing element as well.

52.7 Installing Electric Motors

A commercial refrigeration system must have the correct electrical power to operate motors, controls, and solenoid valves. Before installing a condensing unit, check the compressor motor's rated voltage, frequency (Hz), and phase to make sure they are the same as the electrical power source. This information is located on a nameplate attached to the compressor or condensing unit, **Figure 52-14**. The identification plates

Copyright Goodheart-Willcox Co., Inc. 2017



Goodheart-Willcox Publisher

Figure 52-14. The electrical specifications for compressor motors are listed on a nameplate attached to the condensing unit.

on evaporator fans, condenser fans, solenoid valves, and other controls must also be checked to make sure the data matches the power available.

Most municipalities require all high-voltage wiring to be completed by a licensed electrician during an installation. In general, this means circuits with 120 V or more should be wired by an electrician. However, HVACR technicians are permitted to connect and service low-voltage wiring and wiring within a unit. This is usually control wiring that is classified as part of a Class 2 circuit. For more information, see Chapter 13, *Electrical Power*.

Condensing units have wiring diagrams either fastened to them or supplied in the shipping crate. See **Figure 52-15**. Wire should have a capacity 50% over the load it will carry. Always consult the manufacturer's specifications for the correct wire size to use and follow all applicable codes in the National Electrical Code®.

Caution

Proper Wiring Practices

Do not turn on electrical power until all circuits are correctly wired and all connectors are clean and tight. Use an ohmmeter to check the circuits for continuity before turning on the power. Overloaded electrical circuits are dangerous and can cause burnouts or electrical fires.

52.7.1 Installing Open-Drive Compressor Motors

In an open-drive compressor, the compressor's crankshaft is connected either directly to the motor shaft or by means of a belt. In either case, the motor must be carefully aligned when installed. Proper alignment, balancing, and support can reduce damage from vibration. Always lock out the power before starting work.

For belt-driven arrangements, start by loosely installing the bolts that hold down the motor base. Usually, the motor base has slots for the bolts, which require you to reach under the mounting surface to hold the bolts in place. This often makes it difficult to put a wrench on the bolts. As a result, some technicians use caulking compound to hold the bolts in place until the motor is aligned and the washers and nuts are started on the bolts.

Before tightening the bolts, install the belts. Use a lever to move the motor until the belts are tight and the motor is in-line. While holding the motor in this position, tighten at least two of the bolts, and then tighten the others. Motors are usually fastened to their mounting surface with nut-bolt-washer combinations. However, mounting brackets, arrangements, hardware, and wiring vary with a motor's application.

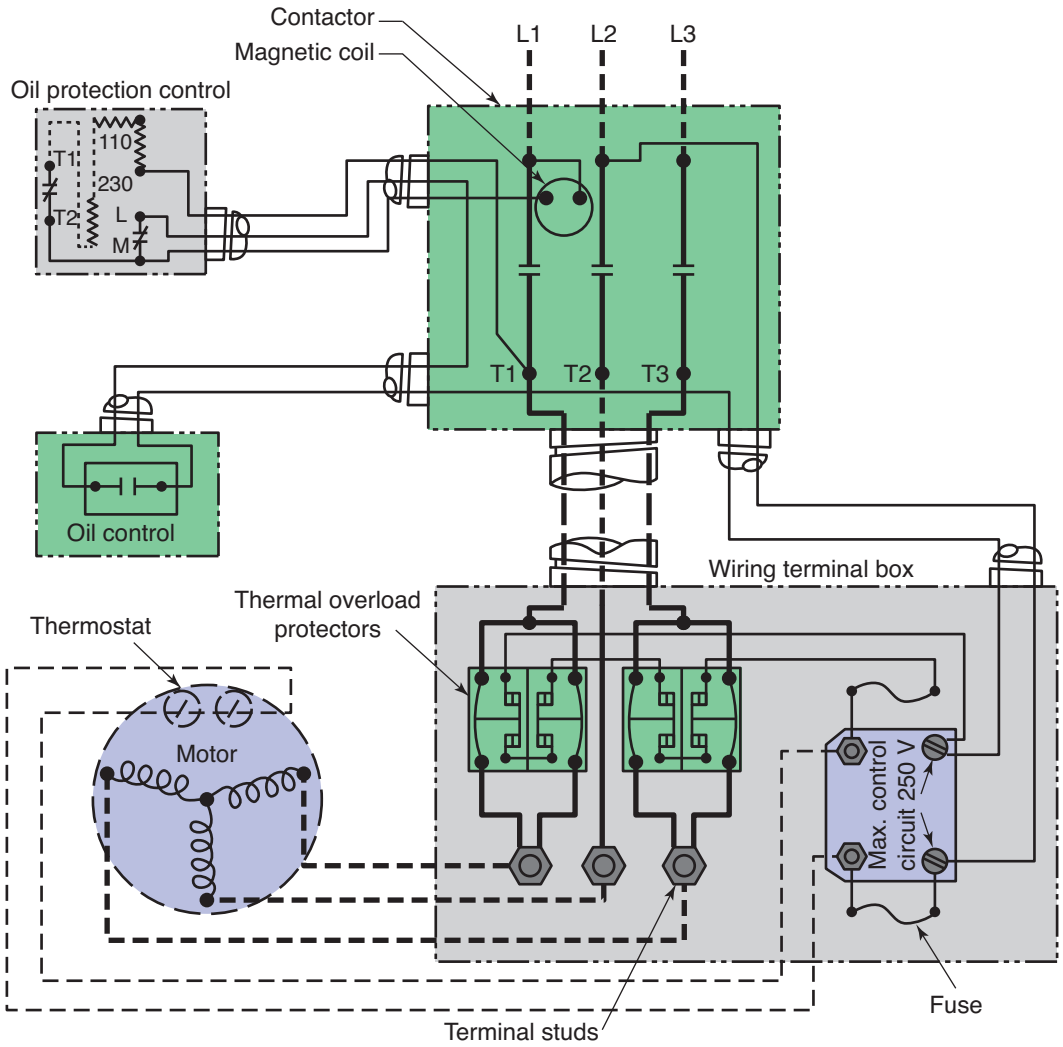
For direct-drive arrangements, including water pump motors, set the motor on its part of the stand. Then assemble and install the coupling that connects the compressor crankshaft to the motor shaft. Check the alignment carefully. The motor shaft center must be the same height as the crankshaft center, and the two shafts must be in alignment when looking down at them. A dial indicator should be used to check the alignment before installing and tightening the bolts.

If possible, always turn the motor by hand before undoing the lockout and turning on the power. This will determine if the assembly will rotate freely.

52.7.2 Installing Hermetic Compressors

Hermetic compressors may be designed for low-, medium-, or high-temperature applications. A hermetic compressor is usually furnished with the following:

Copyright Goodheart-Willcox Co., Inc. 2017



Goodheart-Willcox Publisher

Figure 52-15. Wiring diagram for a commercial condensing unit that uses three-phase power.

- Starting relay.
- Capacitors.
- Overload protectors.
- Other accessories.

Carefully mount the hermetic compressor in place. Use all safety precautions while lifting the compressor, such as steel toe shoes and protection for floors and equipment. Install the mounting bolts. The springs, grommets, and bolts must be in the correct position. If you are replacing a compressor, use an exact replacement. Review the data on the nameplate to ensure compatibility.

Install the electrical devices (such as the overload protectors and the starting relay) and the electrical wires. All wires, including insulation and wire terminals, must be in good condition. All connections must be clean and tight.

Caution

Aluminum and Copper Electrical Connections

Avoid connecting aluminum wires to copper wires or copper terminals. Galvanic corrosion may result.

After mounting the compressor in place, install the refrigerant lines. Some hermetic compressors have service valves while others are provided with short tubing stubs. In either case, the openings of the valves or stubs are usually sealed with plugs; however, some tubing stub ends are sealed by being crimped and brazed. Before the refrigerant lines can be installed, the crimped ends must be cut with a tubing cutter and swaged.

If brazed connections are used, start by identifying the tubing stubs. Distinguish between the suction connection, discharge connection, process tube, and

Copyright Goodheart-Willcox Co., Inc. 2017

oil connection. Clean the tubing stubs, the suction line, and the liquid line with a fine grit emery cloth before applying flux. Before brazing, ensure that the area is well ventilated. After brazing, clean the connections with warm water to remove any remaining flux.

52.8 Testing Installations

There may be several inspections required during the phases of an installation. During these inspections, the code enforcement officer or inspector may issue a yellow tag, which means work may proceed, but certain items must be brought up to code. If the inspector issues a red tag, the work must stop until a plan to repair code violations is approved. Upon successful final inspection, the job is granted a green tag, which indicates the job is complete and approved by the code authority.

If the installation is not inspected in phases, an inspector is called on completion of the work. Approval must be given by the inspector before the system may be run. The inspector observes the installation to see if all the work has been done according to specifications and code. Then the system is tested for leaks and safety.

Leak testing involves using nitrogen, or another inert gas such as carbon dioxide, to build up pressure in the system's high and low sides. There must be a hand shutoff valve, a pressure regulator, a pressure gauge, and a pressure-relief valve installed between the nitrogen cylinder and the system. The pressure-relief valve should be adjusted to open 1 psi or 2 psi above the recommended testing pressure. The recommended testing pressure is typically provided on the system nameplate and varies based on the type of refrigerant in the system. See **Figure 52-16**. The inspector may observe this test or ask the HVACR technician to provide documentation that tests have been performed.

Caution

Leak Testing Pressures

Exceeding a system's recommended testing pressure can cause damage to the system and may even cause an explosion. If the system's high side and low side cannot be sealed from each other during testing, never exceed the recommended low-side testing pressure. If the recommended testing pressure is not listed, the pressure should not exceed 170 psig (1170 kPa).

After pressures are built up in the system, each joint should be gently rapped with a rubber mallet to ensure the joint will be leakproof under working conditions. Paint or flux may otherwise temporarily stop a leak. With nitrogen, either a bubble solution or an ultrasonic leak detector can be used to check for leaks. If no leaks are found, perform a standing pressure test by leaving the nitrogen in the system under pressure for 24 hours.

If the system pressure drops during the standing pressure test, the system has a leak. In some cases, the leak cannot be found with a bubble solution or an ultrasonic leak detector, which means a trace amount of refrigerant must be added to the system so that an electronic leak detector can be used. First, purge the system of nitrogen and pull a vacuum to eliminate as much moisture as possible. Then, charge the system to a low pressure, usually around 10 psig (70 kPa), with the same refrigerant that will be used in operation.

Most leaks can be found with an electronic leak detector at this low pressure. However, if the leak still cannot be found at low pressure, pressurize the system to the recommended testing pressure using nitrogen and check for leaks with the electronic leak detector again. Once the leaking joint is found, take it apart to repair it. In the case of brazed joints, take the joint completely apart and then assemble, flux, and braze again.

Once the system passes the standing pressure test, the inspector sometimes requires the system to undergo a standing vacuum test. To perform a standing vacuum test, a technician pulls a deep vacuum (less than 250 microns) on the system. If this vacuum is maintained over a specified period of time, the installation is approved. However, if the vacuum pressure rises during this time, there is a leak.

Recommended Design Testing Pressures (psig)

Refrigerant	Low Side	High Side	
		Evaporative or Water-Cooled Condenser	Air-Cooled Condenser
R-22	144	211	278
R-123	15	15	18
R-134a	88	135	186
R-401A	85	133	182
R-404A	174	253	331
R-407C	167	243	320
R-410A	238	344	449
R-507A	180	262	344

Goodheart-Willcox Publisher

Figure 52-16. Design testing pressures for different refrigerants as recommended by Underwriters Laboratories.

Copyright Goodheart-Willcox Co., Inc. 2017

After the installation is approved, the system's running behavior should be recorded for at least 24 hours. Any variations in operating temperatures or pressures outside of the expected operating range for the given ambient temperature reveal a need for an adjustment.

52.9 Charging Commercial Systems

After a commercial refrigeration system has been assembled, tested, and approved, it must be evacuated prior to charging. When charging a system, refer to the manufacturer's directions if they are available. Manufacturers design and test their products under various operating conditions. From these tests, specific charging procedures are developed. For more information on evacuation and charging procedures, see Chapter 11, *Working with Refrigerants*. In general, there are two methods used to charge commercial refrigeration systems:

- Low-side method.
- High-side method.

52.9.1 Low-Side System Charging

Low-side charging is a method of injecting refrigerant vapor into the low side of a commercial refrigeration system through a low-side service valve, often the suction service valve (SSV). Since refrigerant vapor is much less dense than liquid refrigerant, it takes longer to charge a system with vapor than it would with an equal weight of liquid refrigerant. As a result, low-side charging should only be used to charge smaller commercial systems or to "top off" the existing refrigerant charge in a system. The main advantage of low-side charging is that it prevents the possibility of slugging the compressor.

Caution

Liquid in the Compressor

Liquid refrigerant should never be charged through the low side. Liquid refrigerant entering through the suction line can immediately cause liquid slugging and permanent damage to the compressor.

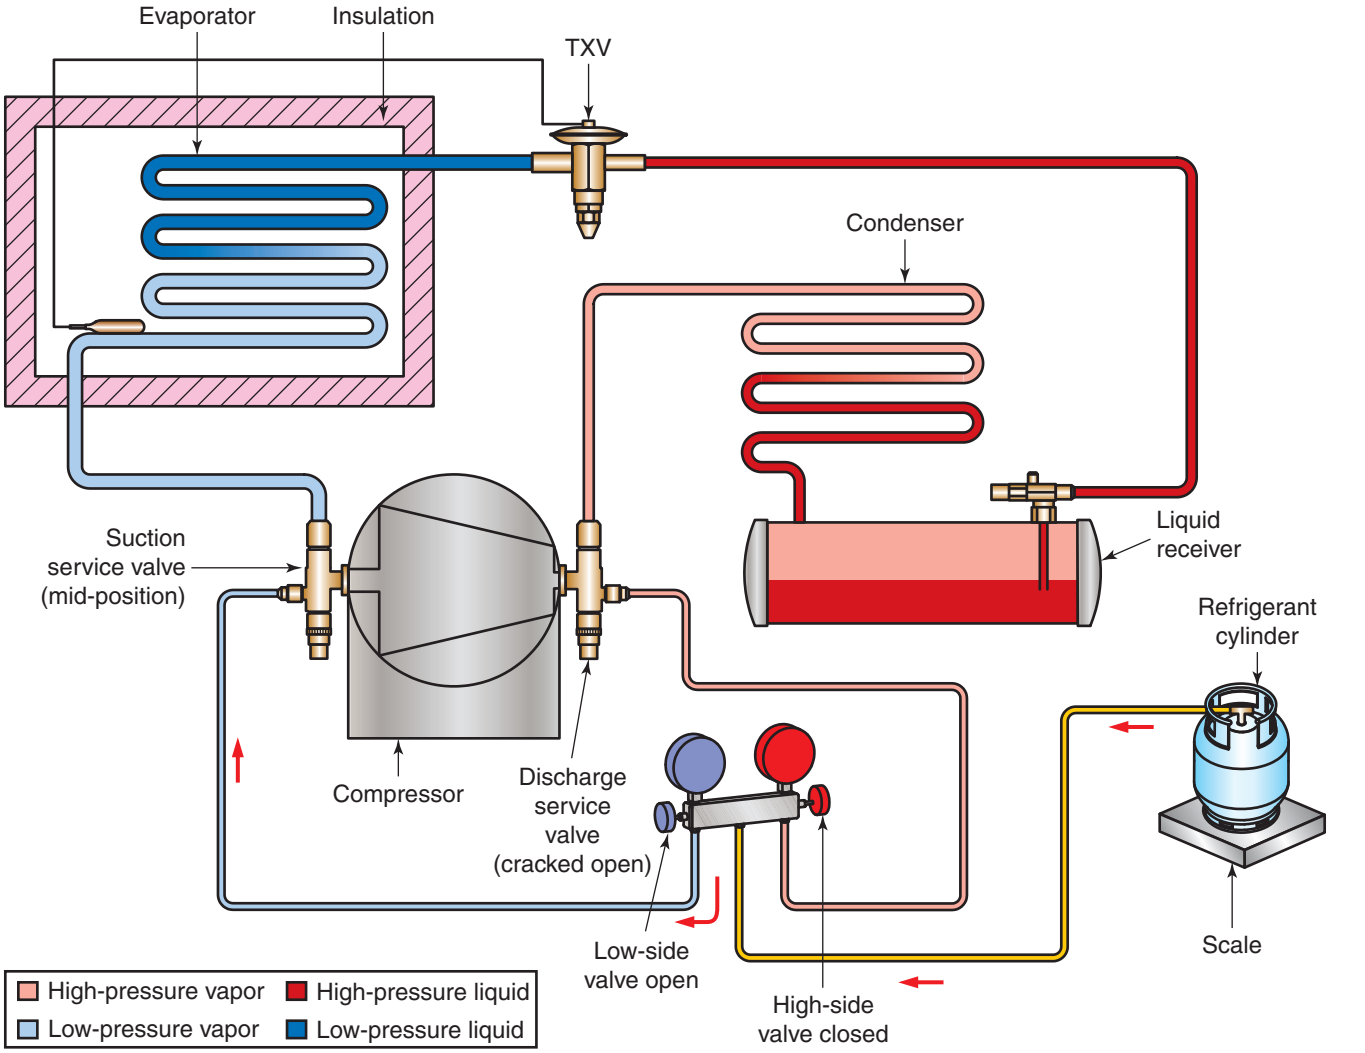
Low-side charging can only be done with pure refrigerants, such as R-123 or R-134a. Zeotropic refrigerant blends, such as R-404A, cannot be charged as a vapor to the low side because the different refrigerants that make up the blend vaporize at different pressures. This means that if the blend is charged as a vapor, it will fractionate and create an improper mixture of refrigerants in the system. Zeotropic refrigerant blends should only be charged into a system as a liquid.

Low-Side Charging Procedure

Remember to wear goggles when transferring refrigerants. To prevent the venting of refrigerant to the atmosphere, use quick-connect fittings to connect and disconnect service lines.

1. Connect a refrigerant cylinder and gauge manifold to the system as shown in **Figure 52-17**. Place the refrigerant cylinder in the upright position on the charging scale. Leave the connections to the service valves loose.
2. Open the low-side and high-side valves on the gauge manifold.
3. Crack open the refrigerant cylinder valve to purge the service lines. Once the lines have been purged, close the cylinder valve and tighten the service valve connections.
4. Close the high-side valve on the gauge manifold, but keep the low-side valve open.
5. Put the suction service valve in the mid-position and crack open the discharge service valve. Although the gauge manifold's high-side valve is closed, cracking open the discharge service valve allows you to monitor the high-side pressure during the charging procedure.
6. Open the refrigerant cylinder valve to add refrigerant vapor to the system through the low side.
7. When the pressure equalizes between the cylinder and the system, the refrigerant will stop flowing into the system. Turn on the system to operate the compressor to draw in the remaining refrigerant charge.
8. Closely monitor the scale to ensure the system is not being overcharged. Some scales can be programmed to stop the charging process automatically when the proper weight has been charged into the system.
9. When the proper weight of refrigerant has been added to the system, close the gauge manifold's low-side valve and the refrigerant cylinder valve to stop the charging process.
10. Back seat both the suction and discharge service valves. Disconnect service lines and replace service valve caps.
11. Let the system operate for 10 to 15 minutes to stabilize temperatures and pressures. Check superheat, subcooling, head pressure, and suction pressure to verify that the system has the correct charge.

Copyright Goodheart-Willcox Co., Inc. 2017



Goodheart-Willcox Publisher

Figure 52-17. Diagram showing the system setup for low-side charging.

To speed up the low-side charging process, a technician can heat up the refrigerant cylinder using hot water, a heat lamp, a heat gun, or an electric blanket. By increasing the temperature of the cylinder (a closed volume), its pressure is increased. This follows the principles of Gay-Lussac's law. Creating a greater pressure difference between the cylinder and the system forces more refrigerant out of the cylinder. Never use a torch to warm a cylinder.

A technician must be present at all times during a charging process to monitor pressures and refrigerant charge level. A refrigerant cylinder cannot be left connected to a system unattended.

52.9.2 High-Side System Charging

High-side charging is a method of injecting liquid refrigerant into the high side of a commercial refrigeration system through a high-side service valve, often the liquid receiver service valve (LRSV). Liquid charging through the high side is faster than vapor charging because liquid refrigerant is much denser than refrigerant vapor. High-side charging is best done with the system off to prevent overcharging the system. As liquid refrigerant is added to the system, the system pressure rises until it equals the pressure in the refrigerant cylinder. At this point, the charging process stops because there is no longer a pressure difference between the system and the cylinder. If this occurs before the full amount of refrigerant has been charged into the system, the charge may be "topped off" by using the low-side charging method discussed in the previous section.

Another method of "topping off" the refrigerant charge is to isolate the liquid line from the liquid receiver, connect the liquid line to the refrigerant cylinder, and then operate the compressor. The running compressor draws liquid refrigerant

Copyright Goodheart-Willcox Co., Inc. 2017

out of the liquid line into the low side of the system, which reduces the liquid line pressure and allows additional refrigerant from the cylinder to flow into the system. However, not all systems can be charged with liquid refrigerant when the compressor is running. In order for this method to work properly, the liquid receiver must be isolated from the service port, and the liquid line must be open to the service port. The system design and the location and build of the LRSV determine if this is possible. Also, a technician must ensure that only liquid is being fed into the liquid line and at an adequate rate. If vapor is drawn in or forms in the liquid line, it can wear or damage an expansion valve.

Caution

Liquid Receiver Isolation

If the liquid receiver cannot be isolated from the service port and liquid line, refrigerant at high pressure will be pumped from the compressor into the refrigerant cylinder. This can cause the cylinder to rupture or explode.

Note that service valves used on the high side of commercial refrigeration systems vary. Chapter 10, *Equipment and Instruments for Refrigerant Handling and Service* describes the different service valves available on systems. Some liquid receivers have an inlet service valve (queen valve) and an outlet service valve (king valve). When a system has both a queen valve and a king valve, different methods of liquid charging are possible depending on the build and orientation of these service valves. See what is possible with each system and determine the best solution.

High-Side Charging Procedure

Remember to wear goggles when working with refrigerants. To minimize refrigerant loss, use quick-connect fittings to connect and disconnect service lines.

1. Connect a refrigerant cylinder and gauge manifold to the system as shown in **Figure 52-18**. At first, leave the refrigerant cylinder upright and the hose connections to the service valves loose.
2. Open the low-side and high-side valves on the gauge manifold.
3. Crack open the refrigerant cylinder valve to purge the service lines. Once the lines have been purged, close the cylinder valve and tighten the hose connections to the service valves.
4. Close the low-side valve on the gauge manifold, but keep the high-side valve open.
5. Place the refrigerant cylinder in the upside-down position on the charging scale. Program the scale and any associated components with the proper charge value.
6. Crack open the suction service valve. Although the gauge manifold's low-side valve is closed, cracking open the suction service valve allows you to monitor the low-side pressure.
7. Examine the liquid receiver service valve to determine its build and orientation in the system. Often, front seating the valve will block the liquid line, allowing you to charge liquid refrigerant into the liquid receiver. If the liquid line cannot be blocked, adjust the valve to mid-position.
8. Open the refrigerant cylinder valve to add liquid refrigerant to the system through the high side.
9. Refrigerant will stop flowing into the system when the charging scale automatically stops (if programmed to do so) or when the pressure equalizes between the refrigerant cylinder and the system.
10. If the system still needs more refrigerant, either follow the low-side charging procedure to charge the system with refrigerant vapor or continue following this procedure to charge the system with liquid refrigerant.
11. Adjust the liquid receiver service valve to block off the liquid receiver and allow the service port to access the liquid line.
12. Cycle on the system to operate the compressor and charge the remaining refrigerant. Ensure that only liquid refrigerant flows into the liquid line. This prevents vapor from forming, which can damage expansion valves. Monitor the charging scale to know when to close the different valves. Do not rely entirely on the charging scale to automatically stop the process.
13. When the proper weight of refrigerant has been added, close the gauge manifold's high-side valve and the refrigerant cylinder valve to stop the charging process.
14. Back seat both the suction service valve and liquid receiver service valve. Disconnect service lines and replace service valve caps.
15. Let the system operate for 10 to 15 minutes to stabilize temperatures and pressures. Check superheat, subcooling, head pressure, and suction pressure to verify that the system has the correct charge.

Goodheart-Willcox Publisher

Figure 52-18. Diagram showing the system setup for high-side charging.

Caution

Charging Systems with Hermetic Compressors

A running hermetic compressor requires refrigerant vapor to cool its windings or else its motor will overheat. For this reason, it is best to "top off" the refrigerant charge in systems with hermetic compressors by charging refrigerant vapor through the low side with the system running.

52.10 Starting a Commercial Refrigeration System

A planned procedure should be followed when starting a newly installed commercial refrigeration system. This also applies when starting a commercial refrigeration system that has been shut down for a long period of time. Before a system is put into operation, its motor controls should be adjusted. The settings of motor controls

Copyright Goodheart-Willcox Co., Inc. 2017

vary with the demands of the conditioned spaces and the type of refrigerant used. For a review of motor controls, see Chapter 16, *Electrical Control Systems*.

Starting a Commercial Refrigeration System

To avoid overloading electrical circuits, the compressor, and any other motors, begin by verifying that the system's power source supplies the correct voltage and phase. Also, make sure that all electrical connections made during the installation use conductors capable of carrying the system's required current draw.

1. Connect a multimeter to the compressor circuit to monitor current draw and source voltage. Multimeters with recording features are preferred. A clamp-on ammeter is the most convenient method of measuring electrical amperage.
2. Install a gauge manifold to monitor high-side and low-side pressures.
3. If the condenser is water cooled, make sure the water circuit is turned on.
4. After starting up the system, check the electrical meters, pressure gauges, and water flow (if applicable) as soon as possible for proper levels. Shut down the system at the first sign of trouble.
5. Determine if the refrigerant metering device adjustment is correct for each evaporator by checking superheat. Suction line frosting is often an indication that a refrigerant metering device is opened too far. Suction line sweating may indicate that the valve is not open far enough.
6. Determine if the system has enough refrigerant. Check the manufacturer's charts for recommended high-side pressure, low-side pressure, and evaporator temperature for the given ambient condition.
7. For the first week of the system's operation, use instruments, such as thermometers and multimeters, with recording features. Accurate records make adjustments easier. Maintain these records for use during future maintenance and service operations.

When a refrigeration system is started for the first time or after having not run for an extended time, conditioned space temperature will be well above its set point. Such operation is called a hot pull down. Starting a multiple-evaporator system under the full heat load of all the evaporators may overload the compressor. This is because the TXVs fully open on start-up. The system will not exhibit proper temperatures or pressures until the conditioned space is much closer to its set point.

There are a couple of ways of handling a full heat load when starting a multiple-evaporator system. One method involves adjusting individual evaporator shutoff valves during start-up. Another method involves throttling the suction service valve.

52.10.1 Starting a Multiple-Evaporator System Using Shutoff Valves

To avoid overloading the compressor and to compensate for start-up under a full heat load, close each of the shutoff valves on the suction line manifold before the compressor is started. After starting the compressor, immediately but slowly open one of the shutoff valves. This allows a limited amount of refrigerant from one evaporator to be pumped to the compressor.

Monitor low-side pressure. It should only be a little higher than the pressure motor control's cut-in pressure. If the low-side pressure is higher, begin to slowly close the open shutoff valve. As low-side pressure levels off to a normal measurement, gradually open the shutoff valve. Continue this monitoring and adjustment until the shutoff valve is completely open.

After refrigerant has been circulating through the evaporator for a few minutes, the evaporator will cool. This tends to make the TXV choke off the refrigerant flow. It also gives the compressor a chance to gradually reduce its load. This is when the other evaporators may be brought into service one at a time in the same way as the first evaporator.

52.10.2 Starting a Multiple-Evaporator System by Throttling the Suction Service Valve

When throttling the suction service valve (SSV) to compensate for start-up under a full heat load, begin by connecting a gauge manifold to the service port on the SSV. Adjust the SSV so that it is cracked open. This leaves a small opening between the suction line and the compressor to allow a limited amount of refrigerant from the suction line to be pumped by the compressor.

Turn on the compressor and closely monitor low-side pressure. Measurements should be just over the pressure motor control's cut-in pressure. If the low-side pressure is higher, gently and gradually turn the valve stem on the SSV to move the valve closer to the front-seated position. As the compressor operates, the evaporators will cool, and the low-side pressure will begin to drop. As the low-side pressure drops, gradually open the SSV more. Continue monitoring pressure and slowly opening the SSV until the SSV is in mid-position and the system reaches normal operating pressures and temperatures.

Copyright Goodheart-Willcox Co., Inc. 2017

Chapter Review

Summary

- Commercial refrigeration system installations fall into two broadly defined groups: packaged systems and split systems. Split systems may have a single refrigerated cabinet or multiple refrigerated cabinets that operate at different temperatures.
- Codes regulate the installation of commercial systems to ensure quality and safety. Codes often require that the installer be licensed, the installation have a permit, the refrigerant lines be clearly labeled, and the installation be inspected before operation.
- When installing a condensing unit, avoid placing the unit where it can be exposed to heat sources or freezing temperatures. Use mounting grommets for the compressor to absorb vibrations that could damage parts of the system.
- Proper sensing bulb placement is necessary for proper TXV operation. Based on the size of the suction line tubing, a sensing bulb is mounted at a position aligning with a particular hour hand position on a clock.
- Evaporators in refrigerated display cases are usually mounted on stands or brackets. Evaporators should be carefully checked after mounting to make sure they are level. If an evaporator is mounted vertically, the outlet should always be below the inlet to allow for oil return to the compressor.
- Refrigerant lines in commercial refrigeration systems are usually made of hard-drawn ACR tubing. Supports, such as tubing clamps, should be used at intervals frequent enough to prevent the tubing from pinching. When installing components in refrigerant lines with brazing, remove any inner parts possible or use a wet cloth to protect them against heat transfer.
- Regardless of whether an open-drive compressor is direct drive or belt driven, the motor must be carefully aligned. For belt-driven arrangements, install the belts before tightening the mounting bolts. For direct-drive arrangements, check the alignment carefully using a dial indicator. After installation, turn the motor shaft by hand to test whether it will rotate freely.
- To test a newly installed system for leaks, technicians charge the system with nitrogen to perform a standing pressure test. Sometimes a system is charged with a trace amount of its refrigerant and nitrogen so that leaks can be found with an electronic leak detector. A standing vacuum test is often performed once the system passes the standing pressure test.
- Refrigerant can be charged into either the low side or the high side of a system. Low-side charging involves running the compressor to draw vapor from a refrigerant cylinder through the suction service valve (SSV). High-side charging injects liquid refrigerant into the system through the liquid receiver service valve (LRSV) while the compressor is off.
- After starting a newly assembled commercial refrigeration system, measure and compare the system's electrical, pressure, and temperature variables to ensure they are at the proper levels. When starting a multiple-evaporator system, limit the refrigerant that can reach the compressor by adjusting shutoff valves on the suction line manifold or by throttling the suction service valve (SSV).

Review Questions

Answer the following questions using the information in this chapter.

1. Most municipalities require a technician to obtain a(n) _____ before a commercial refrigeration installation can be made.
   A. inspection
   B. permit
   C. specification sheet
   D. standing pressure test
2. The discharge line from the compressor should be _____ to the condenser.
   A. kept as level as possible
   B. looped
   C. sloped downward
   D. sloped upward
3. All of the following devices are used to prevent excessive pressure in the condensing unit, *except* _____.
   A. check valves
   B. pressure controls
   C. rupture discs
   D. spring-loaded relief valves

Copyright Goodheart-Willcox Co., Inc. 2017

4. A sensing bulb for a thermostatic expansion valve should never be mounted on the _____ of a tube.
   A. bottom
   B. left side
   C. right side
   D. All of the above.
5. The suction line maintains a gradual slope downward from the evaporator to the compressor in order to _____.
   A. aid liquid refrigerant circulation
   B. aid oil returning to the compressor
   C. prevent moisture from accumulating on the low side
   D. prevent vapor from condensing into liquid
6. When tubing must be run through a floor or wall, use short runs of _____ to protect the tubing.
   A. conduit
   B. ductwork
   C. soft ACR tubing
   D. tubing clamps
7. Shutoff valves in refrigerant lines _____.
   A. require using a refrigeration service valve wrench
   B. should be hand operated
   C. should be operated automatically
   D. should have backup bypass solenoid operation
8. Liquid line filter-driers should be installed as close as possible to the _____.
   A. accumulator
   B. condenser
   C. liquid receiver
   D. refrigerant metering device
9. The size of a filter-drier is based on the following criteria, *except* _____.
   A. compressor horsepower
   B. compressor operating cycle
   C. refrigerant quantity and type
   D. risk of galvanic action
10. The best location for a sight glass is between the _____.
    A. accumulator and compressor
    B. compressor and condenser
    C. condenser and liquid receiver
    D. filter-drier and refrigerant metering device
11. Before a system can be operated, a leak test must be performed by building up system pressure using _____.
    A. ammonia
    B. nitrogen
    C. oxygen
    D. sulfur dioxide
12. When a leak test is performed without any refrigerant inside the system, use a(n) _____ as the method of leak detection.
    A. bubble solution
    B. electronic leak detector
    C. halide torch
    D. All of the above.
13. Low-side charging involves adding refrigerant vapor to a system through the _____.
    A. discharge service valve
    B. liquid receiver service valve
    C. queen valve
    D. suction service valve
14. High-side charging involves adjusting a(n) _____ into position and adding liquid refrigerant through it.
    A. access port on an evaporator pressure regulator
    B. access port on a filter-drier
    C. liquid receiver service valve
    D. suction service valve
15. One method of starting a multiple-evaporator system requires the technician to throttle the _____.
    A. evaporator pressure regulator
    B. discharge service valve
    C. suction service valve
    D. thermostatic expansion valve

CHAPTER 53 Troubleshooting Commercial Systems—System Diagnosis

Chapter Outline

53.1 Commercial Refrigeration Troubleshooting
- 53.1.1 Effect of Lack of Refrigerant
- 53.1.2 Effect of Noncondensables in a System
- 53.1.3 Excessive Head Pressure
- 53.1.4 Excessive Suction Line Pressure Drop
- 53.1.5 Moisture in a Refrigeration System

53.2 Checking Refrigerant Charge

53.3 Diagnosing Common Symptoms
- 53.3.1 Low or No Refrigeration—Unit Runs Continuously
- 53.3.2 Normal to Excessive Refrigeration—Motor Running Continuously
- 53.3.3 Low to Normal Refrigeration—Longer Than Normal Run Time
- 53.3.4 No Refrigeration—Unit Does Not Run
- 53.3.5 Short Cycling
- 53.3.6 Noisy Unit

53.4 Troubleshooting Ice Machines
- 53.4.1 Water Quality
- 53.4.2 Drain Problems
- 53.4.3 Head Pressure in Ice Machines
- 53.4.4 Capacity Check
- 53.4.5 Cube Ice Machine Service
- 53.4.6 Flake Ice Machine Service

Learning Objectives

Information in this chapter will enable you to:

- Recognize the effects of an undercharged refrigeration system.
- Recognize the effects of an overcharged refrigeration system.
- Recognize the effects of noncondensables in a refrigeration system.
- Identify causes of suction line pressure drop.
- Summarize the effects of having moisture in a refrigeration system.
- Check a commercial refrigeration system's refrigerant charge.
- Differentiate among the different causes of high head pressure.
- Analyze a refrigeration system that runs continuously to determine its root cause.
- Evaluate a refrigeration system that produces little or no cooling.
- Analyze a refrigeration system that will not run to determine its root cause.
- Troubleshoot basic problems in ice machines.

Technical Terms

anti–short cycle control
capacity check
critically charged
ice thickness sensor
inefficient compressor
noncondensables
water level/conductivity probe

Review of Key Concepts

Reviewing these concepts from earlier chapters will help you understand new concepts presented in this chapter:

- Using troubleshooting charts and standard procedures can save time, money, and frustration. (Chapter 3)
- Comparing pressure and temperature conditions can be used in identifying refrigeration system and component problems. (Chapter 24)
- Diagnosing system problems in domestic refrigeration systems is often similar to diagnosing problems in commercial refrigeration systems. Certain conditions produce noticeable symptoms. System diagnosis relies on identifying symptoms and deducing their possible origins. (Chapter 25)
- Analyzing temperature and pressure conditions can provide clues to problems in HVACR system operation. (Chapter 25)
- Service valves can be installed in various places along a refrigerant circuit where they can isolate sections and provide access for measurements and service. (Chapter 10)

Introduction

A thorough knowledge of HVACR fundamentals is essential. Before trying to troubleshoot a commercial refrigeration system, review its basic operating characteristics, such as compressor current draw, superheat, subcooling, suction and head pressures, and evaporator and condenser temperature. When a measurement or a reading differs from normal operating characteristics, consider what might be causing that off measurement. Be aware that some obvious symptoms may be caused by less obvious root problems. Common sense is an invaluable asset needed to service, troubleshoot, and diagnose problems in commercial refrigeration systems.

Copyright Goodheart-Willcox Co., Inc. 2017

53.1 Commercial Refrigeration Troubleshooting

For a commercial refrigeration system to operate correctly, the following parts of the system must exhibit the following capabilities:

- Cooling (low side).
  - A. Enough liquid refrigerant must be in the evaporator.
  - B. Evaporator pressure must be low enough so that the liquid will boil at the correct temperature.
  - C. Heat from the items being cooled must transfer to the liquid refrigerant in the evaporator.
- Condensing (high side).
  - A. Vapor must be pumped into the condenser at the correct pressure and temperature.
  - B. Heat must be removed from the condenser (clean condenser and adequate airflow or water flow).
  - C. There must be enough vapor space (heat transfer surface area) in the condenser.
- Liquid line (high side).
  - A. Tubing must be large enough.
  - B. There must be as few restrictions as possible (pinched pipes, partially clogged screens, filter-driers).
  - C. Only liquid refrigerant should be in the liquid line.
- Suction line (low side).
  - A. Vapor and oil should flow freely in the suction line.
  - B. Only a small pressure drop is allowable.
  - C. Any screens and filter-driers must not be restricted in any way.

System diagnosis starts with the owner's report. Then the low-side and high-side pressures and the evaporator temperature should be measured and compared with normal operating measurements, which should already be recorded after the system's installation. Check the sight glass for bubbles. Feel the suction line. It should be cool but not cold. A cool suction line contains vapor as it should, while a cold suction line contains liquid. Feel the liquid line. It should be warm but not hot. A warm liquid line contains liquid as it should, but a hot liquid line contains hot-gas vapor that did not condense and subcool.

To determine the source of the trouble in a refrigeration system, a technician must determine what is going on inside. Since the system is sealed, gauges are used to check refrigerant pressure throughout the system. Thermometers are used to measure temperatures along the evaporator, refrigerant lines, and condenser. A sight glass and a moisture indicator are used to check the flow of refrigerant and its moisture content.

Much of a troubleshooting investigation is based on logic. Technicians need to know what should be occurring inside a system. Then they must be able to visualize the movement and phase changing of the refrigerant and what each part of the system is supposed to do. A pressure-enthalpy diagram provides considerable aid in this area. The following sections show the effects of some of the more common troubles monitored using a pressure-enthalpy diagram.

53.1.1 Effect of Lack of Refrigerant

If a system is undercharged, each pound of refrigerant will not completely condense (liquefy) on the high side before it passes through the refrigerant metering device into the evaporator. The red vertical line in **Figure 53-1** shows where the refrigerant in an undercharged system passes through the refrigerant metering device. The dotted, black vertical line (left of the red line) represents where the refrigerant would have passed through the refrigerant metering device if the system had been properly charged. The brackets labeled *Heat not rejected from the refrigerant* indicate the amount of heat in Btu that is not absorbed in the evaporator or expelled from the condenser because of the lack of refrigerant. The results of an undercharged system are threefold:

1. The amount of latent heat absorbed into evaporator refrigerant is reduced, as indicated by the dotted red line in **Figure 53-1**. Therefore, the refrigeration or cooling effect is poor.
2. With heat still being absorbed but much less volume of refrigerant, pressure is low on the low and high sides. This does not allow all the high-side refrigerant to condense. Therefore, instead of all refrigerant liquid, some refrigerant vapor now passes through the refrigerant metering device into the evaporator, reducing the refrigerant metering device capacity.
3. This high-side vapor passing between the needle and seat of the refrigerant metering device at high velocity increases wear on the refrigerant metering device needle and seat.

In a dry evaporator or expansion valve system, the appearance of the valve body may be the first sign of low refrigerant. Under normal conditions the valve body frosts over evenly. It frosts evenly as far back as the liquid line connection. When there is too little refrigerant, the expansion valve body next to the liquid line will not frost. This frost method cannot be used for above-freezing evaporator operation conditions.

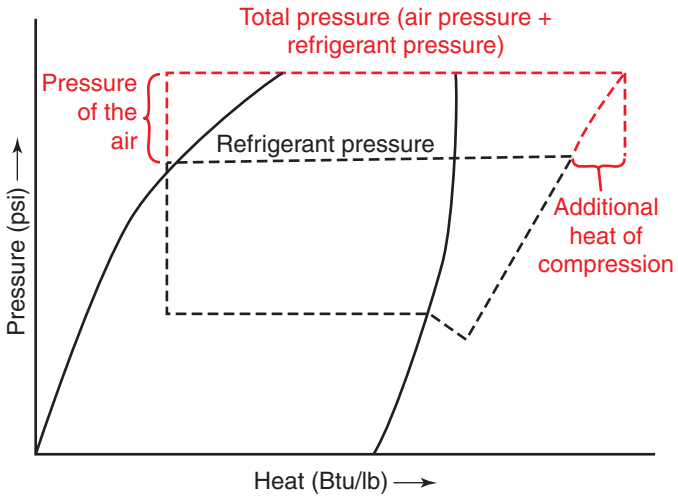
Goodheart-Willcox Publisher

Figure 53-1. Pressure-enthalpy diagram comparing the amount of latent heat of a properly charged system and an undercharged system. The latent heat not absorbed into evaporator refrigerant or rejected through the condenser will require the unit to run for a longer period of time to remove the same amount of heat as it would remove if it had a proper charge.



Goodheart-Willcox Publisher

Figure 53-2. Pressure-enthalpy diagram showing the effect of air in a refrigeration system. The additional heat of compression shows the additional heat energy put into the vapor as a result of the higher pressure the compressor must pump. The wasted energy is in the form of more electrical current needed to run the electric motor of the compressor against a higher head pressure. This consumes more electrical power than it would if pumping against a high side with no air in it.

53.1.2 Effect of Noncondensables in a System

Noncondensables are foreign substances that can enter a refrigeration system but do not phase change along with refrigerant. These substances can enter a refrigerant circuit through careless installation or service techniques.

Air is the most common noncondensable that gets trapped in a refrigeration system. Noncondensables inside the high side of a system increase the total head pressure, following the principles of Dalton's law. This means that total head pressure will equal the refrigerant condensing pressure plus the pressure of the noncondensables in the condenser. The refrigerant will have to condense at a higher temperature and pressure.

Because total head pressure is higher, the compressor has to pump the vapor to a higher temperature and pressure for heat rejection. The extra work performed by the compressor motor is illustrated in **Figure 53-2**.

The heat added to pump to the higher pressure is measured in Btu per pound of refrigerant. The cylinder head (especially the exhaust valve) and the top tube of the condenser will be at above-normal condensing temperatures. This higher temperature may harm the oil, which can lead to the formation of acids in the refrigerant circuit.

53.1.3 Excessive Head Pressure

If a condenser is undersized or dirty (internally or externally), heat cannot be rejected from the condenser as efficiently as it should. An undersized condenser does not have enough surface area to reject as much heat as a properly sized condenser. Dirt or film on a condenser's outer walls acts as an insulator, retaining more heat in the condenser. This extra heat builds up in the form of sensible heat, or heat that can be measured in degrees as a temperature rise. Gay-Lussac's law states that in a fixed volume, such as a condenser, as temperature rises, pressure also rises. Therefore, if a condenser is undersized or dirty, the resulting higher temperature will cause higher head pressure.

Figure 53-3 shows a refrigeration cycle diagram with normal and high head pressure. The higher pressure will require the compressor to draw higher electrical current to pump to the higher pressure and temperature, Loss C. The added heat of compression is shown horizontally between the normal head

Goodheart-Willcox Publisher

Figure 53-3. Pressure-enthalpy diagram showing the effect of a dirty or undersized condenser or an above-average ambient temperature. The pressure and heat increase marked by Loss A shows the unnecessary added heat from the higher compression. Loss B indicates the loss in effective latent heat of liquid. Loss C indicates the extra work of compression required to compress vapor at the higher total pressure, which causes more amps to be drawn by the compressor.

pressure and high head pressure, Loss A. If the liquid does not subcool as much as it could, there is additional heat that is retained in the refrigerant, Loss B. With this additional heat, refrigerant passing into the evaporator has less capacity than if properly subcooled, **Figure 53-3**.

53.1.4 Excessive Suction Line Pressure Drop

Excessive pressure drop can be caused by a clogged low-side, inline component (such as a filter-drier or EPR) in the suction line or a pinched length of tubing. If the pressure of the vapor going into the compressor decreases, the compressor will pump less weight of vapor per stroke. Therefore, less vapor will be pumped per minute. The less vapor pumped, the lower the capacity of the system.

Figure 53-4 shows the effect of excessive suction line pressure drop on the refrigeration cycle. According to the various gas laws, as a substance's pressure decreases, there are three possible results. Firstly, the substance can expand to fill a larger volume. Secondly, the substance can absorb heat to maintain its pressure. Thirdly, the substance can do a combination of both: expand to fill a larger volume and absorb heat. In other words, as pressure decreases, volume can increase and its heat content can increase (which may increase temperature).

Service Call Scenario

53A: Walk-In Cooler—No Cooling

Customer Complaint: No Cooling

Possible Causes: Defective flare fitting, plugged filter-drier, leaks within the system.

Description of Problem: The owner of a florist shop, Ms. Blake, has reported that the walk-in cooler where flowers are stored is not cooling. Prior to arriving at the jobsite, the technician, Jeremy, reviews the work order. Upon arriving at the shop, he identifies himself to Ms. Blake and listens carefully to her comments. Jeremy observes that the unit is running for long periods, but is producing little cooling.

Testing: Jeremy installs the gauge manifold and notes that the low-side pressure is higher than normal. He then performs a superheat reading that indicates high superheat. He surmises that a loss of refrigerant may be the cause of the lack of cooling. Jeremy performs a refrigerant leak test and finds a small leak at the flare fitting at the inlet of the thermostatic expansion valve. He tightens the flare nut and rechecks for leaks. The flare fitting continues to leak. He notes a small oil film under the flare fitting. This is an indication of a leak. He disconnects the flare nut and examines it. He confirms that there is a small split in the fitting that has been allowing refrigerant to leak out. Jeremy informs Ms. Blake that the unit must have been leaking for some time and that the flare should be redone, and provides a cost for such. Ms. Blake agrees to have Jeremy perform the services.

Solution: Jeremy recovers the system's refrigerant. He disconnects the old flare and a new flare is made and tightened. The system is evacuated and recharged. Jeremy starts up the system and tests for refrigerant leaks. No leaks are found. All pressures and temperatures are within normal ranges. The unit is now cooling. He then provides Ms. Blake with the bill and informs her that a follow-up call will occur.

Safety: Always wear eye protection and the correct gloves. Liquid refrigerant will freeze on contact with skin or eyes.

Copyright Goodheart-Willcox Co., Inc. 2017

Service Call Scenario

53B: Walk-In Cooler—No Cooling

Customer Complaint: No Cooling

Possible Causes: Dirty coil, overcharged system, defective compressor windings.

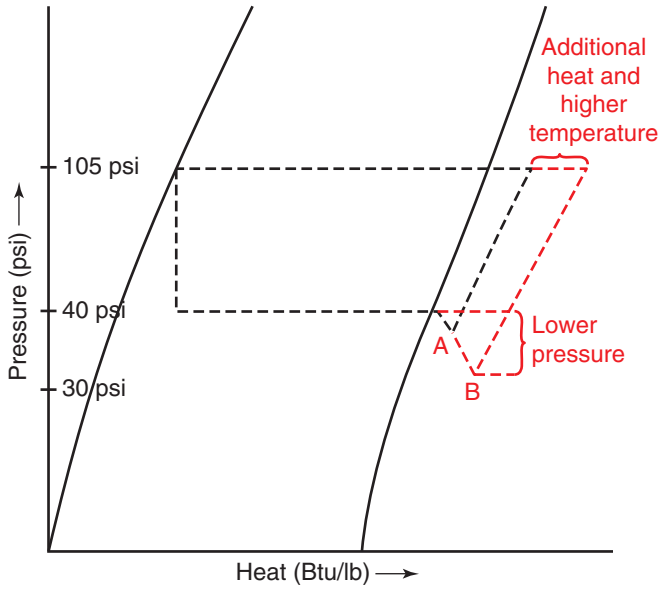
Description of Problem: Mr. Romano, the owner of a small diner, has reported that a walk-in cooler does not appear to be cooling. Prior to arriving at the jobsite, the technician, Manuel, reviews the work order. Upon arriving at the business, he identifies himself to Mr. Romano and listens carefully to his comments.

Testing: Manuel installs the gauge manifold to read the system's pressures. He notices that the compressor is short cycling and shutting down on high-pressure control. The high-side pressure is much higher than normal. When the high-side pressure increases to unsafe levels, the contacts of the high-pressure control open the control circuit. A further check indicates that the condenser coil is extremely dirty. The condensing unit is on the floor level and is exposed to kitchen floor debris. When the condenser coil is dirty, it restricts air movement across the coil, which, in turn, causes high-side pressure to increase. Manuel informs Mr. Romano of the conditions and the effect of the debris on the condenser. He recommends a thorough cleaning of the condenser and provides the cost for such. Mr. Romano agrees to have Manuel perform the service. Manuel turns the electrical power off to the unit. He thoroughly cleans the condenser using a coil cleaning solution. He then restores the electrical power to the unit and checks the system's pressures. All pressures and temperatures are now operating satisfactorily. The system is now cooling effectively. Manuel provides Mr. Romano with the bill and informs him that a follow-up call will occur.

Safety: High refrigerant pressures can be extremely dangerous. It is good practice to observe the condition of all components that may cause abnormal high-side pressures. Condenser and evaporator coils should be inspected on a regular basis for cleanliness. Dirty coils will affect cooling operation.

As a result of the pressure drop in the suction line, a smaller amount of vapor will expand to fill the volume available from the refrigerant held back by the pressure drop. The vapor also picks up heat, increasing its heat content (Btu) and temperature. This additional heat results in higher temperature at the compressor's exhaust valve.

An excessive suction line pressure drop requires the system's condenser to remove more heat from each pound of vapor. This prolongs system operation, wastes energy, and increases the cost of operation. When the exhaust valve temperature becomes too high, there is also a danger of refrigerant lubricant deteriorating.



Goodheart-Willcox Publisher

Figure 53-4. A typical refrigeration cycle is shown when there is an excessive pressure drop and temperature rise along the suction line between Point A and Point B. This causes excessive temperature at the compressor's exhaust valve and cylinder head.

53.1.5 Moisture in a Refrigeration System

Many troubles in refrigeration systems may be traced to the presence of moisture. Moisture circulates in the presence of oil and refrigerant at high temperatures, especially in the compressor and condenser. During circulation through the system, moisture has many complex effects.

Moisture may cause rusting, corrosion, or oil sludging, which could cause a compressor's motor to burn out. If the moisture content is high enough and the temperature low enough, moisture separates from refrigerant and freezes. Sufficient moisture will form ice in capillary tubes, expansion valves, or other refrigerant metering device orifices, thus severely restricting flow and eventually blocking it entirely.

In hermetic refrigeration systems, moisture may also take part in a destructive chemical

Copyright Goodheart-Willcox Co., Inc. 2017

process. When excessive heat breaks down oil and refrigerant, the mixture combines with moisture to form an acid that ruins motor winding insulation. Immediate action must be taken to remove all moisture or to make the moisture harmless. This will eliminate many troubles.

The occurrence and extent of moisture and refrigerant separation depends on temperature and the solubility of water in a given refrigerant. The greater the solubility, the less water separation from the refrigerant in a system and the less ice formed, **Figure 53-5**.

Refrigerants must be stored in sealed containers and must be kept completely dry. Most refrigerant manufacturers supply refrigerants that are dry (virtually free of moisture). The moisture content of previously unused refrigerant never exceeds 5 ppm (parts per million). Liquid refrigerants can hold more moisture in solution as the low-side temperature rises. This enables the refrigerant to circulate without danger of the moisture separating from it. Moisture that separates may freeze or form harmful compounds.

Moisture indicators with a sight glass are used to identify the amount of moisture in a system. They are located downstream from the liquid line filter-drier. The color of the moisture indicator changes with the presence of moisture in the system. For example, R-404A is dry below 20 ppm. An R-404A system has too much moisture above 75 ppm. A table of acceptable moisture content levels for certain refrigerants is shown in **Figure 53-6**.

Any amount of moisture at or above the wet value ppm could be harmful to the system. This is an indication that the filter-drier should be replaced. The presence of moisture in a refrigerant may be determined by a moisture indicator installed in the liquid line. A moisture indicator contains a special material in a sight

Refrigerant Moisture Content Levels		
Refrigerant	**Dry**	**Wet**
R-12	Below 5 ppm	Above 20 ppm
R-22	Below 30 ppm	Above 125 ppm
R-134a	Below 25 ppm	Above 110 ppm
R-404A	Below 20 ppm	Above 75 ppm
R-502	Below 15 ppm	Above 50 ppm

Note: Moisture levels correspond to refrigerant at 75°F (24°C).

Goodheart-Willcox Publisher

Figure 53-6. For best operation, these refrigerants should have a moisture content in the dry range. At the wet levels, moisture will begin freezing on the low side at the expansion valve.

Moisture Solubility, ppm by Weight

Copyright Goodheart-Willcox Co., Inc. 2017

glass that changes color depending on the amount of moisture in the refrigerant, **Figure 53-7**. Moisture indicators are covered in depth in Chapter 22, *Refrigerant Flow Components*.

Moisture must be removed from refrigerant; however, it may be impossible to remove all the moisture from a refrigerant. Nonetheless, the amount of moisture should still be kept very low. The maximum amount of moisture allowed will vary with the kind of refrigerant and the low-side temperature.

A service technician must depend on the moisture indicator to determine the amount of moisture in a system. If the moisture indicator's element changes color to show excessive moisture content, a new filter-drier and moisture indicator should be installed in the liquid line.

Some moisture indicators have replaceable elements that can be exchanged. Others require the entire indicator housing to be replaced. Always recover the refrigerant per EPA Section 608 guidelines and pull a deep vacuum on the system to remove as much moisture as possible from the unit. The system should then be operated until the moisture indicator indicates a dry condition. It may sometimes be necessary to replace the filter-drier several times to remove sufficient moisture from the system.

Pro Tip

Avoid Condensation Infiltration

When servicing a system, avoid exposing cold internal parts to ambient air. Moisture from the air will condense on the parts inside the system. Warm the cold parts to room temperature with a heat lamp before opening the system.

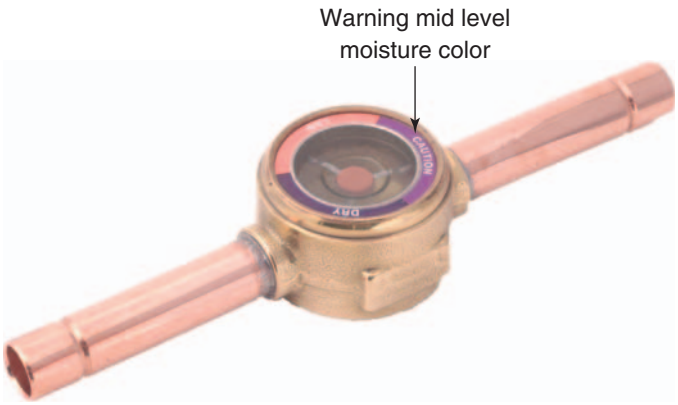
Many moisture indicators have a dry color and a wet color. However, some manufacturers produce moisture indicators with a third color to serve as an intermediate moisture state between dry and wet refrigerant conditions. This middle stage color serves as an early warning that moisture is accumulating. Technicians monitoring these moisture indicators can schedule any necessary preventive maintenance to avoid major breakdowns, **Figure 53-8**.

There are a number of ways of removing moisture from an HVACR system, including:

- Temporarily installing special filter-driers into the system.
- Recovering the refrigerant through special filter-driers.
- Pulling a vacuum on the system after recovering its refrigerant charge.
- Performing the triple evacuation procedure that includes injecting dry nitrogen after the first and second vacuums. Refer to Chapter 11, *Working with Refrigerants*, for more information on these procedures.

Danfoss

Figure 53-7. Moisture indicators are available in different sizes and with different types of connection, such as brazed or flare nut.



Emerson Climate Technologies

Figure 53-8. This moisture indicator monitors moisture at three different levels (dry, caution, and wet) that are represented by three different colors.

As an HVACR system cycles on to begin operation, bubbles will usually appear in the sight glass. This is normal. If bubbles continue to appear, the system may be low on refrigerant or the liquid line filter-drier may be partially clogged. In this case, if the filter-drier is clogged, the filter-drier will feel cooler than normal to the touch. This is because the filter-drier is acting much like a metering device and creating a pressure drop across the refrigerant line. This cooler temperature happens because the clog is reducing pressure and allowing liquid refrigerant to evaporate. The evaporating refrigerant is absorbing heat, which produces a cooling effect. Compare the temperature of the filter-drier at its inlet and at its outlet. A noticeable temperature difference generally indicates a pressure drop caused by a clog.

Copyright Goodheart-Willcox Co., Inc. 2017

When bubbles in the sight glass and a cool filter-drier indicate that a filter-drier is clogged, many service technicians will install a large drier in the liquid line of the system on a temporary basis. These large driers quickly clean the system and remove moisture, **Figure 53-9**.

A properly operating drier becomes warmer as refrigerant flows through it and as the drier absorbs water from the refrigerant. This warming may be used as an indication that the drier is absorbing water. A sight glass with a moisture indicator installed further down the liquid line will determine whether the system's refrigerant is dry.

53.2 Checking Refrigerant Charge

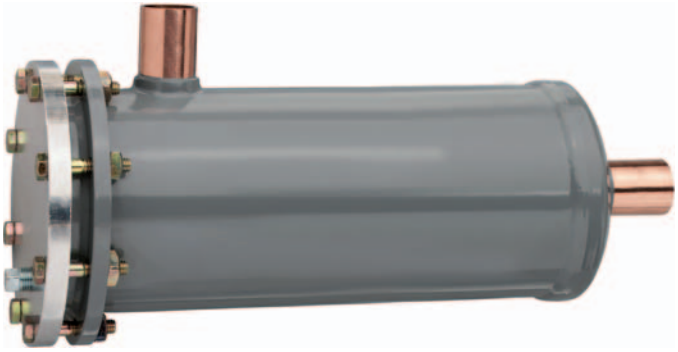
The best way to ensure a proper refrigerant charge is to weigh in the exact amount into a system in vacuum. The proper method for checking a charged HVACR system's refrigerant charge is the superheat/subcooling method. However, in certain circumstances, a technician may need to quickly assess a system's operation and its approximate charge. When time and circumstances permit, weigh in the exact charge or perform the superheat/subcooling methods. Only when necessary, check a system's refrigerant charge by monitoring suction and head pressure and the condition shown in the sight glass.

A popular way to check for sufficient refrigerant charge is by monitoring a sight glass in the liquid line. When head and suction pressure are near manufacturer specifications and no bubbles appear in the sight glass, the refrigerant charge should be acceptable. Chapter 22, *Refrigerant Flow Components*, previously covered sight glasses. Most sight glasses are equipped with a moisture indicator. Manufacturers each have their own color-coding to indicate a system's moisture condition. If the sight glass is equipped with a moisture indicator, the technician can also tell at a glance whether there is a safe and acceptable level of moisture in the system.

A sight glass can be installed permanently into the liquid line or temporarily clamped onto the liquid line using an electronic sight glass. With a permanent sight glass, a technician can look into the refrigerant circuit and see if there are bubbles present in the liquid line. Bubbles may indicate an insufficient refrigerant charge in the system. An electronic sight glass is convenient in that installation does not require opening the refrigerant circuit, **Figure 53-10**.

A sight glass is not a sure-fire method of evaluating a system's refrigerant charge. Conditions other than a low refrigerant charge may cause bubbles in the liquid line. Two conditions to consider are location and insulation.

Where is a liquid line installed? Is it outdoors in extreme weather conditions or passing through uninsulated or unconditioned parts of a building? Does the liquid line have insulation that will protect the refrigerant from these outside influences? These factors may cause liquid refrigerant to change phase into a vapor. This is why a sight glass should be installed as close to a system's refrigerant metering device as



Courtesy of Sporlan Division - Parker Hannifin Corporation

Figure 53-9. A large temporary filter-drier is installed to clean the system and remove moisture.

TIF™ Instruments, Inc.

Figure 53-10. This electronic sight glass clamps onto tubing and senses bubbles flowing within liquid refrigerant.

Copyright Goodheart-Willcox Co., Inc. 2017

possible. Also, whenever possible, a sight glass should be mounted in the liquid line downstream or after the filter-drier (between the filter-drier and refrigerant metering device) and any other in-line components.

Other conditions may cause bubbles in the liquid line. Bubbles may appear if tubing or a component upstream of a sight glass has a restriction. Even when there is sufficient refrigerant in the system, bubbles may appear in a sight glass. Be aware of these circumstances before using a sight glass as a way of checking refrigerant charge. Nonetheless, as a quick check method when suction and head pressures are acceptable, no bubbles appearing in a sight glass is a decent indication that an HVACR system probably has enough refrigerant.

53.3 Diagnosing Common Symptoms

Methods of testing to locate sources of trouble are based on a system's operating principles. Checking pressures, temperatures, running time, and electrical current or voltage helps to pinpoint the faulty part.

Technicians must have a thorough knowledge of refrigeration fundamentals and cycles. Only then can they become reliable and competent at trouble tracing and diagnosis. Troubles in a refrigeration system should be located before dismantling. This keeps the cost of servicing at a minimum and ensures proper operation of the unit after repair and assembly.

Methods of locating troubles vary with the type of system. This is especially true when comparing systems using direct expansion refrigerant metering devices with those using a capillary tube. A capillary tube is a passive device designed to provide only a fixed pressure drop. Most expansion valves are able to vary their pressure drop if necessary depending on high-side pressure and superheat.

A call for service should include at least one of the symptoms of the underlying trouble. The owner may say that the unit is not freezing but still runs continuously, or, the unit is freezing but runs continuously. The owner may say that it costs too much to operate a system. These complaints will usually give some indication as to what the trouble may be. Always verify these statements by checking over the refrigeration system before attempting any troubleshooting or service work.

In trouble tracing, first classify the type of service call. Then determine what caused the trouble described in the service call. The following troubleshooting pointers have been prepared to help in this procedure. Naturally, it is impossible to give every detail. However, once a technician learns the method of tracing trouble, there should be no difficulty.

Check all of the following variables in a refrigeration system before deciding what the trouble is:

- Suction pressure: _____ psi.
- Head pressure: _____ psi.
- Evaporator temperature: _____ °F/°C.
- Liquid line temperature: _____ °F/°C.
- Suction line temperature: _____ °F/°C.
- Superheat: _____ °F/°C.
- Subcooling: _____ °F/°C.
- Refrigerant charge amount: _____.
- Dryness of refrigerant (sight glass): _____.
- Running time of mechanism: _____ minutes.
- Probability of leaks.
- Noise.

Several basic fundamentals make locating trouble easier. When there is poor or no refrigeration, either or both of two things can be wrong:

- There is little or no refrigerant.
- The compressor is not moving the refrigerant. Pressures are not correct.

If there is no refrigerant, there will be no liquid refrigerant in the evaporator. This could mean that refrigerant has leaked out or is being held in a certain part of the system. It could be held due to clogged needles, clogged screens, or pinched lines. Clogging on the low side causes a high vacuum reading on the suction service valve.

A lack of refrigerant throughout the system causes a hissing sound at the refrigerant metering device. This indicates the refrigerant passages are not entirely closed. The sight glass will show bubbles.

The hissing sound at the refrigerant metering device always indicates a lack of refrigerant. The dry gas going through the restriction causes the hissing noise. This may be from the system being undercharged or perhaps having a restriction in the liquid line.

If a compressor is not functioning properly, the low-side pressure will be above normal. The condenser and discharge line from the compressor will be below normal temperature.

To determine what is responsible for a poor condensing condition (usually excessively high head pressure due to a dirty condenser or an overcharge of refrigerant), install the gauge manifold. Then measure the head pressure. Compare this pressure reading with what the pressure should be for the refrigerant being used. Check that the airways of an air-cooled condenser are free from

Copyright Goodheart-Willcox Co., Inc. 2017

obstructions, that the tubing and fins are clean, and that the condenser fan is operating properly.

53.3.1 Low or No Refrigeration—Unit Runs Continuously

A common service call is low or no refrigeration with the unit running nonstop. This refrigeration system is not performing adequate cooling and continuously operating in an attempt to reach its cutout point. This type of condition is handled differently depending on whether the system has an expansion valve or capillary tube as its refrigerant metering device.

Undercharged System with a Capillary Tube

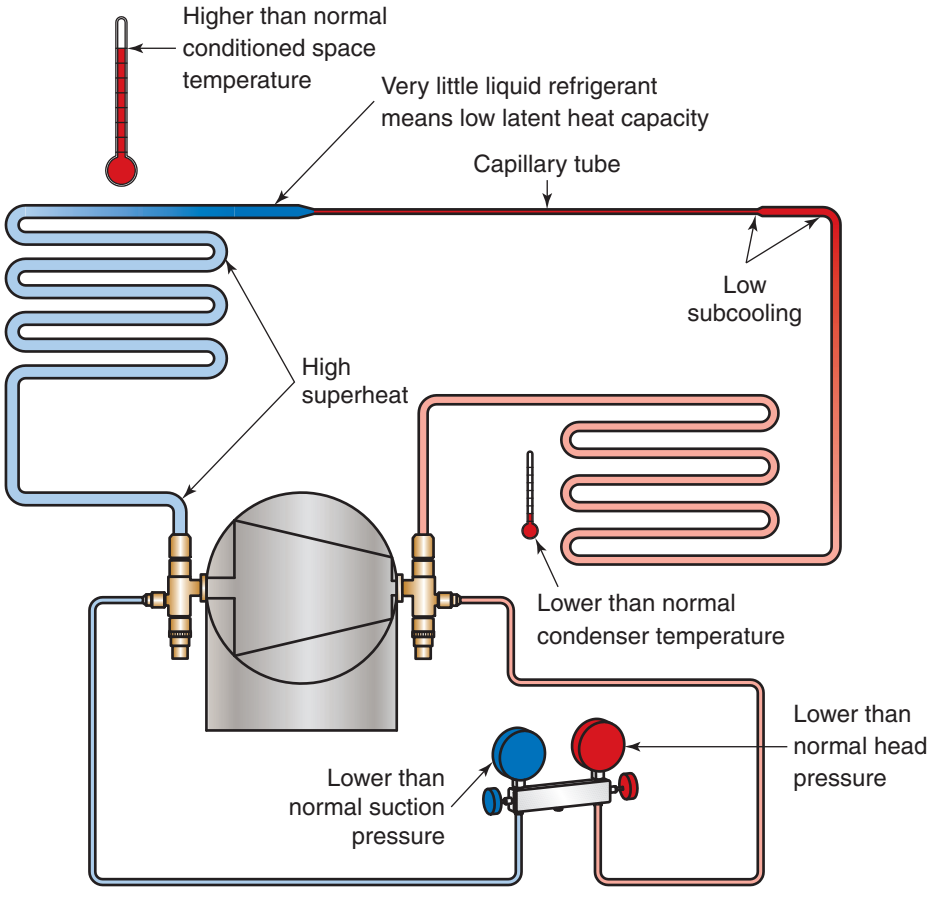
No or low refrigeration in a system with a capillary tube as its refrigerant metering device will probably not be able to remove enough heat to reach its cut-out point. It will run continuously. A likely cause is an undercharge of refrigerant.

Conditioned space temperature will be higher than normal, as not as much refrigerant will be available to absorb heat. Suction pressure will be lower than normal, as there is less refrigerant than normal.

Since there is very little liquid refrigerant in the evaporator, there will be less evaporation and less latent heat absorbed. This severely reduces the amount of heat absorbed. Much of the heat that is absorbed in an undercharged system will be sensible heat, which will mean a high superheat. This high superheat is still a much lower amount of heat (in Btu) than if there were more refrigerant and more latent heat being absorbed.

With less heat and less refrigerant for the compressor to pump, condenser pressure and temperature will be low. This lack of heat will also mean low subcooling. A low refrigerant charge in a capillary tube system will produce a hissing sound as the compressor shuts off.

A continuously running capillary tube system producing no or low refrigeration probably has an undercharge of refrigerant. Both low-side and high-side pressures will be below normal. Review the diagram in **Figure 53-11** for system characteristics of an undercharged capillary tube.



Goodheart-Willcox Publisher

Figure 53-11. An undercharged refrigeration system with a capillary tube as its refrigerant metering device will exhibit characteristics as shown in this diagram.

Undercharged System with a Thermostatic Expansion Valve (TXV)

A refrigeration system with a TXV that produces low refrigeration may be undercharged. This system will have a higher than normal conditioned space temperature, but suction pressure will be lower than normal. Since the evaporator will be starved of liquid refrigerant, any liquid refrigerant will quickly boil off and absorb sensible heat, creating a high superheat.

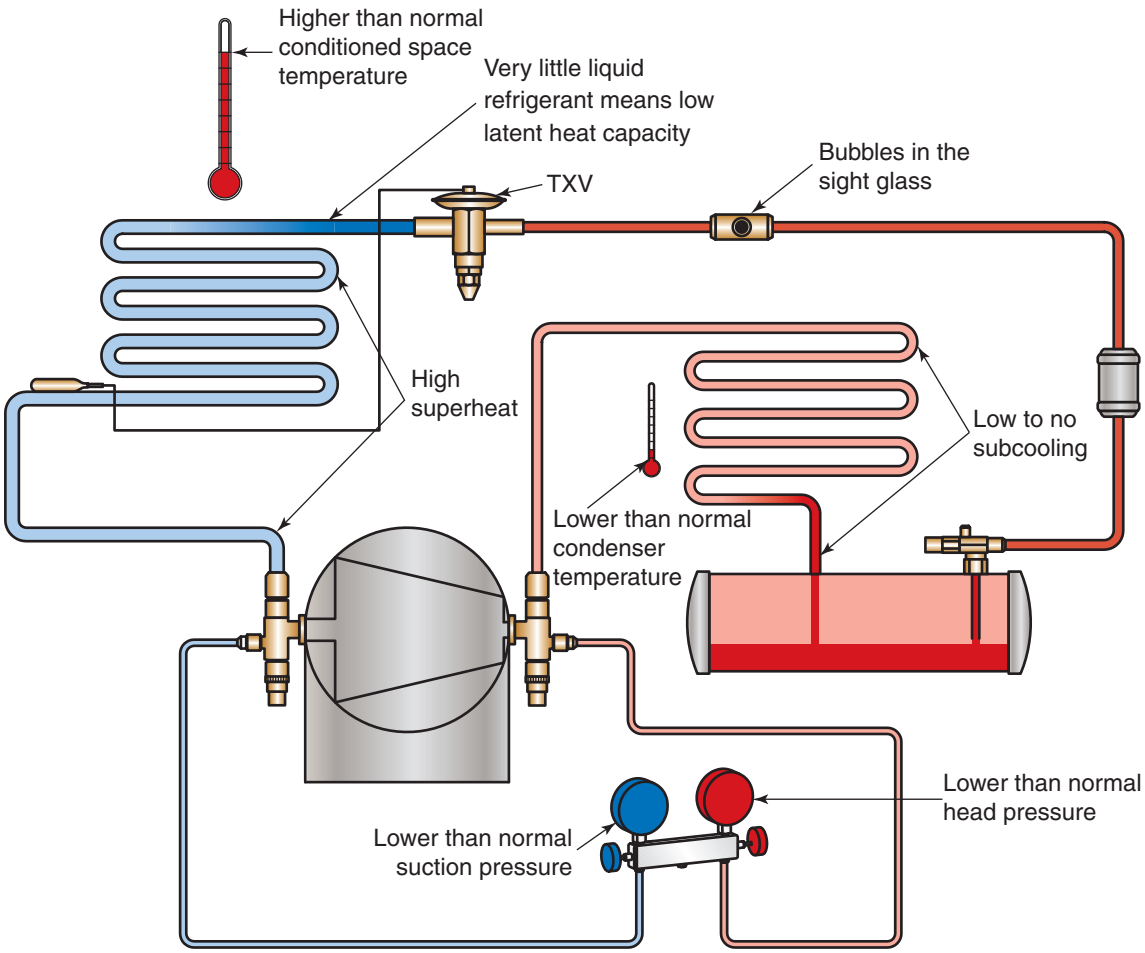
With less than normal heat being absorbed in the low side, less heat will be transferred to the high side. This will result in lower than normal condenser temperature and pressure. With so little heat, the refrigerant will have a low subcooling. With less heat and less liquid refrigerant available, some vapor will travel through the liquid line. This is evident as bubbles appear in the sight glass. Review the system diagram in **Figure 53-12**.

In an undercharged system with a TXV, frost or sweat may collect on the evaporator outlet tubing and reach as far as the TXV's sensing bulb. Another indication of refrigerant shortage is a warmer than normal or hot liquid receiver and liquid line. The extra heat indicates hot-gas refrigerant that has not condensed or subcooled. This vapor refrigerant should be visible as bubbles in the sight glass.

System with a Restriction in Its Capillary Tube

A refrigeration system that runs continuously but cannot cool down to normal temperature may have a restriction in its capillary tube. A restriction allows a smaller than normal amount of refrigerant to pass from the liquid line into the evaporator. Less refrigerant means less evaporation and less latent heat being absorbed. This reduces evaporator heat-absorbing capacity. Since less heat is being absorbed, conditioned space temperature rises above normal levels. Much of the heat that is absorbed is sensible heat, which means there will be a high superheat.

Meanwhile, the system's compressor continues pumping. With a constant compressor and less refrigerant and less heat absorbed, the suction pressure



Goodheart-Willcox Publisher

Figure 53-12. An undercharged refrigeration system with a thermostatic expansion valve will exhibit characteristics as shown in this diagram.

Copyright Goodheart-Willcox Co., Inc. 2017

drops. Lower pressure means a lower refrigerant temperature. However, since there is less refrigerant, the lower temperature is not enough to lower conditioned space temperature to the cut-out point, but the low temperature means that superheat will be high.

With less heat absorbed on the low side, less heat is moved into the high side. Since capillary tube systems do not use a liquid receiver, refrigerant accumulates in the condenser. There it has enough time to expel more heat than usual, which increases subcooling. Since capillary tube systems do not have a large charge of refrigerant and the subcooling is higher than normal, head pressure will be normal or lower than normal. Review operating characteristics of a refrigeration system with a restriction in its capillary tube in the diagram in **Figure 53-13**.

If a continuously running system with low or no cooling due to a capillary tube restriction does have high head pressure, it may be due to one of the following factors:

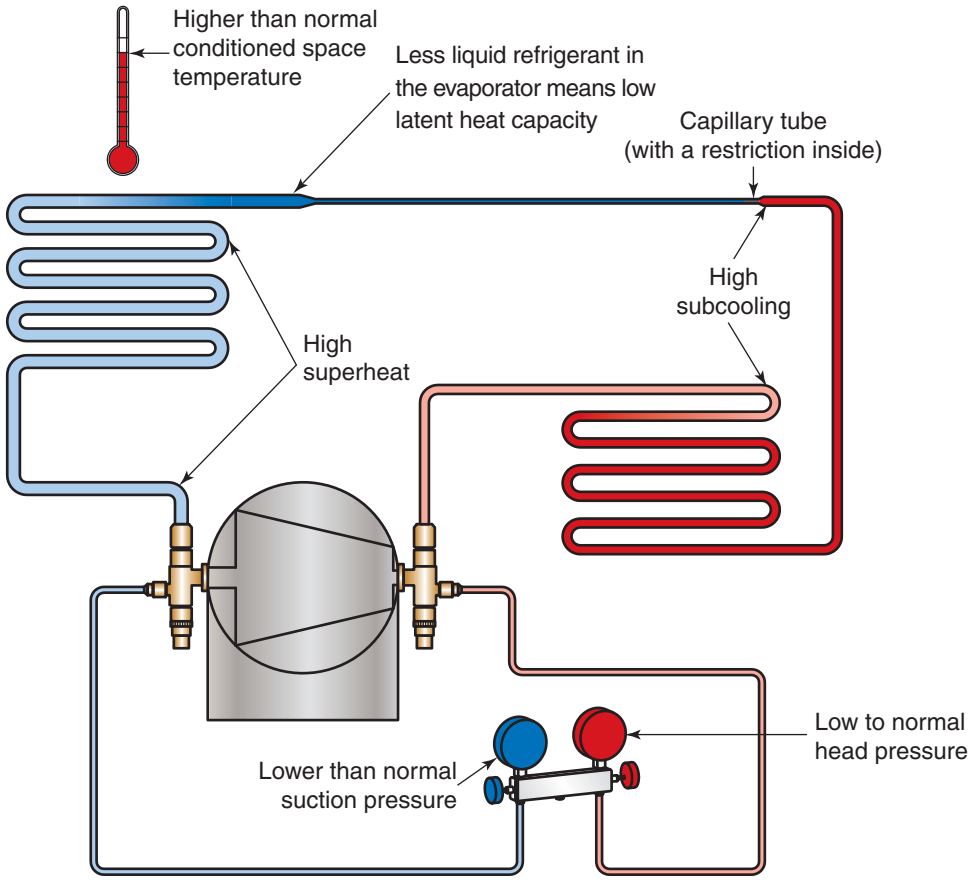
- An overcharge of refrigerant—especially in a critically charged system (one that requires a very precise charge).
- High ambient temperatures.
- Reduced airflow through the condenser.
- A thick coating of dirt and grime on the condenser.

As a capillary tube's restriction gets worse, an evaporator's cooling ability decreases. Suction pressure will decrease proportionally. Often, a customer will not realize that a system is malfunctioning until the evaporator is in or nearly in vacuum.

A restriction in a capillary tube may be due to clogging debris or frozen moisture. Upon opening a system, a technician often finds the restriction at the inlet end of a capillary tube, which will be clogged with debris. This may result from a filter-drier's beads gradually breaking apart and slowly accumulating over time. Often, a technician may cut off an inch or two of the clogged end of the capillary tube. This should not adversely affect operation. Also, the filter-drier should be replaced.

System with a Restriction in Its Thermostatic Expansion Valve (TXV)

A system's TXV can become clogged in more than one way. A piece of dirt or debris may become lodged in the valve, restricting flow and possibly making it impossible for the valve to fully close. Also, the TXV's inlet screen may become clogged. Also, moisture circulating



Goodheart-Willcox Publisher

Figure 53-13. A refrigeration system with a restriction in its capillary tube will exhibit characteristics as shown in this diagram.

Copyright Goodheart-Willcox Co., Inc. 2017

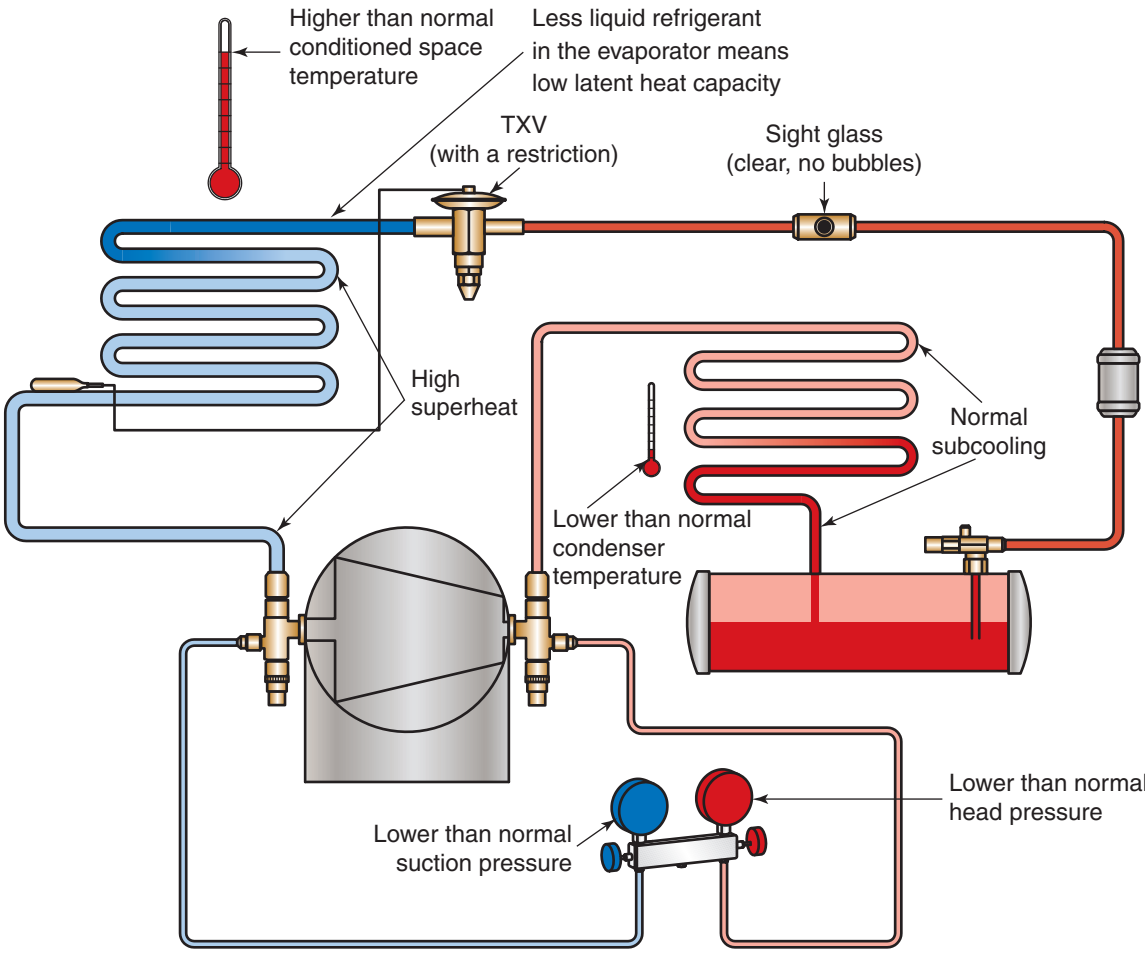
with refrigerant can separate and freeze at a cold spot. A common point of freezing is on an expansion valve, where it can restrict the passageway. Screen clogging and moisture freezing at the refrigerant metering device each cause a system to behave in the same manner. The difference is in how to fix the problem.

When a system's TXV has a restriction, such as a clog or ice formation, less refrigerant passes from the liquid line through the TXV into the evaporator. Less refrigerant results in a reduced low-side pressure. Less refrigerant also means less latent heat available for absorbing heat, so the conditioned space temperature will be higher than normal. The low-temperature, low-pressure refrigerant absorbs more sensible heat, which results in high superheat.

On the high side, condenser temperature is lower than normal, since less heat than normal was absorbed in the evaporator. Condenser pressure may be reduced somewhat; however, subcooling remains normal, as the bulk of the refrigerant is stored in the liquid receiver. Condenser pressure will only be higher than normal due to other common outside influences, such as high ambient temperature, reduced airflow, or an overcharge of refrigerant. Since sufficient liquid refrigerant will flow through the liquid line, no bubbles will appear in the sight glass. Review the characteristics of a system with a restricted TXV in the diagram in **Figure 53-14**.

Sometimes a restricted TXV is caused by a particle of dirt or some other minor contaminant. If a system needs to be quickly brought back into operation to preserve a product, a technician can use liquid refrigerant to flush the expansion valve. A more thorough repair can be scheduled at a later, more appropriate time for the customer.

If a restriction is thought to occur in a TXV, it may be one of three problems: ice formation, clogged valve, or restricted inlet screen. The simplest repair (without opening the system) is to first melt any ice in the TXV. The next step is to cycle the system to remove any debris trapped in the valve. If these procedures do not work, the system must be opened and the valve screen (if present) or entire valve replaced.



Goodheart-Willcox Publisher

Figure 53-14. A refrigeration system with a restriction in its thermostatic expansion valve will exhibit characteristics as shown in this diagram.

Copyright Goodheart-Willcox Co., Inc. 2017

Moisture frozen in a TXV may cause more than one problem. It may restrict refrigeration flow during the On cycle, and it may also prevent the TXV from closing properly during the Off cycle.

When a TXV cannot fully close, the evaporator will become flooded during the Off cycle. This could result in short cycling the system. Flooding during the Off cycle may be visibly evident in frosting or sweating on the suction line.

During the On cycle, an ice restriction in a TXV may reduce flow so much that temperature cannot drop enough to satisfy the thermostat. Even if the compressor operates long enough to satisfy the thermostat, there may be too much refrigerant continuing to flow into the evaporator to satisfy the pressure control, which will keep the compressor operating. An ice restriction often causes low-side pressure to fluctuate. A service technician must carefully review and analyze system behavior and measurements to determine what is causing a system to operate as it is.

SPX Corporation

Figure 53-15. A heat gun will provide safe and gentle heat for situations like melting frozen moisture in a TXV.

Fixing a System with a Frozen Moisture Restriction in the TXV

Moisture frozen in the refrigerant circuit at an expansion valve must be melted away before the system can return to normal operation.

1. If the refrigeration system has a liquid receiver, pump down the refrigerant into the liquid receiver. This will make it easier to heat the expansion valve. If a liquid receiver is not present, shut down the system and let the TXV warm up to room temperature.
2. Turn off the system. Use lockout tags to ensure that no one accidentally turns on the system.
3. Gently warm the expansion valve with a heat gun or wrap a warm rag around the valve, **Figure 53-15**. Warming an expansion valve above 32°F (0°C) for a while will melt any frozen moisture inside. Never use a torch or any type of flame to warm a TXV.
4. Return any line and service valves to the proper positions for normal operation.
5. Remove lockout tags and turn on the system.
6. Monitor evaporator temperature and both low-side and high-side pressure. Normal refrigeration should return when operation resumes.

If moisture continues to be a problem in a system, perform this procedure but also install a new filter-drier before returning the system to normal operation. If the customer will allow an even more thorough service call, suggest recovering and dehydrating the system's entire refrigerant charge and pulling a vacuum on the entire system.

Restrictions from ice formation in valves may occur when a filter-drier is saturated with moisture and releases some back into the refrigerant.

Flushing a Dirty Expansion Valve

If the expansion valve is stuck open, there may be dirt on the needle. To remedy this, the valve may be flushed.

1. Cycle the refrigeration system on.
2. Alternately open and close either the liquid receiver service valve (LRSV) or the liquid line hand shutoff valve. This will cause surges of liquid to rush past the expansion valve needle, cleaning it and removing any stuck debris.
3. Monitor evaporator temperature and both low-side and high-side pressures. If a restriction was properly removed, normal operating characteristics should be measured.

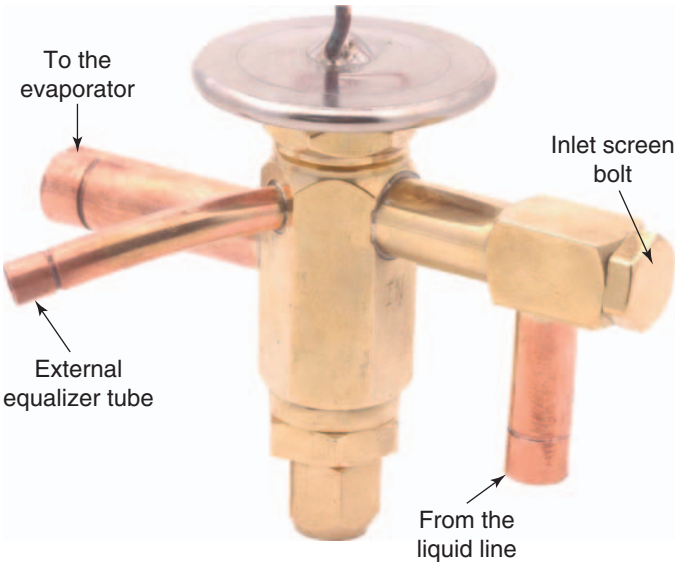
If this procedure fails to remedy the TXV restriction, follow a procedure on replacing a clogged inlet screen. If the valve does not have an inlet screen, replace the TXV.

Copyright Goodheart-Willcox Co., Inc. 2017

Replacing a Clogged Inlet Screen

A clogged inlet screen (strainer) can cause a system to operate poorly and eventually lead to equipment failure. Replace any clogged inlet screens with new, clean screens and replace a system's filter-drier.

1. Pump down the system.
2. Turn off and lock out system power.
3. Close any line valves possible to limit what parts of the system will be exposed to atmosphere.
4. Examine the system's TXV. Some TXVs have an easily removable inlet screen that is held in place with a bolt, **Figure 53-16**. Many of these may be removed without disconnecting the liquid line. Other TXVs have their inlet screens located just inside the inlet at the liquid line connection.
5. Replace the old, clogged screen with a new, clean screen or thoroughly clean as best as possible.
6. Reassemble the system parts. If the inlet screen was held in place with a bolt, discard the old gasket and install a new gasket.
7. A clogged inlet screen is an indication that the current liquid line filter-drier is beyond its point of usefulness and possibly beginning to disintegrate. It is a good idea to replace the liquid line filter-drier before restarting the system.
8. Close up the system and draw a vacuum on the parts of the system that were open to atmosphere during the replacement of the inlet screen.
9. After a satisfactory vacuum has been determined, check for and repair any leaks that may have previously gone unnoticed or developed during the replacement procedure.
10. Reopen the closed line valves and service valves, allowing refrigerant back into the rest of the system.
11. Undo the power lockout and restart the system.
12. Measure pressures and temperatures to ensure that normal operation has resumed.



Emerson Climate Technologies

Figure 53-16. TXV with an inlet screen (strainer) that is easily removed for inspection and cleaning.

Inefficient Compressor

Another cause of low or no cooling in a refrigeration system may be an ***inefficient compressor***. A compressor becomes inefficient after its working parts have sustained wear and tear. The compressor develops a noticeably reduced pumping ability. Low-side pressure will be higher than normal, and high-side pressure will be lower than normal.

With an inefficient compressor, discharge pressure at the compressor outlet will be low, due to leaking valves; however, subcooling should be normal. Refrigerant will spend enough time in the condenser to condense and subcool.

Low-side pressure will be high, due to compressor vapor pushing back into the low side through leaking compressor inlet valves. Since not as much refrigerant is being pumped through the refrigerant metering device, the evaporator will be somewhat starved of refrigerant. The refrigerant that does pass into the evaporator will quickly evaporate and then absorb mostly sensible heat. This will result in high superheat but low total heat absorption. The diagram in **Figure 53-17** shows operating characteristics that apply to a system with an inefficient compressor. These characteristics are the same whether the refrigerant metering device is a TXV or a capillary tube.

Overcharged System with a Capillary Tube

An overcharged refrigeration system using a capillary tube as the refrigerant metering device will not be able to cool its conditioned space sufficiently. Excess refrigerant creates higher pressure throughout the system. Higher pressure liquid in the condenser will force a greater quantity of liquid refrigerant into the evaporator. Liquid refrigerant will accumulate and flood the evaporator, raising evaporator pressure and

Goodheart-Willcox Publisher

Figure 53-17. A refrigeration system with an inefficient compressor will exhibit characteristics as shown in this diagram. These characteristics apply whether the refrigerant metering device is a TXV or a capillary tube.

temperature. Higher evaporator pressure and temperature will cause conditioned space temperature to be higher than normal. Liquid refrigerant pressure in the evaporator will be so high that there will be low or no superheat.

Excess refrigerant in the high side will cause high pressure in the condenser. The high pressure will raise condenser temperature higher than normal. The excess liquid refrigerant at higher temperature will result in higher subcooling. Review overcharge characteristics in a capillary tube system diagram in **Figure 53-18**.

Overcharged System with a Thermostatic Expansion Valve (TXV)

An overcharged refrigeration system using a thermostatic expansion valve (TXV) as the refrigerant metering device may not be able to cool its conditioned space sufficiently. Excess refrigerant creates higher pressure on the high side. Unlike a system with a capillary tube, a system with a TXV can better hold back the higher pressure of liquid refrigerant pushing its way into the evaporator. The TXV will do its best to meter refrigerant into the evaporator based on superheat. The superheat should remain normal; however, high-side pressure will be above normal and pushing more liquid refrigerant into the evaporator than normal. This will raise evaporator pressure and temperature somewhat. However, this all depends on the amount of overcharge and the operation of the thermostatic expansion valve.

With the TXV holding back much of the liquid-line refrigerant, the bulk of the overcharge will remain on the high side. Much of it will be in the liquid receiver, though there may be enough to flood much of the condenser. An overcharge of refrigerant raises condenser temperature and head pressure. Since refrigerant is crowded and not moving as much as normal, it will have enough time to subcool in ambient air. An overcharged system will have higher than normal subcooling. Review

Goodheart-Willcox Publisher

Figure 53-18. An overcharged refrigeration system with a capillary tube as its refrigerant metering device will exhibit characteristics as shown in this diagram.

overcharge characteristics in a TXV system diagram in **Figure 53-19**.

High-Side Restriction

A restriction can develop in any part of a system's refrigerant circuit. Determining its location depends on noticing the symptoms that do not correspond with normal operation and isolating the cause. With a restriction on the high side, a technician will first notice that the conditioned space is not cooling well and will be above its normal temperature. Evaporator temperature and pressure will be lower than normal. Superheat will be high.

High superheat and high conditioned space temperature indicate that the evaporator is starved and is not getting enough refrigerant. A system using a TXV should be responding to these conditions by opening wider to allow in more liquid refrigerant to lower the superheat. Perhaps the TXV is out of calibration or the sensing bulb is poorly installed. Perhaps something further upstream is restricting refrigerant flow. In any case, less liquid refrigerant in the evaporator means less heat will be absorbed from the conditioned space.

With less heat being absorbed in the evaporator, less heat is transferred to the condenser. Head pressure and condenser temperature should be lower than normal. Subcooling should be normal. If this is the case, then the restriction should be somewhere along the liquid line.

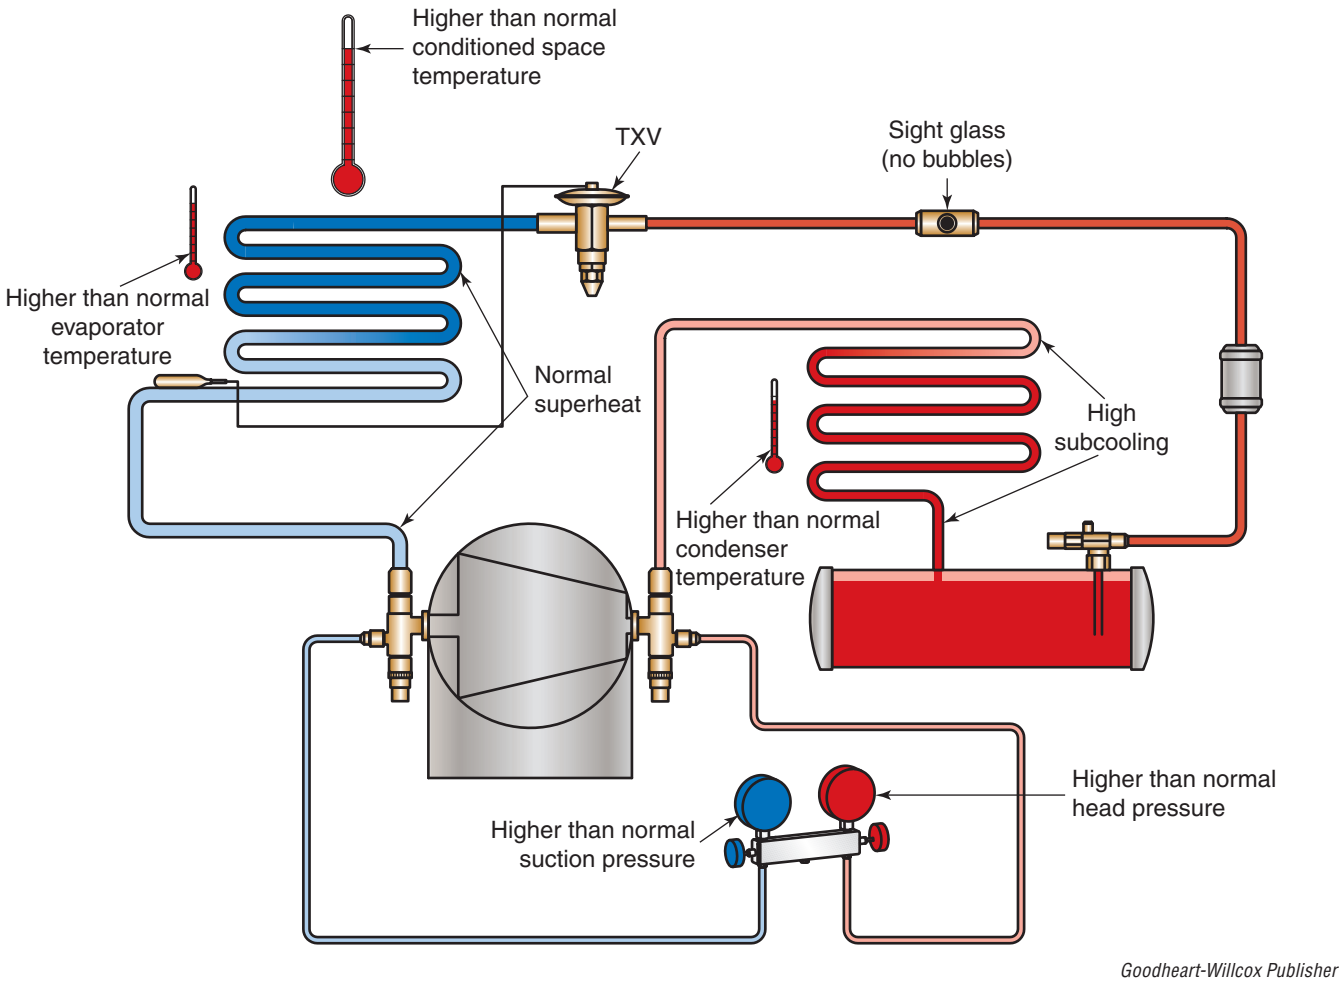
Pro Tip

High-Side Restrictions

There are only a few places upstream of a liquid line for a high-side restriction to develop. If it occurs at the inlet to the liquid receiver, three measurements will be higher than normal: head pressure, condenser temperature, and subcooling. However, most high-side restrictions occur along the liquid line where more inline components are installed, and there is a greater chance of a restriction.

Measure, record, and compare two temperatures: the condenser condensate line (outlet tubing)

Copyright Goodheart-Willcox Co., Inc. 2017



Goodheart-Willcox Publisher

Figure 53-19. An overcharged refrigeration system with a thermostatic expansion valve as its refrigerant metering device will exhibit characteristics as shown in this diagram.

and the end of the liquid line connected to the TXV. If these temperature values are close, then the problem may be the TXV. However, if there is a significant temperature difference, then the problem should be somewhere between these two points along the liquid line. To confirm this, check the sight glass, which should show bubbles from refrigerant evaporating in the liquid line.

Examine the liquid line for any obvious restrictions, such as kinks or sharp bends in tubing. Use an electronic thermometer to measure the temperature before and after any valves, filter-driers, sight glasses, and other tubing connections or bends. A temperature drop between two points will indicate a pressure drop, which will be the restriction. Review the characteristics of a refrigeration system with a restriction in the liquid line in the diagram in **Figure 53-20**.

Pro Tip

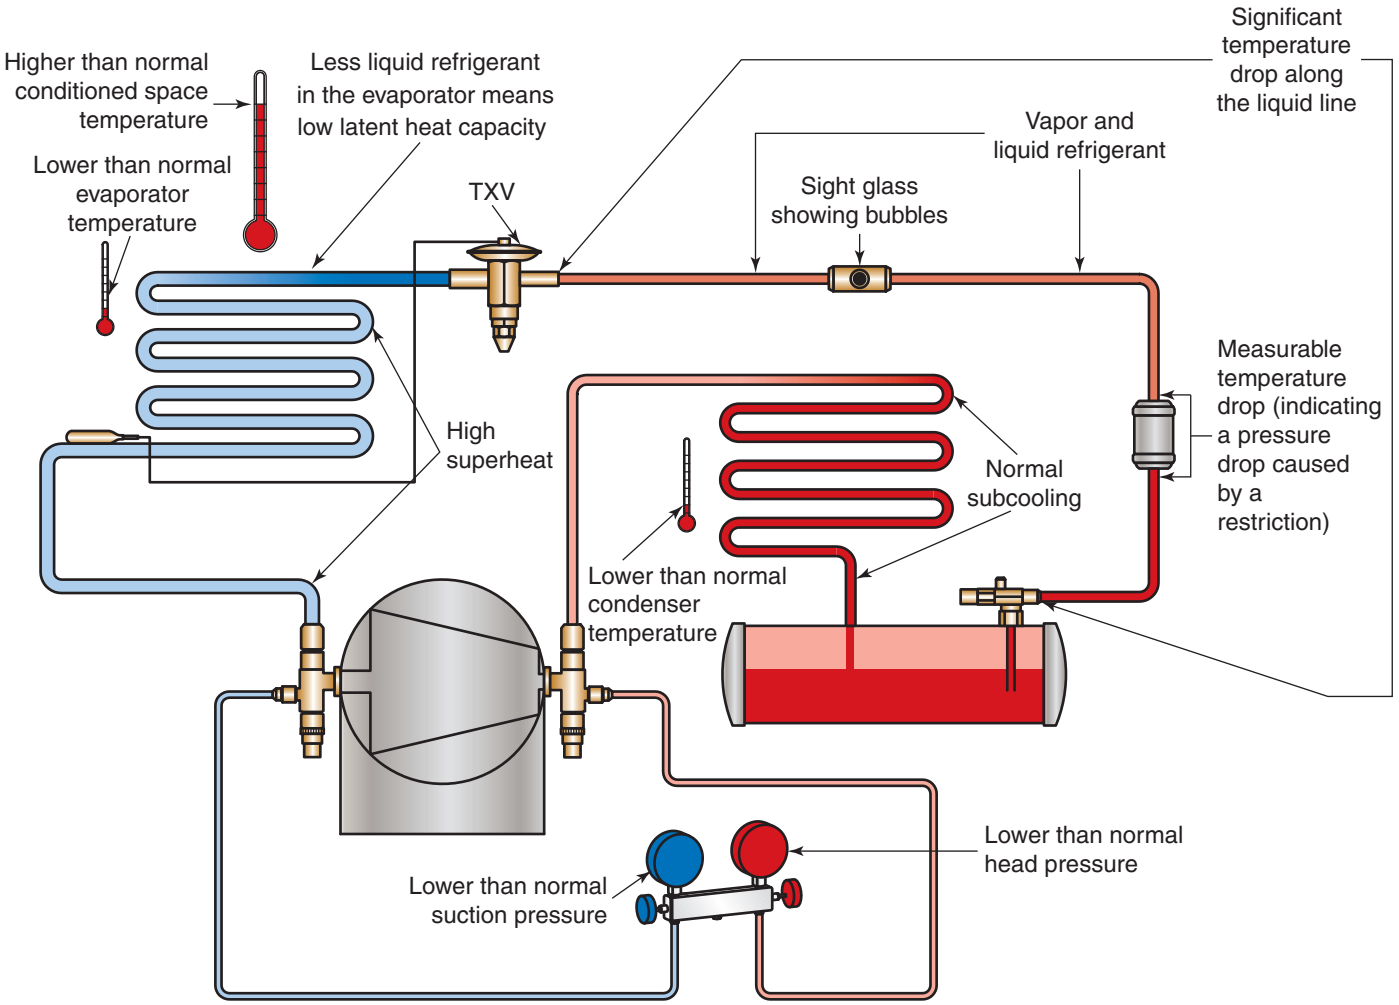
High-Side Restriction in a Capillary Tube System

If a refrigeration system with a capillary tube as its refrigerant metering device has a restriction on its high side, it will have different system characteristics than a system using a TXV. The restriction will most likely be along the liquid line. Like the TXV system, a capillary tube system will have an above normal conditioned space temperature, a low suction pressure, and a low evaporator temperature. However, it will have a high condenser temperature, high head pressure, and high subcooling. These are the same characteristics as a TXV system that has a restriction between the condenser and liquid receiver.

Low-Side Restriction

A restriction on the low side of a refrigeration system may develop somewhere along the suction

Copyright Goodheart-Willcox Co., Inc. 2017



Goodheart-Willcox Publisher

Figure 53-20. A refrigeration system using a TXV as its refrigerant metering device and having a restriction in the liquid line will exhibit characteristics as shown in this diagram. Taking a temperature survey throughout the length of the liquid line will reveal the location of the restriction.

line. This restriction will reduce the evaporator's cooling capacity, as it will hold back refrigerant, causing it to accumulate in the evaporator. This will increase evaporator pressure and temperature, which will raise the conditioned space temperature above normal. The TXV will try to stabilize superheat by holding back liquid refrigerant from the liquid line. Depending on how well the TXV pushes back against head pressure, superheat could be normal or low.

Often, a restriction on the low side is caused by a clogged suction line filter-drier. While evaporator pressure will be above normal, suction pressure (read by the suction service valve on the compressor) will be low (a vacuum). Condenser temperature and head pressure will be below normal. If the system has a proper refrigerant charge, subcooling should be normal. Review the characteristics of a refrigeration system with a restriction in the suction line in the diagram in **Figure 53-21**.

53.3.2 Normal to Excessive Refrigeration—Motor Running Continuously

Sometimes when a compressor runs continuously, a system will produce normal or too much refrigeration. The probable cause of the trouble is a faulty motor control.

Place a gauge manifold on the system and monitor conditioned space temperature. Check that the motor control is cutting out the compressor at the set point pressure and that this pressure corresponds to the desired evaporator case temperature.

Remember, there is a relationship between the control cut-out point and the low-side evaporating pressure. The control cannot stop a compressor's motor if the setting is lower than the evaporating pressure.

Goodheart-Willcox Publisher

Figure 53-21. A refrigeration system using a TXV as its refrigerant metering device and having a restriction in the suction line will exhibit characteristics as shown in this diagram.

A service technician should also check that the unit is not being overloaded. Examples include excessive door openings, placement of hot foods in the refrigerated space, and a faulty air curtain.

53.3.3 Low to Normal Refrigeration—Longer Than Normal Run Time

Some refrigeration systems take a longer than normal time to cool products in their conditioned space. This may happen gradually after years of operation, it may develop soon after a refrigeration system has been serviced. A likely cause of this condition is the presence of noncondensables trapped in the condenser.

Noncondensables flow through the refrigerant circuit until they reach the condenser. Liquid refrigerant typically blocks noncondensables from entering the liquid line. As a result, noncondensables become trapped in a system's condenser. They occupy part of the condenser where hot-gas refrigerant should be expelling heat. With less space in which to reject heat, condenser temperature and head pressure both rise. The compressor must work harder to push against the increased head pressure. The compressor's motor pulls more amps, consuming more electrical power than normal. Since noncondensables in the refrigerant circuit cause above average energy consumption by the compressor and less than normal heat rejection in the condenser, overall system efficiency decreases.

Noncondensables in a Capillary Tube System

Noncondensables trapped in the condenser of a capillary tube system increase head pressure and condenser temperature. The rise in condenser temperature increases subcooling. The higher head pressure pushes more liquid refrigerant through the capillary tube into the evaporator than normal.

Copyright Goodheart-Willcox Co., Inc. 2017

A capillary tube is a fixed pressure drop device that is intended to work with a limited incoming pressure. It cannot hold back against higher pressure caused by noncondensables in the condenser. The increased liquid refrigerant floods the evaporator. It also raises suction pressure. With so much extra refrigerant, superheat is low, as not all the refrigerant can evaporate. Review these characteristics in the system diagram in **Figure 53-22**.

Noncondensables in a TXV System

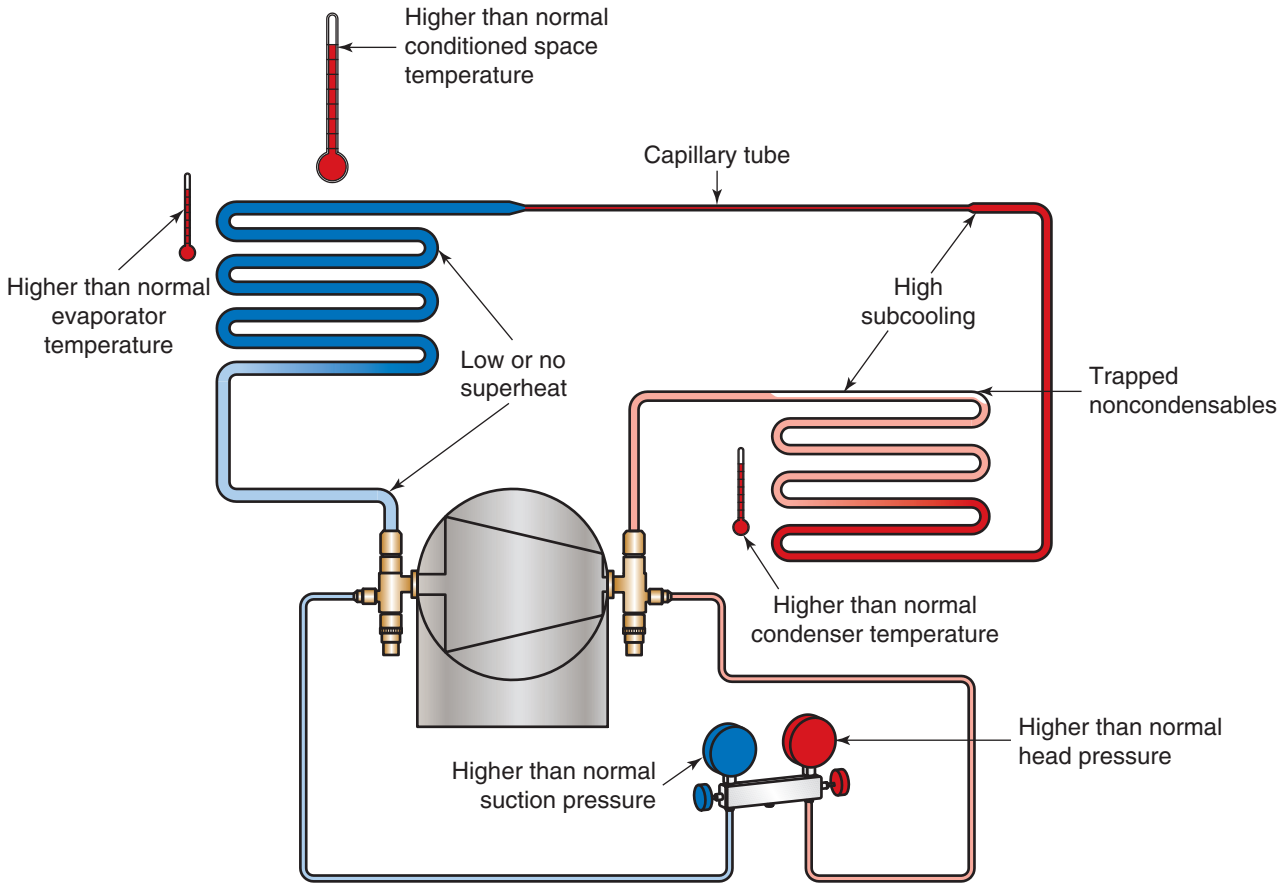
Noncondensables trapped in the condenser of a TXV system produce many of the same effects as in a capillary tube system. They will occupy part of the condenser surface area, reducing a condenser's ability to reject heat. This will raise head pressure and condenser temperature. Subcooling will also be high.

A TXV is better than a capillary tube at holding back the high head pressure pushing from the liquid line. However, a TXV's spring may not be able to withstand fully the increased head pressure, and more liquid refrigerant than normal may enter the evaporator. Liquid refrigerant may even flood the evaporator. In either case, suction pressure and evaporator temperature will be higher than normal. The conditioned space temperature will probably be higher than normal. Review these characteristics in the system diagram in **Figure 53-23**.

Servicing a System with Noncondensables Trapped in the Condenser

Unfortunately, refrigeration systems containing noncondensables trapped in the condenser exhibit symptoms similar to an overcharged system or a condenser with restricted airflow. The subcooling caused by noncondensables is higher than subcooling caused by a refrigerant overcharge or restricted condenser airflow. However, differences in system application and variable outside factors make it difficult to establish exact numbers to distinguish which condition is responsible.

The quickest way to determine whether a system's condenser contains noncondensables is to



Goodheart-Willcox Publisher

Figure 53-22. A refrigeration system using a capillary tube as its refrigerant metering device and having noncondensables trapped in its condenser will exhibit characteristics as shown in this diagram.

Goodheart-Willcox Publisher

Figure 53-23. A refrigeration system using a TXV as its refrigerant metering device and having noncondensables trapped in its condenser will exhibit characteristics as shown in this diagram.

measure and monitor head pressure after shutting off the system. Since condenser refrigerant continues to expel heat into ambient air during the Off cycle, head pressure drops in a continuous, gradual manner after shutdown. With noncondensables present, head pressure does not drop immediately. If head pressure remains constant for several minutes, noncondensables are probably trapped in the condenser. To accelerate this process, use a jumper to wire the condenser fans to run even after the compressor cuts out.

A more precise way of checking for noncondensables trapped in the condenser is to compare measurements with a P/T (pressure-temperature) chart. To service a refrigeration system with noncondensables trapped in the condenser, recover the refrigerant, pull a vacuum, and weigh in an exact refrigerant amount.

Quick Check for Trapped Noncondensables

1. Connect a gauge manifold to the refrigeration system.
2. Cycle on the compressor for several minutes to allow the system to reach normal operating conditions.
3. After levels have stabilized, write down system measurements for your records and to use in comparison after service procedures:
   - Suction pressure: _____ psi.
   - Head pressure: _____ psi.
   - Evaporator temperature: _____ °F/_____ °C.
   - Condenser temperature: _____ °F/_____ °C.

Copyright Goodheart-Willcox Co., Inc. 2017

- Superheat: _____ °F/_____ °C.
- Subcooling: _____ °F/_____ °C.
- Temperature in the conditioned space: _____ °F/ _____ °C.
- Bubbles in the sight glass: Yes _____ No _____.

4. Use a jumper wire as a temporary method of keeping the condenser fans running during the Off cycle.
5. Cycle off the compressor.
6. Check the condenser to ensure that condenser fans are still operating during the Off cycle.
7. Monitor head pressure levels for the next several minutes. Did head pressure begin to decline steadily after the compressor cycled off? _____
   - If yes, head pressure did steadily decline after compressor shutdown, then any measurements out of the ordinary were probably caused by an overcharge of refrigerant or restricted airflow through the condenser. There probably are not any noncondensables trapped in the condenser. Pursue other possible causes of high system measurements.
   - If no, the head pressure remained at the same level for several minutes after compressor shutdown, then any measurements out of the ordinary were probably caused by noncondensables trapped in the condenser. Perform the following steps:
8. Recover the refrigerant using inline filter-driers.
9. Pull a vacuum on the system to remove any noncondensables.
10. Charge the system with the exact amount of refrigerant recommended by the manufacturer.
11. Cycle the system on for a while and allow enough time for the conditioned space to return to normal temperature levels.
12. After the conditioned space is at its normal temperature, measure system characteristics, record them below, and then compare with previously recorded measurements:
    - Suction pressure: _____ psi.
    - Head pressure: _____ psi.
    - Evaporator temperature: _____ °F/_____ °C.
    - Condenser temperature: _____ °F/_____ °C.
    - Superheat: _____ °F/_____ °C.
    - Subcooling: _____ °F/_____ °C.
    - Temperature in the conditioned space: _____ °F/ _____ °C.
    - Bubbles in the sight glass: Yes _____ No _____.
13. Keep one copy of these normal operation measurements in your company files and leave another copy with this system.

P/T Chart Check for Trapped Noncondensables

1. Connect a gauge manifold to the refrigeration system.
2. Cycle on the compressor for several minutes to allow the system to reach normal operating conditions.
3. While waiting for system levels to stabilize, check labels and system records to determine which refrigerant is used in this system. Write down the type of refrigerant: _____. This information will be used in later steps of this procedure.
4. After levels have stabilized, write down system measurements for your records and to use in comparison after service procedures:
   - Suction pressure: _____ psi.
   - Head pressure: _____ psi.
   - Evaporator temperature: _____ °F/_____ °C.
   - Condenser temperature: _____ °F/_____ °C.
   - Superheat: _____ °F/_____ °C.
   - Subcooling: _____ °F/_____ °C.
   - Temperature in the conditioned space: _____ °F/ _____ °C.
   - Bubbles in the sight glass: Yes _____ No _____.
5. Use a jumper wire as a temporary method of keeping the condenser fans running during the Off cycle. This will more quickly bring condenser temperature down to ambient temperature.
6. Cycle off the compressor.
7. Check the condenser to ensure that condenser fans are still operating during the Off cycle.
8. Measure and record ambient temperature: _____ °F/_____ °C.

Copyright Goodheart-Willcox Co., Inc. 2017

9. Monitor the temperature of the condenser inlet and outlet tubing. Wait until these parts of the system are equal to ambient temperature.
10. Once condenser inlet and outlet tubing have dropped to ambient temperature, read and record head pressure on the high-pressure gauge: _____ psi.
11. Consult a pressure-temperature (P/T) chart to find the condensing temperature that corresponds to the head pressure reading: _____ °F/ _____ °C. Refer to Chapter 9, *Introduction to Refrigerants*, and the *Appendix* for various P/T charts. Be sure to use the proper row and column for the type of refrigerant used in this system.
12. Compare ambient temperature and the P/T chart's condensing temperature that corresponds to the head pressure reading. Are these numbers the same? _____
    - If yes, the condensing temperature and ambient temperature are equal, then noncondensables are not trapped in the condenser. Any high or low system measurements are a result of some other cause. Pursue other possible causes of high system measurements.
    - If no, the condensing temperature and ambient temperature are different, then noncondensables are trapped in the condenser. Perform the following steps:
13. Recover the refrigerant using inline filter-driers.
14. Pull a vacuum on the system to remove any noncondensables.
15. Charge the system with the exact amount of refrigerant recommended by the manufacturer.
16. Cycle the system on for a while and allow enough time for the conditioned space to return to normal temperature levels.
17. After the conditioned space is at its normal temperature, measure system characteristics, record them below, and then compare with previously recorded measurements:
    - Suction pressure: _____ psi.
    - Head pressure: _____ psi.
    - Evaporator temperature: _____ °F/_____ °C.
    - Condenser temperature: _____ °F/_____ °C.
    - Superheat: _____ °F/_____ °C.
    - Subcooling: _____ °F/_____ °C.
    - Temperature in the conditioned space: _____ °F/ _____ °C.
    - Bubbles in the sight glass: Yes _____ No _____.
18. Keep one copy of these normal operation measurements in your company files and leave another copy with this system.

Reduced Condenser Efficiency

An air-cooled condenser's job is to reject heat from its circulating refrigerant into ambient air. Its efficiency can be reduced multiple ways. Dirt or debris can accumulate on condenser fins and tubing and act as an insulator, reducing heat transfer. Objects can become lodged in condenser airflow passageways, reducing or stopping the flow of air, which limits heat transfer. Condenser fan blades can become damaged and move less air. Condenser fan motors can burn out and stop operating. Probably the most common cause of reduced condenser efficiency is the accumulation of dirt and grime on condenser tubes and fins.

A capillary tube system with reduced condenser efficiency will have higher head pressure and higher condenser temperature. However, subcooling will remain normal, as there will still be enough condenser surface area to subcool. This would not be the case with an overcharge of refrigerant or noncondensables trapped in the condenser.

The higher head pressure will force more liquid refrigerant through the capillary tube into the evaporator. This will somewhat flood the evaporator and raise suction pressure. Not all the excess refrigerant will be able to evaporate, so there will be no or low superheat. Conditioned space temperature will be higher than normal. Review system characteristics of a capillary tube system with reduced condenser efficiency in **Figure 53-24**.

Like a capillary tube system, a TXV system with reduced condenser efficiency will have higher head pressure and condenser temperature. Also, subcooling should remain normal. The higher head pressure will push harder against the TXV. The TXV's spring will only be able to hold back head pressure to a certain extent. More liquid refrigerant than normal will probably enter the evaporator.

Superheat will depend on head pressure and the TXV's response to it. If the TXV is strong enough, superheat will remain normal. If higher head pressure overcomes the TXV, then superheat will drop. In general, as

Service Call Scenario

53C: Walk-In Freezer—No Cooling

Customer Complaint: No Cooling

Possible Causes: Defective potential relay, defective start capacitor, shorted compressor windings.

Description of Problem: Mr. Delano, the owner of a restaurant, has reported that the walk-in freezer, which is used to store meat, is no longer cooling. Prior to arriving at the jobsite, the technician, Jessica, reviews the work order. Upon arriving at the restaurant, she identifies herself to Mr. Delano and listens carefully to his comments.

Testing: Jessica places the refrigeration unit in the cooling mode and observes its operation. She installs the gauge manifold to read the pressures. She notes that the compressor is humming but not starting. This is an indication that the problem is most likely in the compressor circuit. Jessica then checks the start capacitor and the potential relay. The microfarad rating of the start capacitor is confirmed to be within the normal range. The electrical source to the unit is turned off and the potential relay is checked with an ohmmeter. The contacts and coil of the potential relay are checked for resistance and it is noted that the coil is opened. This indicates that the coil is defective. Jessica informs Mr. Delano that the potential relay is defective and must be replaced. Mr. Delano agrees to have Jessica replace the potential relay.

Solution: After installing a new potential relay, Jessica starts the system. She notes all components are now operating satisfactorily. The unit's pressures and temperatures are all within normal ranges. Jessica then provides Mr. Delano with the bill and informs him that a follow-up call will occur.

Safety: Remember to bleed the electrical charge of a start capacitor before handling and performing a microfarad reading. The charge stored in the capacitor may hold a very high voltage spark. Some start capacitors are not equipped with a bleed resistor that assists in dissipating the charge.

Copyright Goodheart-Willcox Co., Inc. 2017

head pressure increases, superheat decreases. As superheat decreases, evaporator temperature increases. As evaporator temperature increases, conditioned space temperature increases. These examples show cascading effect of reduced condenser efficiency and the importance of regularly cleaning condensers. Review system characteristics of a TXV system with reduced condenser efficiency in **Figure 53-25**.

Reduced Evaporator Efficiency

The job of a refrigeration system's evaporator is to absorb heat from the conditioned space into the system's refrigerant. Its efficiency can be reduced multiple ways. Dust can accumulate on evaporator fins and tubing and act as an insulator, reducing heat transfer. Ice and frost formation can block airflow and insulate the refrigerant from the heat of the circulating air. Air filters can become dirty and clogged, reducing airflow. Blower motors can burn out and stop operating.

A capillary tube refrigeration system with reduced evaporator efficiency will have lower suction pressure and a lower evaporator temperature. This is due to less heat being absorbed, which will allow conditioned space temperature to rise above normal. With less heat absorbed, there will be no or low superheat.

The reduced heat load will allow head pressure and condenser temperature to drop below normal. As long as the refrigerant charge is adequate, subcooling will be normal. Review system characteristics of a capillary tube refrigeration system with reduced evaporator efficiency in **Figure 53-26**.

A TXV refrigeration system with reduced evaporator efficiency will have a somewhat lower suction pressure and evaporator temperature. The TXV will be reacting to the reduced heat absorption to maintain a normal superheat.

With reduced heat absorbed in the evaporator, head pressure and condenser temperature will be below normal. If the system is properly charged, subcooling will be normal. Review system characteristics of a TXV refrigeration system with reduced evaporator efficiency in **Figure 53-27**.

53.3.4 No Refrigeration—Unit Does Not Run

With no cooling and the refrigeration system not running, the trouble may be in the electrical circuit. Use a test light or a voltmeter to check whether power is being supplied to the compressor or condensing unit.

If there is power, a compressor's motor may be burned out or the circuit open. Disconnect power from the motor. Test it with a voltmeter to ensure that power is disconnected. Review the various procedures in Chapter 16, *Electrical Control Systems*, and Chapter 17, *Servicing Electric Motors and Controls*, such as checking relays, checking hermetic motor windings, and finding unwanted voltage drops.

With power turned off and wiring disconnected, use an ohmmeter (set to its lowest setting of R × 1, if an option) to test the resistance between the motor windings and the shell of the compressor or motor. If the reading is at 0 Ω or some other low-resistance value, there is a short to ground. Review the megohmmeter and insulation test procedures in Chapter 17, *Servicing Electric Motors and Controls*, for more motor testing information.

An ineffective temperature control may prevent the motor from starting. An ineffective temperature control might have a leaking power element (a bellows or diaphragm). It may also have a broken spring.

Further circuit checking may show a manual switch or overload in the open or Off position. Otherwise, an internal overload switch may be open. Internal overload switches cannot be manually reset. They reset automatically after cooling down for a period of time. Become familiar with a system's safety switches. This will allow you to quickly check manual resets and know when to wait for internal overloads.

If a compressor's motor is hot, this may indicate electrical trouble. The motor windings should be checked for a short with an ohmmeter. If the problem is an internal or external overload, allow the compressor time to cool off. Once the compressor can be

Service Call Scenario

53D: Walk-In Freezer—No Cooling

Customer Complaint: No Cooling

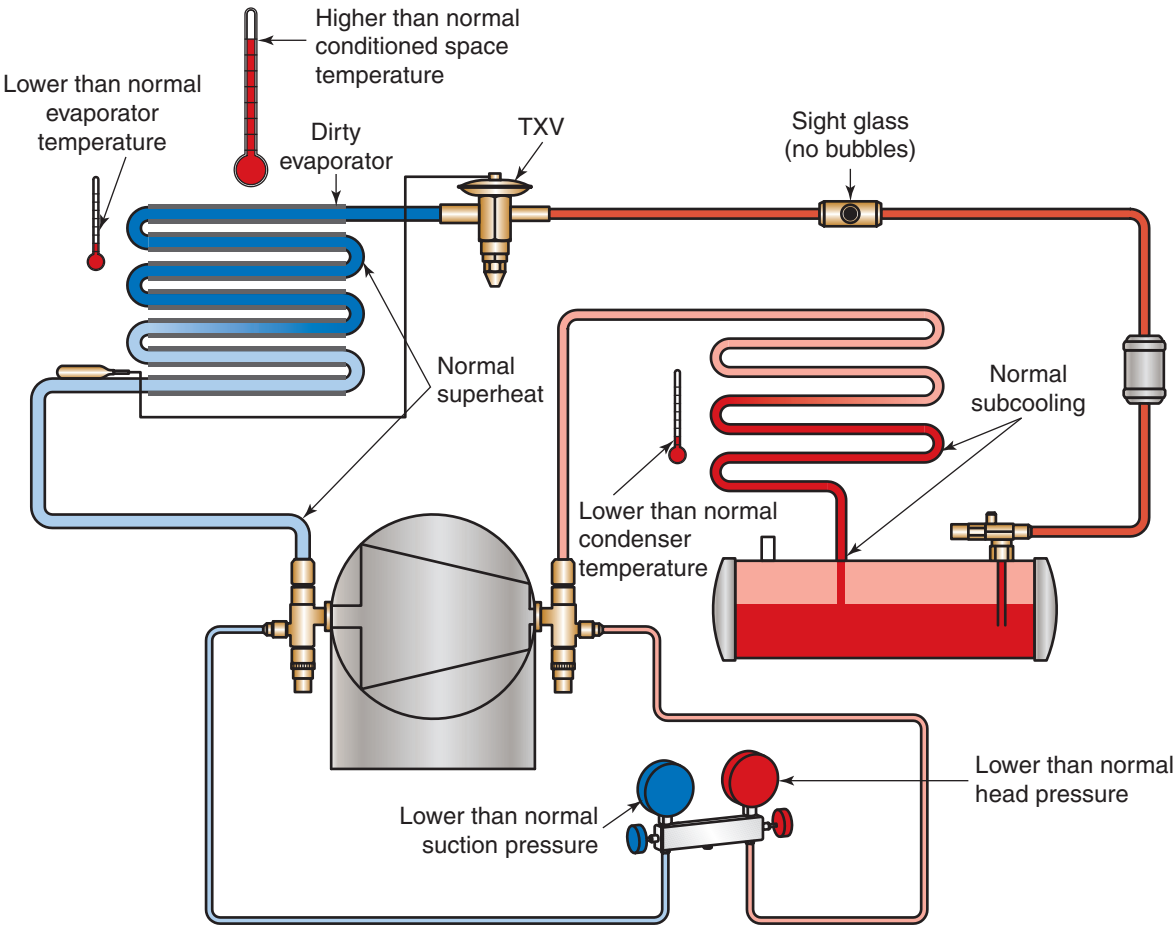
Possible Causes: Faulty circuit breaker, grounded compressor, locked compressor.

Description of Problem: Mrs. Cohen, the owner of a small neighborhood grocery store, has reported that her walk-in freezer is not cooling. Prior to arriving at the jobsite, Seth, the technician, reviews the work order. Upon arriving at the store, he identifies himself to Mrs. Cohen and listens carefully to her comments. Mrs. Cohen says that the unit keeps shutting off and tripping the circuit breaker when she attempts to restart the unit.

Testing: Seth observes the unit in operation. He notes that the compressor is very hot to the touch. With the electrical power off and the compressor wiring isolated, Seth checks the resistance across the compressor terminals. The resistance readings indicate that the compressor windings are grounded. Seth concludes that the compressor will need to be replaced. He informs Mrs. Cohen of the issue and offers solutions and the costs for such. Mrs. Cohen agrees to have Seth perform the needed service.

Solution: Seth recovers all refrigerant from the system. He removes the faulty compressor from the unit. Seth installs a new compressor as well as new filter-driers. A new capacitor and potential relay are installed to match the new compressor. With the system having been evacuated and recharged to manufacturer's specifications, all system pressures and temperatures are now within the normal range. Seth confirms the system is now cooling. Seth provides Mrs. Cohen with the bill and informs her that a follow-up call will occur.

Safety: Over time, some system's lubrication may have become acidic and toxic. Eye and hand protection should be used when replacing major components. It is good practice to recover the system's refrigerant into an acceptable recovery tank in the event the refrigerant is contaminated.



Goodheart-Willcox Publisher

Copyright Goodheart-Willcox Co., Inc. 2017

restarted, use a clamp-on ammeter to check the starting amps and running amps. Compare these measurements with those values provided by the manufacturer, **Figure 53-28**.

Check the source voltage to make sure that the unit is receiving proper power. Review electrical measurements to make sure that the compressor is within the manufacturer's specifications. Continuously drawing too much current is a sign that the motor may have an internal mechanical or electrical problem.

53.3.5 Short Cycling

Short cycling means that a refrigeration system stops and starts too frequently. A short-cycling system will cycle off and cycle back on after a very short amount of time. It is necessary to locate the control or controls that are turning the system on and off. Note that one set of controls may cycle on the compressor and a different set of controls may cycle off the compressor. Review system measurements to determine which controls may be responsible. Controls that may cause short cycling include the following:

- Temperature controls.
- Low-pressure controls.
- Overload controls.
- High-pressure safety controls.
- Oil pressure safety controls.

York International Corp.

Figure 53-28. A clamp-on ammeter is clamped around only one conductor of a particular circuit to measure the conductor's current draw.

Temperature Controls

A temperature control (thermostat) cycles on a compressor when a conditioned space requires cooling. This temperature control calls for cooling based on the temperature of one of the following:

- Return air (conditioned space temperature).
- Supply air.
- Evaporator.
- Suction line.

A technician should check and test the settings of a temperature control. Often a temperature control with a small differential causes short cycling. Increase the range of the differential and monitor pressures and evaporator temperatures to ensure proper system cycling. Ensure that a temperature control's sensing bulb is properly placed and mounted for accurate readings.

Low-Pressure Controls

Rapid pressure rise may occur on the low side when an expansion valve leaks, allowing high-side refrigerant to pass into the evaporator during the Off cycle. Review earlier coverage of diagnosis and remedies for common TXV problems. Two likely causes of a leak are loose contaminants and ice formation. Sometimes a foreign particle circulating with the refrigerant becomes lodged in an expansion valve. Sometimes a small amount of moisture is released from a filter-drier. This moisture circulates with the refrigerant and can freeze on the expansion valve. A small particle or ice formation can prevent an expansion valve from closing completely. Below is a summary of how this affects a refrigeration system.

After the compressor cycles off as usual, the TXV responds to the pressure change by closing its valve. However, this TXV cannot close completely due to the ice formation or lodged particle. As a result, liquid refrigerant quickly fills the evaporator. The liquid refrigerant entering the evaporator raises pressure quickly, which actuates the low-pressure controls into short cycling. The compressor has just shut off, and it is cycled on again after only a short time, due to the

Copyright Goodheart-Willcox Co., Inc. 2017

leaking TXV allowing the rapid rise in evaporator pressure. A TXV leak will also cause frosting or sweating on the suction line.

Poorly seated or failing compressor valves can allow refrigerant to flow back into the suction line. Low-side pressure will rise rapidly during the Off cycle. The rising pressure sensed by the low-pressure control will cause the compressor to start. The system will short cycle while providing little or no cooling. Compressor valve troubles in a hermetic compressor require replacement of the compressor.

Overload Controls

Most refrigeration systems are equipped with one or more overload safety devices in the electrical system. These devices stop the compressor's motor if the motor becomes too hot or draws too much current. The overload safety devices will reset after the motor cools, allowing the compressor to restart once motor controls call for cooling.

If a system is short cycling due to an overload, the supplied power should be checked for proper voltage and current. The compressor should also be checked for proper starting and running voltage and current draw. In rare cases, the overload itself may be faulty or undersized for the compressor. This is more likely if it is not the original manufacturer's overload protection.

High-Pressure Safety Controls

Systems equipped with a high-pressure safety control on the high side will sometimes cause the system to short cycle. A pressure sensor mounted in the discharge line monitors head pressure and shuts off the compressor if head pressure rises too high, **Figure 53-29**. High head pressure will cause the system to stop running before the temperature control ends its call for cooling. Once head pressure drops, the system will start again.

The cause of the high head pressure must be addressed. High head pressure could result from numerous causes. A few common causes are refrigerant overcharge, restricted condenser airflow (reduced condenser efficiency), or noncondensables trapped in the condenser.

Anti–Short Cycle Controls

To prevent a refrigeration system from short cycling, a technician may install an anti–short cycle control. An ***anti–short cycle control*** is a type of solid-state relay that will stop a compressor from cycling on before a preset time has passed after shutdown, **Figure 53-30**.

While an anti–short cycle control is useful in various applications, these controls will not always address the root cause of a system's short cycling. Anti–short cycle controls protect a compressor from short cycling; however, technicians should investigate and remedy the cause of short cycling whenever possible.

53.3.6 Noisy Unit

Noise in a refrigeration system can come from three principal sources: compressors, electric fan motors, and the mounting hardware of a condensing unit. A compressor is noisy when it pumps too much oil. It is also noisy when valves, piston pins, connecting rods, and pistons have become worn due to a lack of oil or contaminated oil. When a compressor gets very warm, it will sometimes develop knocks. These are usually hard to remedy, but they may be caused by a lack of oil.

If excessive noise is present inside a compressor, check the oil level if the compressor has an oil sump. Hermetic compressors require a refrigerant and oil recovery and the addition of new oil and refrigerant according to the manufacturer's specification. Oil that has been removed should always be tested for acidity and contamination. If the oil is contaminated, this may be an early indication of a compressor about to fail. The compressor should be replaced prior to its causing a burnout and full system contamination.

The metal shaft seal used on open-drive compressors occasionally becomes noisy, giving out a shrill squeal. This is usually caused by a lack of oil at the seal. If not remedied, it will soon score the seal and cause it to leak.

Some open-drive compressors contain an oil level sight glass for quick identification of compressor oil sump level. If the oil appears to be clear and clean, additional oil may be added to the system. If the oil appears dark brown, it may require replacement.

Conventional electric fan motors may produce different noises, such as fan roar, bearing squeak, or motor rumble. The cause of most fan motor issues is actually a result of problems with the fan blades causing stress on the motor bearings or fan blades hitting a shroud.

First, check that the fan rotates smoothly within its shroud. Check for signs of damaged or bent fan blades. Replace the fan if any damage is found. Check for any "slop" or play in the fan bearing as it is attached to the motor shaft. Replace the fan bearing or fan assembly.

Restricted airflow may also cause the fan motor to overheat. Make sure that the condenser is free of obstructions and that there is proper airflow across the condenser. If the fan blades, bearings, and airflow are good, but the motor is still noisy, check the voltage and current at the fan motor. If the fan motor is drawing too much current due to internal winding problems, it may need to be replaced.

Occasionally, if a motor is loaded too heavily (undersized for the application), the starting winding does not cut out. It will cause continuous noisy operation. If allowed to run this way, the motor will burn out.

A motor driving a belt may produce noise when the belt is dry. It may be stopped by using a dressing recommended for belts. Pulleys that are out of line may also cause noise. This may be remedied by realigning the pulleys, **Figure 53-31**. Do not use oil.

Sometimes an entire condensing unit will vibrate excessively. This produces a rumbling sound as the system runs, shaking the cabinet disagreeably. This is probably due to poor mounting or spring suspension. Most condensing units are mounted using rubber isolation absorbers. These may become brittle over time and require replacement. Check for cracks or dryness in the isolation mounts and replace them if necessary. Also check for broken or worn springs at the compressor mounting base. Some obstruction may be in the condensing unit compartment, such as debris in outdoor condensers. Check for any objects that may be rubbing against tubing or the compressor and remove them.

Excessive head pressure will make a condensing unit vibrate more than normal. The compressor pistons or scroll are not circulating oil adequately due to high head pressure causing metal-to-metal contact inside the compressor. The cause of the high head pressure should be remedied and the compressor oil checked to make sure that no internal damage has occurred.

53.4 Troubleshooting Ice Machines

In addition to having many of the same parts as most refrigeration systems, commercial ice machines also have specially designed evaporators for forming and freezing ice. Ice machines also have water circuits and controls necessary for producing and harvesting ice. Problems with ice machines can often be found in these parts of a system, rather than in its refrigeration system.

Many standalone ice machines are refrigeration systems that are ***critically charged***. This means that the refrigerant charge is very precise and must remain at this level for effective, trouble-free operation. Therefore, an HVACR technician troubleshooting an ice machine should learn to diagnose problems without having to connect gauges. This will eliminate the small loss of refrigerant that results from connecting gauges to a refrigerant circuit. Even a small loss of refrigerant from a critically charged ice machine could lead to poor operation and future system breakdowns.

Pro Tip

Gauges on Ice Machines

While it is best to avoid connecting pressure gauges to critically charged ice machines, it will be necessary in some cases. When connecting a pressure gauge to a critically charged ice machine, ensure that there is the least amount of hose or tubing between the access port and the gauge as possible. Rather than using a standard gauge hose, use as few couplings as possible and a quick-connect fitting, **Figure 53-32**.

Technicians servicing ice machines should learn to rely on interpreting temperature and electrical measurements and identifying other signs of poor operation. These other signs could include the presence of moisture in certain amounts and locations, the size and condition of the ice produced, and various sights, sounds, and smells throughout an ice machine. Much of this information is acquired through careful inspection and experience.

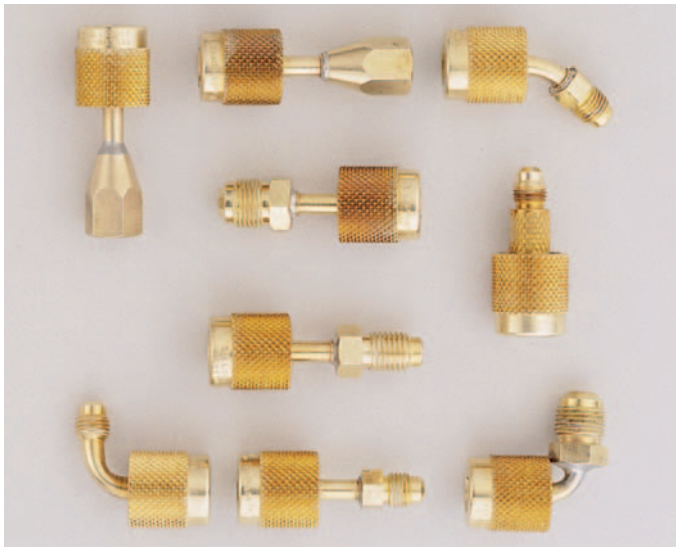
Modern ice machines often have an electronic control unit that displays operational and diagnostic trouble codes. This is extremely helpful in troubleshooting. Trouble codes often identify symptoms of poor operation. The technician must investigate to determine the causes of these symptoms, **Figure 53-33**.

Trouble codes offer good starting points for fixing a particular problem. After reflecting on the implications of a trouble code, consider possible causes of the problem. Closely examine wiring diagrams before attempting a repair to a problem. Study and become familiar with the wiring diagrams of ice machines produced by different manufacturers for a broader understanding of their operation, **Figure 53-34**.

53.4.1 Water Quality

Several types of cube ice machines use a control called a ***water level/conductivity probe***. This device senses the level of the water in an ice machine's sump or water reservoir. It also monitors the conductivity of the water. As water is frozen into ice, less water returns to the water reservoir. When a certain level is sensed by the water level/conductivity probe, the control unit responds by refilling the water reservoir.

Certain ice machines rely on water level/conductivity probes. These ice machines gradually freeze



Ritchie Engineering – YELLOW JACKET Products Division

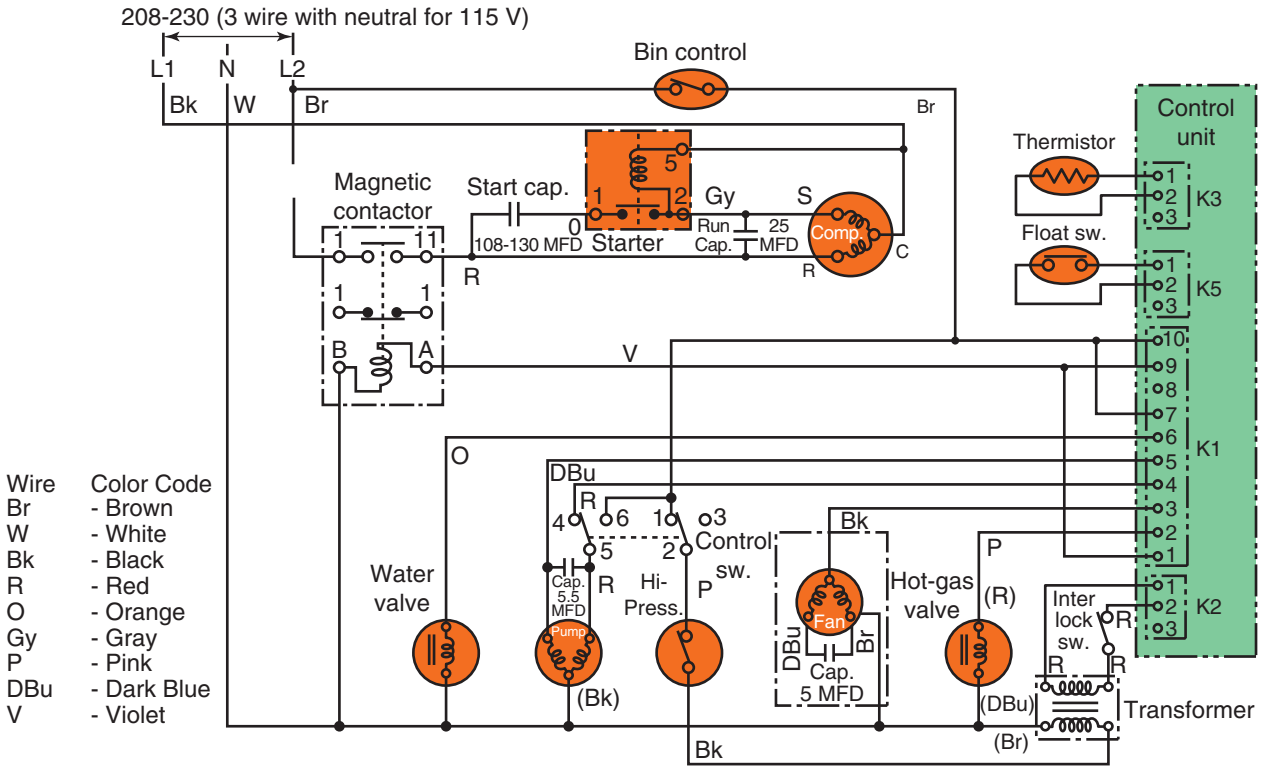
Figure 53-33. In some ice machines, LED codes not only display trouble codes but also indicate in which phase of operation the machine is.

flowing or moving water into ice. Examples include cube ice machines with a vertical evaporator or an inverted evaporator. As water freezes, minerals in the water solution often continue to flow with the unfrozen water. While some of the water is freezing and turning into ice, the minerals continue moving. This can lead to an accumulation of minerals in the sump or water reservoir.

When an ice machine's water level/conductivity probe senses a certain level of conductivity in the water reservoir, it indicates a high concentration of minerals in the water. The most pleasing ice to consumers has the least amount of minerals. The control unit responds to the water level/conductivity probe by draining the water reservoir. It may also activate an LED code, prompting a service technician to replace water filters or perform cleaning of the water-related parts of the ice machine. Review manufacturer literature to locate and service an ice machine's water level/conductivity probe, **Figure 53-35**.

53.4.2 Drain Problems

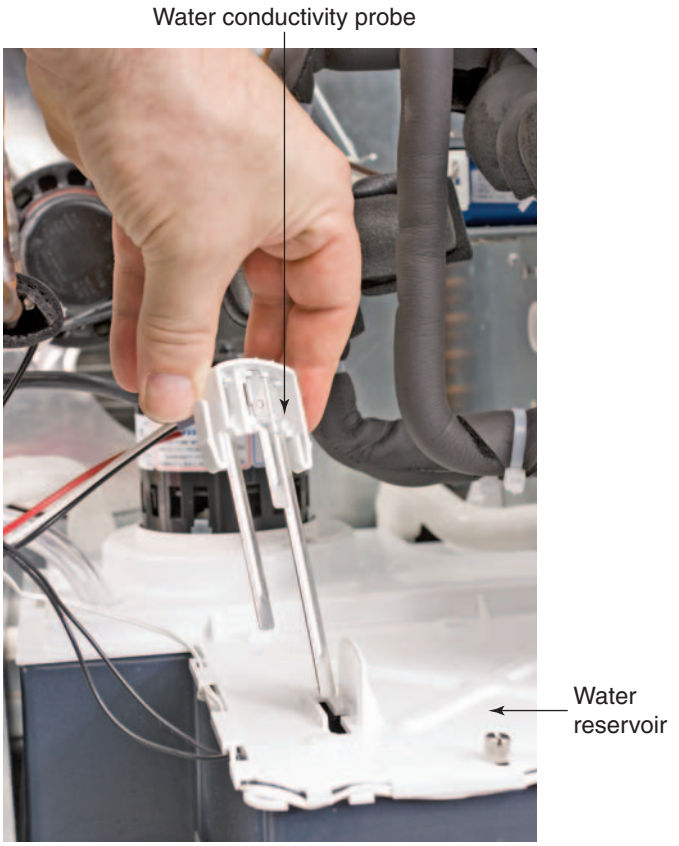
Ice machines often have more than one drain connection. A drain at the bottom of an ice storage bin



Hoshizaki America, Inc.

Figure 53-34. The control unit in this electrical wiring diagram controls all the electrical components in this ice machine.

Copyright Goodheart-Willcox Co., Inc. 2017



Scotsman Ice Systems

Figure 53-35. The level and quality of an ice machine's water used to make ice is monitored using a water level/conductivity probe placed in the water reservoir and wired into the control unit.

allows any melting ice to drain out. A stopped up bin drain could accumulate water that could melt and ruin batches of ice until it is unclogged. If a water reservoir drain is clogged, the water will develop a strong mineral concentration, which will produce low-quality ice and could leave mineral deposits in spray nozzles, ice mould surfaces, and other locations along the water circuit.

A continuous flow of water down a drain could be traced to any number of problems. An excessive amount of ice in the storage bin could be melting. A float switch regulating water level could be out of calibration and dumping water into the ice storage bin. A solenoid valve for draining the water reservoir could be stuck open. A water-cooled condenser's water valve could be out of calibration or stuck open.

Some manufacturers require a separate, dedicated drainpipe from each part of an ice machine to the building's plumbing drain. This means that a water reservoir drain will not connect to the same drain tubing as an ice storage bin's drain tubing. There will be no tee connections among drain tubing within the ice machine. This is especially important when some of the drains are pressurized. If pressurized drains are connected, one drain could back up through another drain and spill into another part of a system. If the installer followed guidelines properly, it should be easier to determine which part of a system is draining excessively. Determining the source of excessive draining is an important first step in servicing drain problems.

Regular cleaning of the evaporator, ice moulds, reservoirs, and other water-circulating parts of an ice machine is important for proper operation. This prevents the buildup of scale and minerals that lower the quality of the ice and reduce system efficiency.

53.4.3 Head Pressure in Ice Machines

As in all refrigeration systems, high head pressure may develop and cause cascading problems. In an ice machine with an air-cooled condenser, the first and easiest checks to perform are inspecting the condition of the condenser and its air filter. An ice machine's condenser and its air filter should be cleaned regularly, according to manufacturer recommendations. This will keep the flow of cooling air across the condenser constant, which will help to keep head pressure from rising above normal, **Figure 53-36**.

For checking head pressure in an ice machine with a water-cooled condenser, measure the temperature of the water leaving the condenser. For many models, this value should be between 95°F (35°C) and 105°F (40.6°C) when the machine is running and at its proper head pressure. The temperature of the water will correlate with head pressure, as specified in manufacturer literature.

When a water temperature measurement is lower than normal, use your gauge manifold to measure head pressure. A low water temperature and a head pressure measurement that are within a manufacturer's recommended range indicate a reduced heat transfer between high-side refrigerant and condenser water. The likely cause is the formation of a light coating of mineral deposits in the condenser water circuit. This formation would reduce water temperature and raise head pressure.

The water valve in an ice machine with a water-cooled condenser may be able to respond sufficiently to high head pressure and a reduced heat transfer with increased water flow. Refer to **Figure 53-37**.

In this ice machine, the water valve's sensing element is connected to the discharge line. There it senses and responds to head pressure. As head pressure

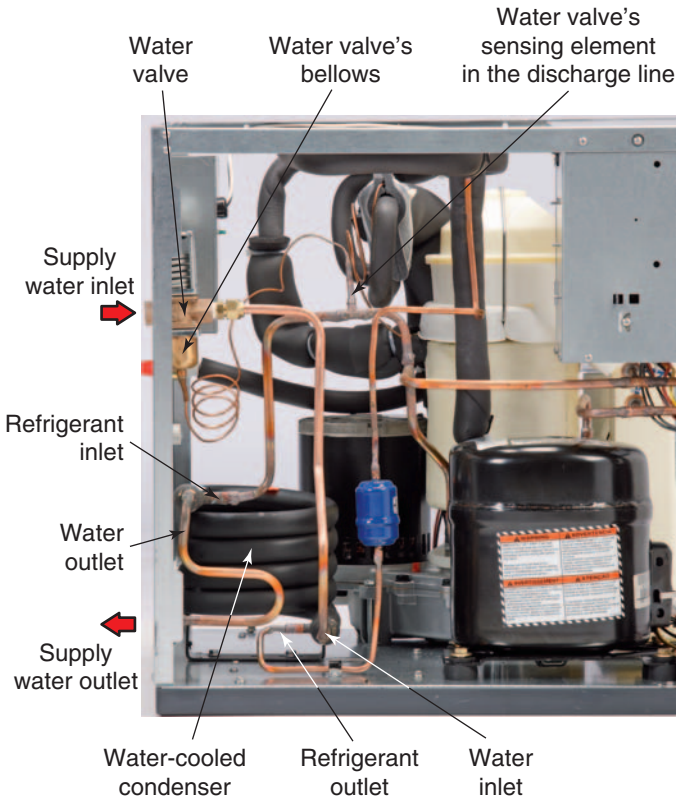
Scotsman Ice Systems

Figure 53-36. A—Since an ice machine's condenser air filter is so frequently inspected, manufacturers often design their machines with convenient access in mind. B—Check the cleanliness of condenser tubing and fins, as well as fan cleanliness and operation.



Scotsman Ice Systems

Figure 53-37. Notice how a water valve is installed in this flake ice machine. Its sensing element in the discharge line monitors head pressure, which determines the amount of water to enter the condenser.

Copyright Goodheart-Willcox Co., Inc. 2017

increases, the water valve opens more to increase water flow to absorb and remove more heat from the condenser.

If an ice machine's operating head pressure is below normal but still within the manufacturer's recommended range, system shutdown and service can be briefly postponed. Though this condition may force the ice machine to consume more water than normal, it could allow the owner to plan for scheduled service at a convenient time, rather than shut down the ice machine at an inopportune time.

When a condenser's water circuit is suspected of having a thin layer of mineral deposits, it should be flushed with scale remover. After flushing, normal head pressure and condenser water temperature should return.

If head pressure is above the manufacturer's recommended range of operation, a thick layer of scale probably developed in the water circuit. As head pressure rises, a condenser's water valve will try to compensate for the reduced heat transfer by opening wider and allowing more water to flow through the condenser. However, at some point, the thickness of the mineral deposit and its insulating ability will exceed the water valve's ability to compensate. Head pressure will rise until a high-pressure safety device shuts off the ice machine. The system may need to be restarted manually by resetting the safety device. However, the system may need time for head pressure to reduce before the safety device will allow the system to restart.

Heavy mineral deposits in the water circuit of a water-cooled condenser may require an acid cleaning. However, cleaning does not always alleviate problems related to reduced heat exchange and high head pressure. If the scale buildup is severe, the condenser may need to be replaced.

53.4.4 Capacity Check

Ice machines are engineered to produce a certain amount of ice each day. This is important information for owners, as they need to ensure that there is an adequate amount of ice for their customers. When an owner asks for service due to not having enough ice, a service technician should perform a capacity check.

A ***capacity check*** for an ice machine involves running through an ice production cycle, measuring temperatures, timing the length of the cycle, weighing the ice batch produced, and calculating the total daily production potential. These values should be compared with manufacturer specifications.

- Ambient (condenser) air temperature: _____ °F/ _____ °C.
- Supply water temperature: _____ °F/_____ °C.
- Total cycle time: _____ minutes.
- Total ice batch weight: _____ lb.
- Calculated potential daily ice production weight: _____ lb.

Ice Machine Capacity Check

1. Turn off and lock out the ice machine.
2. Perform a brief visual inspection to see if there are any noticeable problems that should be investigated and remedied before starting the ice production cycle. Check for dirty air filters, excess moisture or condensation, or other symptoms that may need to be addressed immediately.
3. Locate the ice machine's condenser. If it is an air-cooled condenser, measure and record ambient air temperature: _____ °F/°C. If it is a water-cooled condenser, use the water temperature measurement later in this procedure for this value.
4. Measure the temperature of the supply water at the ice machine's water inlet: _____ °F/°C. If the ice machine has been sitting idle for a while, monitor water temperature throughout the ice production cycle to see if this value changes from your initial measurement. If it differs, update your previously recorded value.
5. Completely empty the machine's storage bin of all its ice and moisture. Check the bin drain. If it is blocked, unclog it and make notes on this in your service record.
6. Set and prepare a stopwatch or other time-recording device for timing the ice production cycle.
7. Undo the lockout and turn on system power. Start the stopwatch and ice machine at the same time to synchronize operation.
8. Monitor the ice machine during the ice production cycle. Refer to the ice machine's control unit or display that indicates its current stage of operation.
9. Occasionally check water temperature to see if it still corresponds to your previously recorded value. Update your records if the measurement changes.

Copyright Goodheart-Willcox Co., Inc. 2017

10. When the ice machine ends its ice harvest and cycles off, record the total length of the cycle time: _____ minutes.
11. Weigh the batch of ice produced during this cycle: _____ lb.
12. Divide the length of time recorded by the total number of minutes in a day (1,440) to get the total possible number of daily ice production cycles:

    1,440 minutes ÷ _____ minutes = _____ potential daily cycles.

13. Multiply the number of potential daily cycles by the recorded weight of the ice batch:

    _____ potential daily cycles × _____ lb = _____ lb of daily ice production potential.

14. Compare the weight of the daily ice production potential with the manufacturer's recommended daily ice production. If the calculated value is within 10% of the manufacturer's recommendations, the ice machine is operating properly.

If an ice machine is producing less than 10% of the manufacturer's recommendations, review manufacturer literature for operational characteristics that may be measured. Inspect the machine for plugged drains and other water circuit problems. Reference any diagnostic codes on the control unit.

If an ice machine is producing over 10% of the manufacturer's recommendations, inform the owner that the ice machine is producing over capacity, which is a good problem. If the owner routinely runs out of ice, explain the following common options: a larger storage bin, a nearby storage freezer, and an additional ice machine.

If the current ice machine is sized to fit a larger replacement storage bin, recommend replacing the current bin with a larger bin. If bin replacement isn't possible, discuss the other options.

In many businesses, weekend demand for ice is high, and weekday demand for ice is low. Installing a freezer nearby would allow the owner to move and store ice produced during the week into the freezer and to use the ice throughout the busy weekend. If this isn't possible or convenient, an additional ice machine may be the solution.

Ambient air affects the amount and rate of heat that can be expelled from the refrigerant circuit of an ice machine with an air-cooled condenser. The lower the ambient air, the more heat and the more quickly it is expelled from the refrigerant circuit. This can reduce the length of time of the ice production cycle, which can increase the total daily batch production.

The ambient temperature of an ice machine with a built-in air-cooled condenser that is located in an air-conditioned part of a building should not experience drastic capacity changes throughout a year. However, an ice machine with a remote air-cooled condenser that is outside or in an unconditioned part of a building will be more affected by ambient air temperature.

The temperature of ambient air does not affect ice machines that use a water-cooled condenser. Instead, water temperature affects system operation. Generally, water temperature should remain fairly constant. However, this depends on the installation and whether it can be influenced by the weather.

The supply water temperature affects the production capacity of all ice machines, whether it has an air-cooled condenser or a water-cooled condenser. The lower the temperature of the water, the more quickly it can be frozen and harvested as ice. The faster the cycle time, the more cycles that can happen in a day, and the more ice produced daily.

53.4.5 Cube Ice Machine Service

Troubleshooting cube ice machines varies depending on the evaporator type and ice mould. Vertical evaporator cube ice machines often use an ***ice thickness sensor***. This device monitors the thickness of the ice forming in the moulds. If an ice thickness sensor is calibrated poorly, ice may form too thickly. The ice thickness sensor in this ice machine is located near the water distribution manifold, **Figure 53-38**.

During the ice production cycle, the edges of individual ice cubes join together to form a single sheet of ice. This is an intentional design, which allows the entire sheet of ice to fall at once against a deflector tray and break apart into individual cubes before sliding into the storage bin. However, when an ice thickness sensor is calibrated poorly, the edges formed on the ice cubes will grow to be too thick. When the sheet of ice drops to the deflector tray, groups of ice cubes stick together in large clumps. These clumps of joined ice cubes are too big for consumer use. Reduce the thickness by adjusting the ice thickness sensor.

Ice machines with inverted evaporators may have different problems than vertical evaporator ice machines. If the mineral concentration in the water

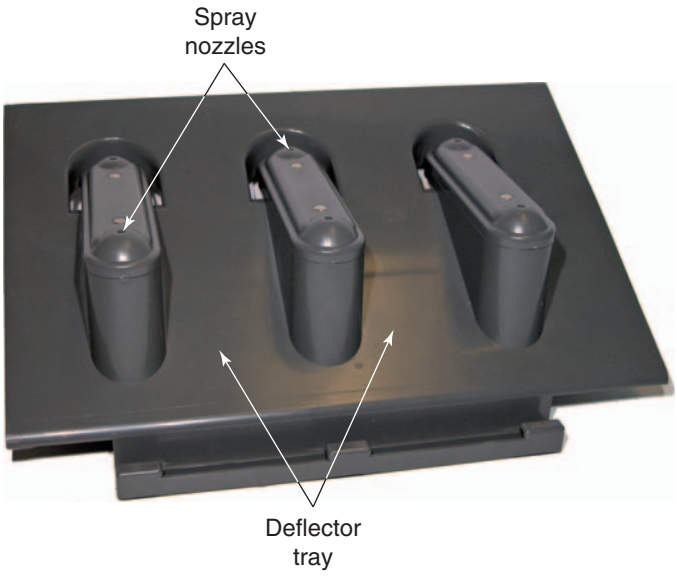
reservoir becomes too high, scale and deposits may form on the spray nozzles, **Figure 53-39**.

A service technician must keep spray nozzles clean to ensure uniform cube shape and formation. If cubes are oddly shaped, inspect the spray nozzles for mineral deposits. Inspect the water reservoir and its probe for mineral deposits. Check the water reservoir drain. Consider replacing any water filters.



Scotsman Ice Systems

Figure 53-39. This spray assembly has several nozzles that shoot upward into an inverted mould that is backed by evaporator tubing.

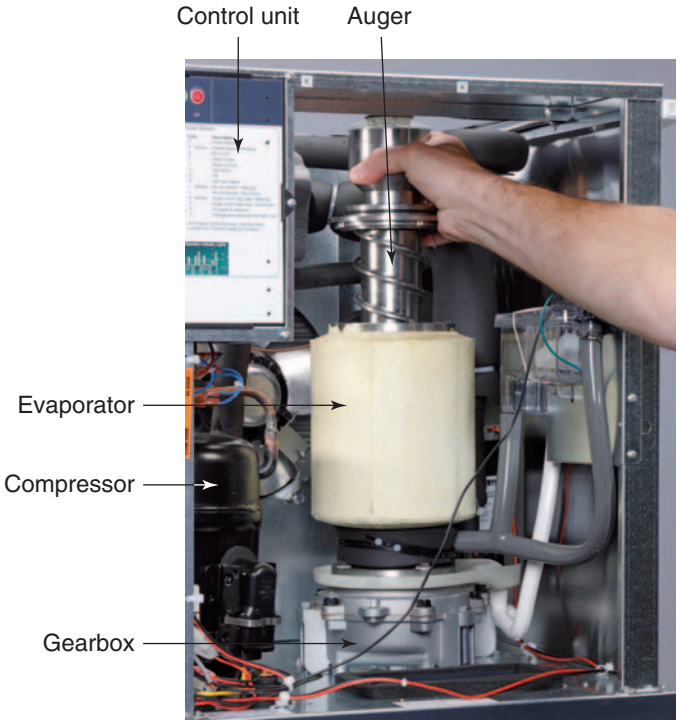
53.4.6 Flake Ice Machine Service

Flake ice machines have more mechanical parts than cube ice machines. Therefore, certain problems in flake ice machines can be easily heard: clicking gears, screeching blades, and crunching mineral deposits. Proper maintenance and service will help to prevent such situations.

In flake ice machines, loud and unfavorable sounds during operation often point to mechanical problems. A crunching sound may be caused by the auger cutting mineral deposits that have formed in the evaporator. This may prompt a service technician to remove the auger for a thorough inspection, **Figure 53-40**.

While disassembling the evaporator, examine the bearings and other parts, **Figure 53-41**. Evaporator disassembly is a good opportunity to ensure that everything is lubricated properly. Follow manufacturer recommendations.

When a flake ice machine's evaporator is disassembled, do not just examine moving parts. Also check the nonmoving parts. Examine the inner wall of the evaporator for scoring, **Figure 53-42**.



Scotsman Ice Systems

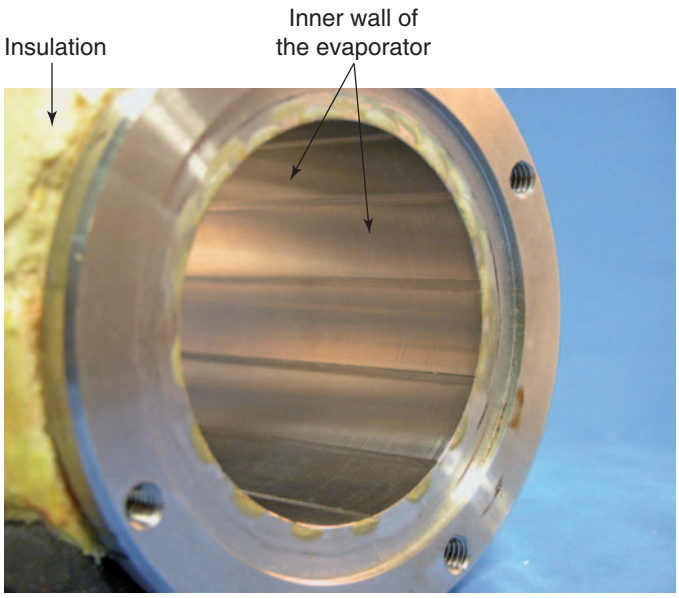
Scotsman Ice Systems

Figure 53-41. Some of a flake ice machine's moving parts.



Scotsman Ice Systems

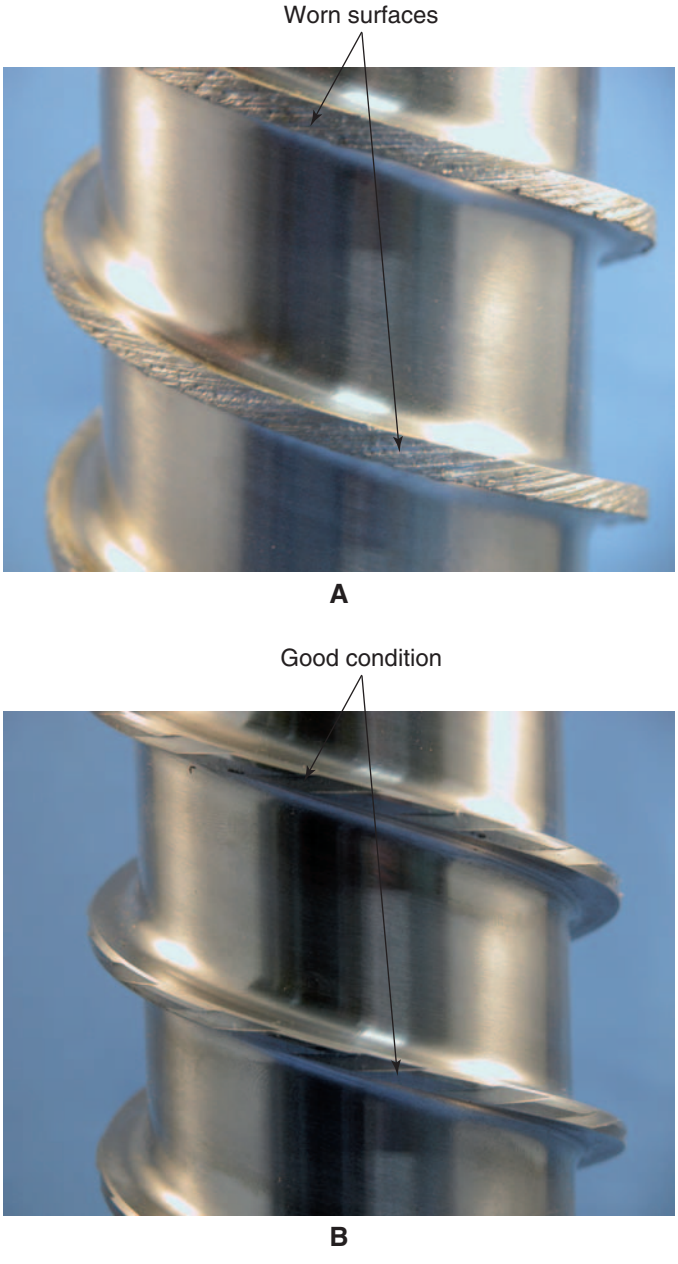
Figure 53-42. The inside of a flake ice machine's evaporator.

Flake ice machines rely on an auger to cut ice flakes from solid ice. With time and use, an auger may become worn and damaged. Compare the photos of a damaged auger and a new auger in **Figure 53-43**.

Flake ice machines rely on a float switch within the water reservoir to maintain enough water in the evaporator. A poorly calibrated or faulty float switch can cause several problems that can be identified by knowledgeable technicians.

Flake ice machines are designed to have ice form only up to a certain level in the evaporator. When a float switch is calibrated to a level too high, there will be more ice than usual for the auger to cut. This will require the auger to work harder and draw more current through its motor, which may trip its overload protection. Often, the overload protection device must be reset manually.

Another problem from a float switch being set too high is water from the evaporator spilling into the ice



Scotsman Ice Systems

bin. This will melt and ruin flake ice in the bin, reducing the capacity of the machine. Refer to manufacturer literature for calibrating a flake ice machine's float switch, **Figure 53-44**.

Chapter Review

Summary

- Troubleshooting begins with an owner's description of system operation. Take and record temperature, pressure, and electrical measurements. Understand what is happening within the system before performing repair work.
- A refrigeration system with insufficient refrigerant will have reduced capacity due to less latent heat available for evaporation and condensation. Excessive suction line pressure drop may be caused by a clogged low-side, inline component or a pinched tube. The compressor pumps less weight of vapor per stroke, reducing system capacity. System operation is prolonged, and the cost of operation increases.
- Noncondensables in the refrigerant circuit reduce heat rejection capacity, raise head pressure, and cause the compressor to draw more current (consume more electrical power). These same symptoms can happen from other causes of high head pressure, such as a dirty condenser or restricted condenser airways.
- Moisture in the refrigerant circuit may cause rusting, corrosion, oil sludging, acid formation, and restrictions when frozen in valves. Check moisture indicators frequently to monitor for moisture content within the refrigerant circuit.
- A sight glass is a quick way to check whether a refrigeration system has an adequate charge. A properly charged system will have acceptable suction and head pressure levels and no bubbles in the sight glass. When possible, check superheat, subcooling, and other performance measurements to confirm proper charge.
- An undercharged refrigeration system will have low suction and head pressures. Subcooling will be low, and superheat will be high. A sight glass will show bubbles.
- A system with a restriction in its refrigerant metering device will have insufficient cooling or run a very long time to cool enough to cycle off. The evaporator will have high superheat, and no bubbles will appear in the sight glass. Suction pressure will be lower than normal, and head pressure will be low to normal.
- A system with an inefficient compressor will produce poor cooling. Suction pressure will be high, and head pressure will be low. Superheat will be high, though subcooling should be normal.
- An overcharged system will have poor cooling, high suction pressure, and high head pressure. Subcooling will be high, but superheat will be low to normal, depending on the type of refrigerant metering device and the amount overcharged.
- A restriction on the high side of a system causes poor cooling. Suction and head pressures will be low. Bubbles will be in the sight glass, and there will be a measurable temperature drop between the inlet and outlet of the liquid line and across the restriction.
- A restriction on the low side of a system causes high evaporator pressure but low suction pressure. Superheat, subcooling, and head pressure will be low. A measurable temperature difference at two points along the suction line will identify the location of the restriction.
- Noncondensables trapped in a condenser raise head pressure, suction pressure, subcooling, and compressor current draw. If head pressure does not drop but remains constant for several minutes after cycling off, noncondensables are in the system.
- Reduced condenser efficiency is often the result of dirt accumulation, blocked airflow passageways, and fan problems. Suction and head pressure rise above normal. Subcooling may be normal. Superheat will be low to normal depending on the type of refrigerant metering device.
- Reduced evaporator efficiency is often the result of dirt accumulation, blocked airflow passageways, and fan problems. Suction and head pressures will be low. Subcooling should be normal. Superheat will be low to normal depending on the type of refrigerant metering device.
- When a refrigeration system does not run, check the electrical circuits (power and control), especially safety controls. Short cycling may be caused by the following controls: temperature, low-pressure, overload, high-pressure, and oil pressure. Anti–short cycle controls can prevent short cycling but do not address the root cause of a system's short cycling.
- Trouble noises in a refrigeration system can come from compressors, fans, and mounting hardware. Listen, visually examine, and take various measurements when diagnosing and fixing noise problems.

Copyright Goodheart-Willcox Co., Inc. 2017

- Problems with ice machines are often found in the water circuit and ice sections of the machine, rather than in the refrigeration system. Critically charged ice machines should be diagnosed with electrical and temperature measurements, symptom recognition, and diagnostic codes.
- A capacity check requires taking various measurements and running through an ice production cycle. This provides a good indication as to the state of the operation of an ice machine and can be used for future diagnosis of problems. Ice machine service largely depends on the type of evaporator a system uses.

Review Questions

Answer the following questions using the information in this chapter.

1. When a refrigeration system's suction line is noticeably cold instead of just being cool, it probably contains _____ refrigerant.
   A. high-pressure liquid
   B. high-pressure vapor
   C. low-pressure liquid
   D. low-pressure vapor
2. When a refrigeration system's liquid line is noticeably hot instead of just being warm, it probably contains _____ refrigerant.
   A. high-pressure liquid
   B. high-pressure vapor
   C. low-pressure liquid
   D. low-pressure vapor
3. It can be reasonably assumed that a refrigeration system has an adequate refrigerant charge when all the following criteria are met, *except* for _____.
   A. bubbles in the sight glass
   B. no bubbles in the sight glass
   C. proper head pressure
   D. proper suction pressure
4. When a refrigeration system that produces low or no cooling has low suction pressure and low head pressure, it probably _____.
   A. has an inefficient compressor
   B. has noncondensables trapped in its condenser
   C. is overcharged
   D. is undercharged
5. When a refrigeration system that produces low or no cooling has high suction pressure and low head pressure, it probably _____.
   A. has an inefficient compressor
   B. has noncondensables trapped in its condenser
   C. is overcharged
   D. is undercharged
6. When a refrigeration system that produces low or no cooling has high suction pressure and high head pressure, it probably _____.
   A. has an inefficient compressor
   B. has a low-side restriction
   C. is overcharged
   D. is undercharged
7. When a refrigeration system that produces low or no cooling has low suction pressure, high head pressure, and high evaporator pressure, it probably _____.
   A. has a high-side restriction
   B. has a low-side restriction
   C. is overcharged
   D. is undercharged
8. When a refrigeration system does not provide its evaporator with enough liquid refrigerant, the evaporator exhibits _____.
   A. reduced latent heat capacity
   B. reduced sensible heat capacity
   C. reduced subcooling
   D. None of the above.
9. When a refrigeration system produces normal to excessive refrigeration and operates continuously without stopping, the probable cause is a(n) _____.
   A. faulty motor control
   B. inefficient compressor
   C. overcharge
   D. undercharge
10. When a refrigeration system producing low to normal refrigeration operates continuously without stopping and has high suction pressure and high head pressure, the probable cause is _____.
    A. an inefficient compressor
    B. a low-side restriction
    C. noncondensables trapped in the condenser
    D. an undercharge of refrigerant

Copyright Goodheart-Willcox Co., Inc. 2017

11. When noncondensables are trapped in a refrigeration system's condenser, its head pressure measurement after cycling off should _____.
    A. drop steadily in a gradual manner
    B. gradually rise higher for several minutes
    C. immediately drop into vacuum
    D. remain constant for several minutes

12. Blocked airflow passageways, burned out fan motors, and dirty fins and tubes are common causes of the reduced efficiency of _____.
    A. accumulators and liquid receivers
    B. augers and solenoid valves
    C. condensers and evaporators
    D. drains and water-cooled condensers

13. When a commercial refrigeration system produces no refrigeration and its compressor does not operate at all, the cause is probably _____.
    A. electrical
    B. mechanical
    C. refrigerant-related
    D. water-based

14. In most cases, excessive noise in a refrigeration system may be caused by the following sources, *except* _____.
    A. a compressor
    B. an electric motor
    C. a liquid line
    D. mounting hardware of a condensing unit

15. It is best to troubleshoot critically charged ice machines using diagnostic codes, visual clues, and the following measurements, *except* _____.
    A. electrical current
    B. pressure
    C. temperature
    D. voltage

16. An ice machine's water level/conductivity probe may be used to determine when to do the following actions, *except* when to _____.
    A. clean the condenser
    B. drain the water reservoir
    C. refill the water reservoir
    D. replace water filters

17. Three common options to suggest to an owner complaining of not enough ice being produced from an ice machine include the following, *except* installing a _____.
    A. larger replacement storage bin for the current ice machine
    B. nearby freezer for overflow ice storage
    C. second ice machine
    D. a tee or other fitting to join all the drain lines together

18. A capacity check for an ice machine involves running through an ice production cycle, measuring temperatures (condenser ambient air and water), and several other steps including all the following, *except* _____.
    A. calculating various measurements for the total daily production potential
    B. tasting the ice
    C. timing the length of the ice production cycle
    D. weighing the ice batch

19. When a cube ice machine with a vertical evaporator harvests ice and the sheet of ice does not break apart into individual cubes, a technician should adjust the _____.
    A. auger
    B. float switch
    C. ice thickness sensor
    D. water level/conductivity probe

20. When water overfills the evaporator of a flake ice machine and spills over into the ice storage bin, a technician should adjust the _____.
    A. auger
    B. float switch
    C. ice thickness sensor
    D. spray nozzle

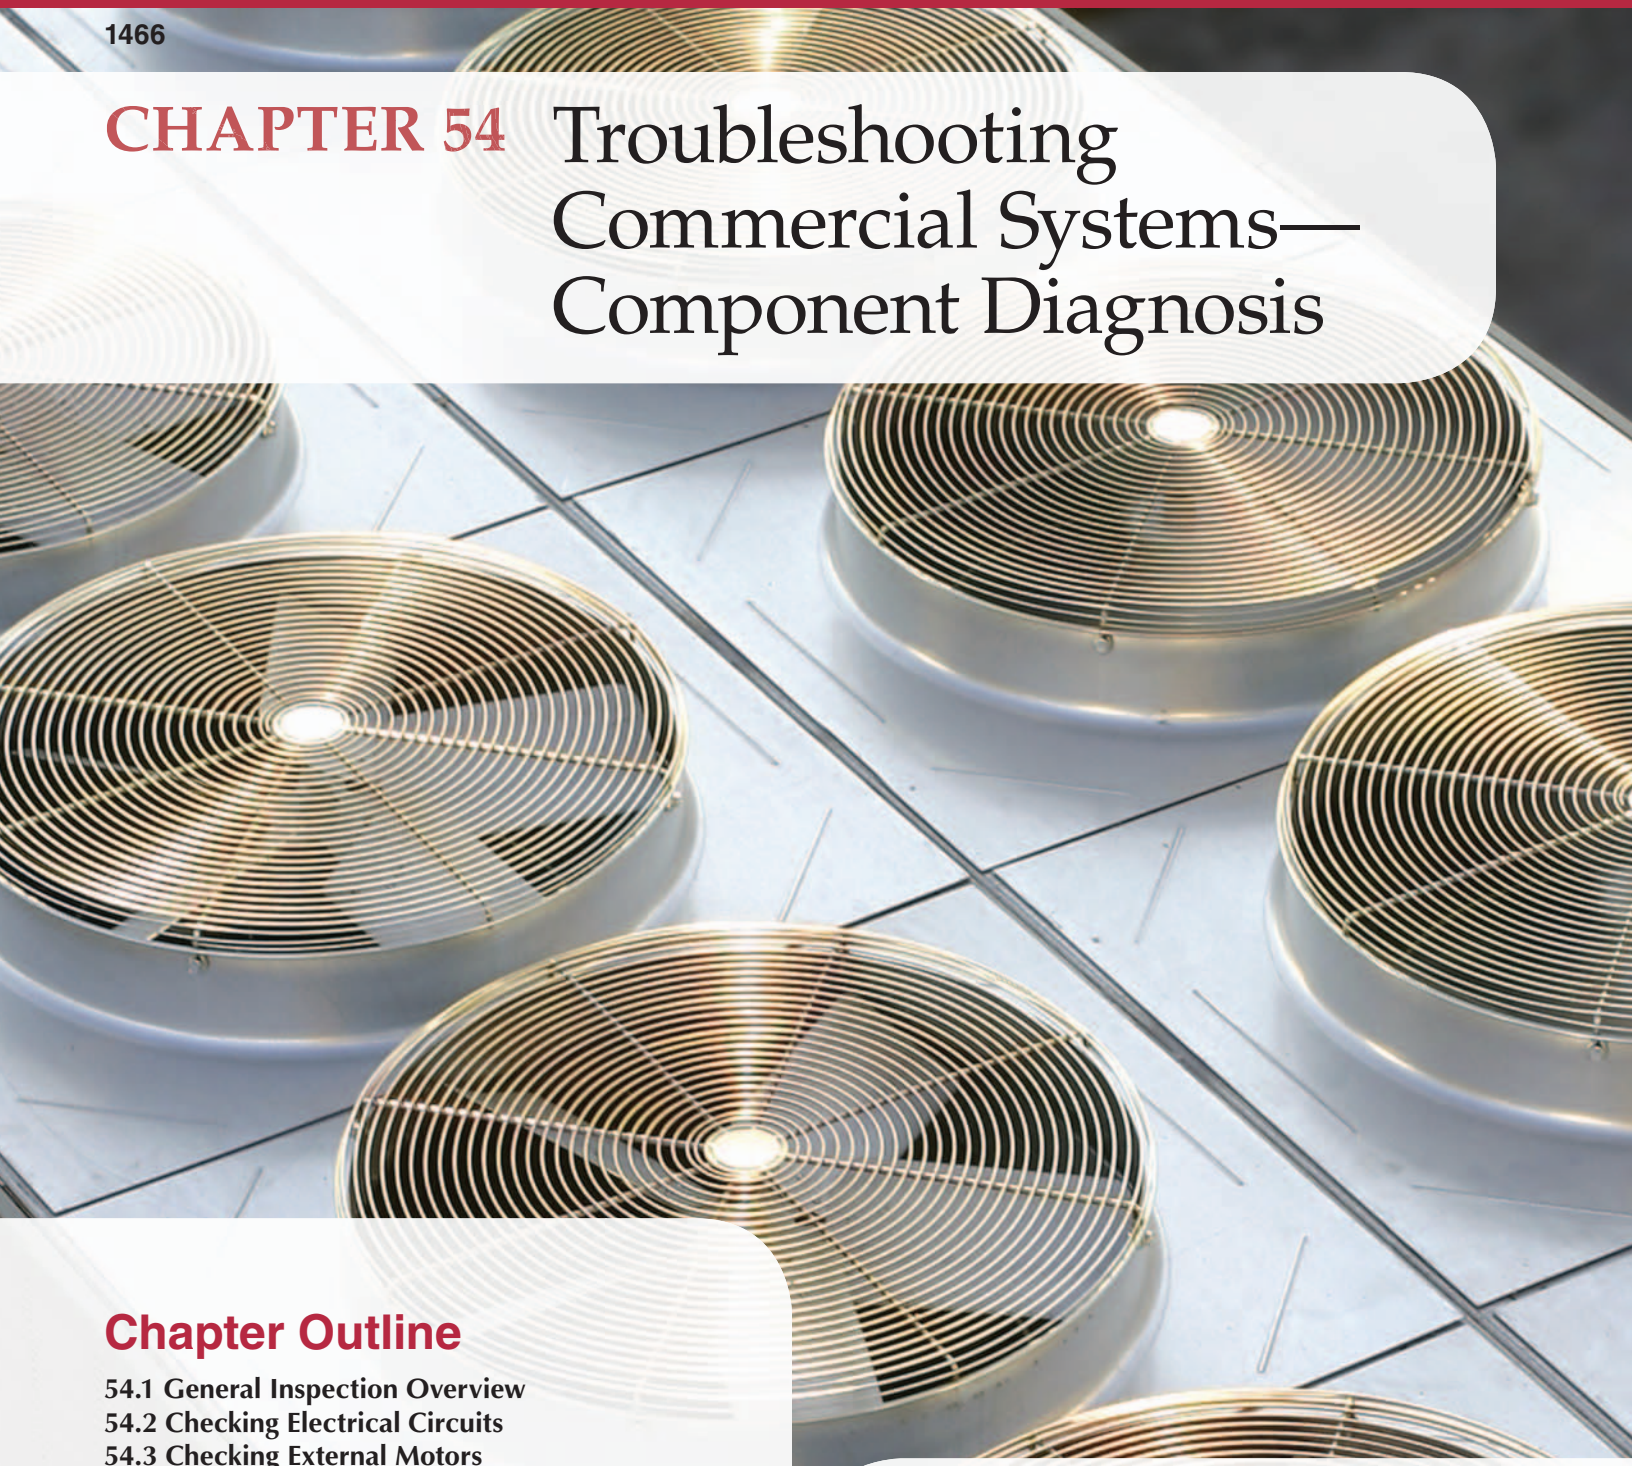
CHAPTER 54 Troubleshooting Commercial Systems—Component Diagnosis



Chapter Outline

54.1 General Inspection Overview
54.2 Checking Electrical Circuits
54.3 Checking External Motors
54.4 Checking Condensing Units
- 54.4.1 Checking Open-Drive Compressors
- 54.4.2 Checking Hermetic Compressors
- 54.4.3 Checking Air-Cooled Condensers
- 54.4.4 Checking Water-Cooled Condensers

54.5 Checking Liquid Lines
54.6 Checking Thermostatic Expansion Valves (TXVs)
54.7 Checking Electronic Expansion Valves (EEVs)
54.8 Checking Evaporator Pressure Regulators (EPRs)
54.9 Checking Hot-Gas Valves
54.10 Checking Solenoid Valves
54.11 Checking Evaporators
54.12 Checking Suction Lines

Learning Objectives

Information in this chapter will enable you to:

- Test the components of a system to determine what causes it to short cycle.
- Identify and distinguish the various causes of abnormal noises created by commercial refrigeration systems before implementing a remedy.
- Identify restrictions and pressure drops in various in-line components using a temperature survey.

wear gauge

Review of Key Concepts

Reviewing these concepts from earlier chapters will help you understand new concepts presented in this chapter:

- Reading electrical diagrams is essential in understanding an HVACR system's operation. Two common types of electrical diagrams are pictorial and ladder. (Chapter 16)
- Proper use of electrical test equipment and meters is necessary in troubleshooting HVACR systems. (Chapter 17)
- Motor controls for a system's compressor may react to pressure, temperature, oil level or pressure, and other measurable variables. (Chapter 16)
- Understanding the operation of the different refrigerant metering devices is necessary in troubleshooting an HVACR system. (Chapter 20)
- Understanding the operation of various refrigerant flow controls and pressure valves is necessary in troubleshooting an HVACR system. (Chapter 22)
- Different refrigeration systems require different refrigerant recovery and charging methods. When possible, use a liquid method and then finish with a vapor method. (Chapter 11)
- Problems with specific components produce certain symptoms. A complete understanding of system operation provides a technician with the discernment necessary for component troubleshooting. (Chapter 25)

Introduction

The financial investment in a commercial refrigeration installation is significant. Since so many mechanisms are dependent on the proper function of another mechanism, one system problem often causes other problems. The system operation and diagnosis information covered in the previous chapter was in preparation for troubleshooting a system down to specific component level. This chapter will cover how to check specific components in a system to tell whether they are responsible for a system's poor operation.

Copyright Goodheart-Willcox Co., Inc. 2017

54.1 General Inspection Overview

It is important that all commercial refrigeration systems be completely inspected periodically. Use a systematic method of doing this. In this way, no detail will be overlooked. All inspections should cover such things as:

- Electrical connections.
- Motor and safety devices.
- Compressor noises.
- Refrigerant charge.
- Moisture content of the refrigerant.
- Oil level.
- Water flow.
- Coil conditions.
- Tubing supports.
- Coil supports.
- Cleanliness.

For a condensing unit with an open-drive compressor, check:

- Belt condition.
- Belt alignment.
- Belt tightness.
- Coupling connection and condition.

For a condensing unit with a hermetic compressor, check:

- Overload cutout.
- Relays.
- Capacitors.

Pro Tip

Inspection Check Lists

Preparing an inspection check list will prevent technicians from forgetting items. Providing a copy for the owner will show the thoroughness of your inspection.

54.2 Checking Electrical Circuits

More and more electrical devices are being used in refrigeration systems. Some of these are electrical defrost systems, crankcase heaters, internal motor winding protectors, solenoid valves, electrical interlocks used between multiple units, and various other accessories, **Figure 54-1**.

A technician must be knowledgeable about electrical devices and electrical circuits. Be sure to review Chapters 12 through 17, which explain the fundamentals of electricity, electric motors, and electric controls. It is important to have a wiring diagram of the system

Transducers Direct, LLC

Figure 54-1. HVACR technician examining a wireless transducer in a cold storage room.

Zero Zone, Inc.

Figure 54-2. Wiring diagram for a compressor control circuit in the primary loop of a secondary loop refrigeration system.

being serviced, **Figure 54-2**. Certain items should always be checked, as modifications may have been made to a system over its service life:

- Are the wires large enough to carry the current of the device?
- Is the voltage correct?
- Is the current draw correct?

With the power on, the current draw and the voltage can be checked. If the unit will not run, turn off and lock out the power before checking the circuits for continuity and high resistance. With power off, using an ohmmeter may be more helpful and reveal more information than using a continuity tester. An ohmmeter can be used to find parts of a circuit with unintentionally high resistance, such as corroded or poorly made connections. Review the procedures in Chapter 16, *Electrical Control Systems* and Chapter 17, *Servicing Electric Motors and Controls*.

Locate a break in circuit continuity by measuring resistance in sections of a circuit with the ohmmeter or using the continuity check function on a multimeter. If a motor hums but will not start, check the starting capacitor. Use a capacitor tester or the capacitance measurement function on a multimeter, **Figure 54-3**.

Caution

Overload Protection

When servicing a compressor, do not start the unit without having fully functioning overload protection devices in the circuit. The motor control should be inspected to determine whether it trips freely. All contact points must be clean. Dirty or pitted contact points should be replaced.

54.3 Checking External Motors

Some municipalities require a licensed electrical contractor to remove, repair, and install motors. However, licensed HVACR technicians are generally able to work on electrical items within a unit. They

Sealed Unit Parts Co., Inc.

Figure 54-3. Digital multimeters designed for use in HVACR work often have a capacitance measurement function.

Copyright Goodheart-Willcox Co., Inc. 2017

must be able to diagnose motor troubles. Motor problems can be classified as either mechanical troubles or electrical troubles.

Mechanical troubles include misalignment, excessive end play, and faults in the bearings and pulleys. The sound of a motor can indicate trouble. Under normal conditions a motor will make a steady low hum. A problem exists if there are erratic beats in the humming or rotors chatter. In any case, the trouble could be one of the following:

- Worn bearings.
- Cracked or worn out rubber isolators.
- Dry bearings.
- Lack of voltage.

With the motor running, rotor position should be between the two extremes of the rotor end play. The motor shaft will not spin in an even manner, causing wobble and noise in the fan or belt attached to the shaft. When the rotor is out of alignment, it runs inefficiently. The endplay should never exceed 1/16" (1.587 mm). This may be adjusted by using endplay washers, which may be obtained at electrical supply houses.

The motor commutator should move freely. Brush releasing mechanisms or commutators of small motors can be checked by mounting a V-belt on the motor pulley. A load is put on the motor by pulling on the belt. Also, check the wear in the pulley by measuring a sheave's V-groove with a ***wear gauge***, **Figure 54-4**.

There are various causes of a noisy motor, including a loose pulley, a loose fan on the pulley, or a loose flywheel. These items should be checked when a noise complaint is received. Pulley bearing temperatures should be checked after operation if the unit is noisy. Use a thermometer to determine if the bearings are getting excessively hot. This would indicate that the bearings need to be lubricated or replaced.

Gates Corporation

Figure 54-4. A wear gauge will help in determining a sheave's condition.

Small fans are often driven by shaded-pole motors, and their most common trouble is worn bearings. Many of these motors are designed not to need lubrication. However, scoring of the bearings or wear marks indicate that lubrication or replacement of the bearings is required. Always use an approved bearing and grease that does not absorb dirt and moisture. Practice has proven that many do need oiling.

Some fans in newer installations and in remodeling are electronically commutated motors (ECMs). These motors often have manufacturer-specific diagnostic tools used to indicate problems and conditions. The motor may have a series of LED lights that indicate motor troubleshooting codes, such as a shorted winding or a circuit board that needs to be replaced.

Always be sure each motor is wired correctly. Voltage must be sufficient, and conductors must be sized sufficiently to carry the required current. Motors should be tested for grounds. Always ground the frame of a motor.

54.4 Checking Condensing Units

A condensing unit contains many important parts of a refrigeration system. The most important part is the compressor. This component creates the low pressure on the low side of the system and the high pressure of the high side of the system. In some commercial refrigeration applications, compressors are located with the condenser. In other applications, compressors are installed in a parallel rack or separate cabinet away from the condenser, **Figure 54-5**.

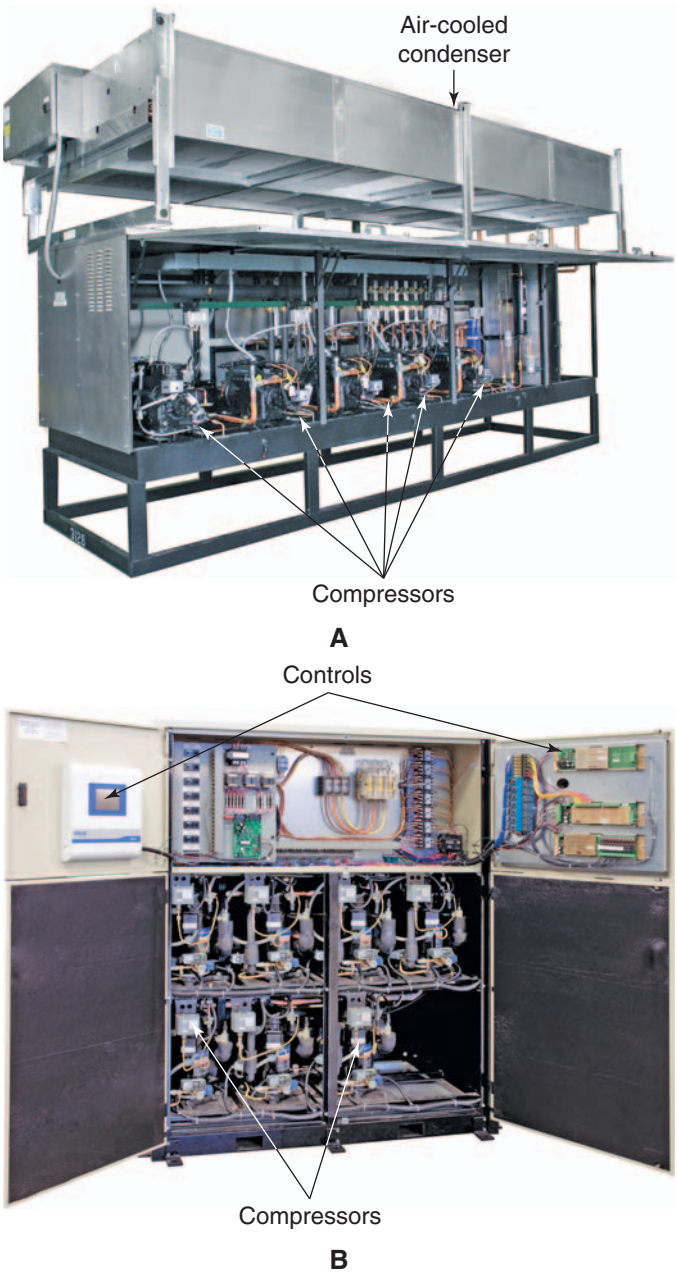
There are several types of compressor construction:

- Open-drive (external-drive) compressors.
- Semi-hermetic compressors (field-serviceable compressors).
- Hermetic compressors (welded, non-field-serviceable compressors).

Compressors may also be divided into categories based on their method of compression:

- Reciprocating.
- Rotary.
- Centrifugal.
- Screw.
- Scroll.

Copyright Goodheart-Willcox Co., Inc. 2017



Zero Zone, Inc.

Figure 54-5. A—This parallel rack of compressors has an air-cooled condenser installed on top. B—This distributed system contains just compressors and their controls. Refrigerant is drawn from the evaporators of nearby conditioned spaces and pumped to a remote condenser located elsewhere.

Condensers may be divided into groups based on their cooling method:

- Air-cooled.
- Water-cooled.
- Evaporative.

The variety of mechanisms and applications is a great challenge to the service technician. However, there are certain basic problems all these condensing units have in common:

- Compressor efficiency.
- Condenser efficiency.
- Refrigerant charge.
- Refrigerant cleanliness.
- Electric circuit problems.

54.4.1 Checking Open-Drive Compressors

In most cases of a "no cooling" service call, the operation of the compressor should be checked first. Look for other indications of problems while checking the compressor, such as frosting of refrigerant lines or parts, oil spatter indicating a refrigerant leak, damaged parts, or smoking electrical components.

The amount of oil and its condition in a compressor are important. Erratic refrigeration and constant oil slugging or pumping in a compressor indicates excess oil in the system. This frequently occurs at start-up. Some compressors have a plug located at the proper oil level. Others have an oil level sight glass or port, **Figure 54-6**.

Two of the most common causes of trouble with open-drive reciprocating compressors are faulty seals

Bitzer

Figure 54-6. Compressor oil level sight glass.

Copyright Goodheart-Willcox Co., Inc. 2017

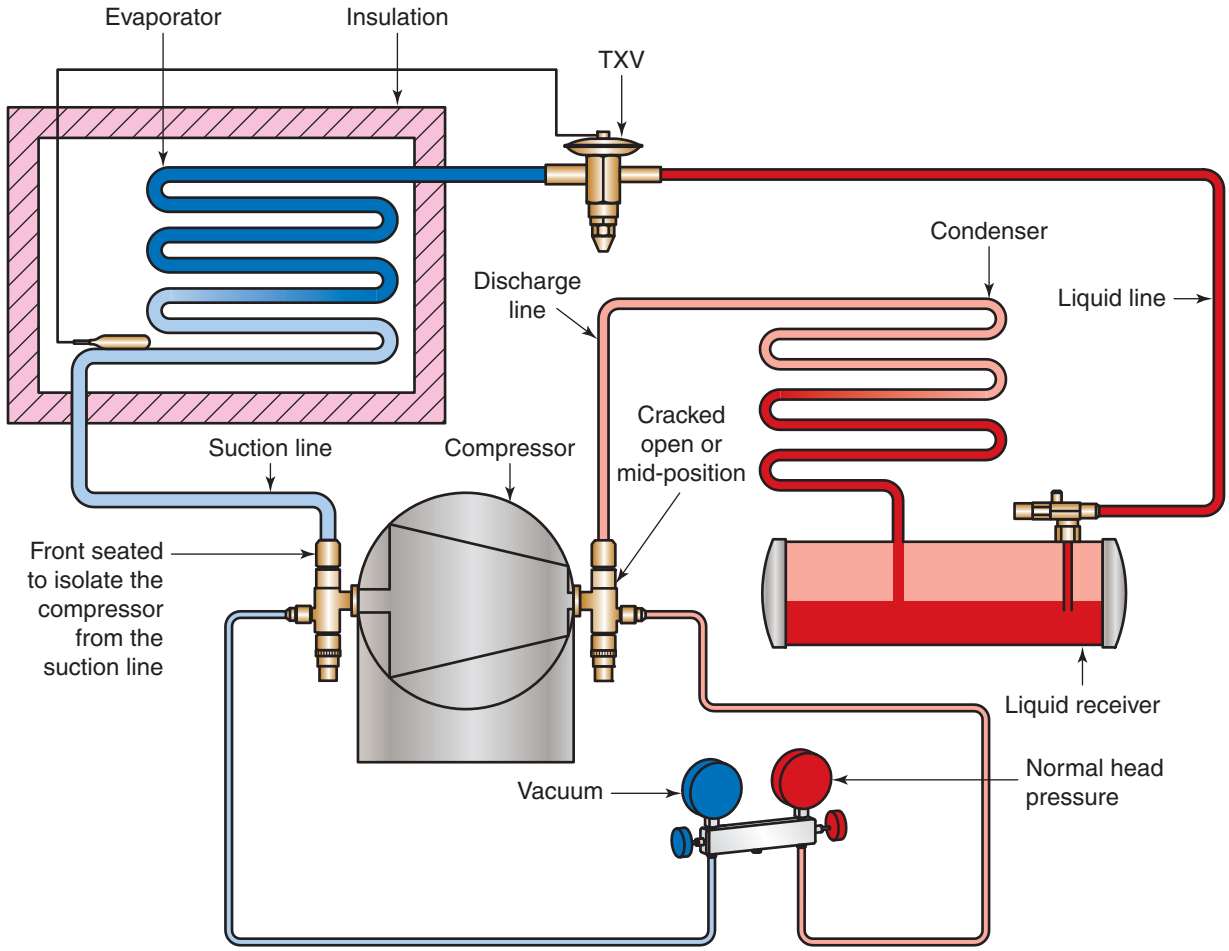
and faulty inlet and discharge valves. Faulty valves may be detected by a sharp clicking noise in the compressor as it operates. Faulty valves will lead to compressor inefficiency. An inefficient compressor will have a high suction pressure and a low head pressure during operation.

Valves on open-drive compressors are serviceable by a manufacturer-approved repair facility and are sent out for remanufacture of the compressor. However, this may lead to significant downtime. Replacing the compressor may be more cost effective if valves are faulty.

Identifying Leaking Compressor Valves

Follow the steps below to determine if a compressor has leaking valves. It is important to identify such problems, as they reduce system efficiency and cooling capacity. This procedure tests leaking compressor valves for an open-drive compressor.

1. Install a gauge manifold and test for leaks, **Figure 54-7**.
2. Front seat the suction service valve by turning in the valve all the way. This will isolate the compressor from the suction line.
3. Turn the power on and off for a few seconds at a time. This allows a small amount of oil to circulate through the compressor, rather than pulling a large volume of oil through the valves when the suction side is under a vacuum. Then turn on the compressor and allow it to run.
4. Record the best vacuum obtainable against the normal head pressure for the refrigerant



Goodheart-Willcox Publisher

Figure 54-7. To conduct an efficiency test for an open-drive compressor, close the suction service valve and run the compressor. Pumping efficiency will be indicated by the maximum vacuum obtainable and the time it takes to develop this vacuum.

Copyright Goodheart-Willcox Co., Inc. 2017

being used: _____ in. Hg. Also record the time required to reach this level: _____ minutes/seconds.

The compressor should produce a vacuum greater than 20 in. Hg against normal head pressure. This is an indication that the valves are seating properly and the compressor is able to pull a full vacuum. If the compressor cannot pull a full vacuum, in most cases, it should be overhauled or replaced. Determine which option is more cost-effective.

A worn piston or cylinder is indicated by a clicking noise. This noise is somewhat duller than the clicking noise of a faulty valve. Worn connecting rods and main bearings are quite noisy when the compressor runs with a low-suction pressure. Open-drive compressors may be sent to a manufacturer-approved rebuild center or may be replaced, depending on which option is most cost-effective.

A compressor must pump a specified quantity of gas at a certain pressure difference. This is necessary to do the work required for refrigeration. It is difficult to check this, so the methods just described are used as secondary checks. Some compressor manufacturer-approved repair shops use a shop-mounted tank. The compressor pumps air into one of these tanks while being tested. The time required to pump to a set pressure around 150 psi (1035 kPa) is recorded for each size compressor. In this way, a relative volumetric efficiency check is possible.

Three conditions are important to determine if a compressor is operating within the manufacturer's specifications:

- Ability to produce a vacuum.
- Ability to produce high pressure.
- Ability to hold both vacuum and head pressure.

There are two ways to check if a compressor's exhaust valve leaks:

- In the first way, the SSV and DSV are front seated to close off the compressor from the rest of the system. A gauge manifold is installed across the compressor. The compressor is run shortly and then cycled off. The compressor pulls the compound gauge into a vacuum while building up high pressure at its discharge. Care should be taken to run the compressor only momentarily to prevent build-up of excessively high pressure. The suction and discharge pressure are monitored. If the exhaust valve leaks, the high head pressure will leak back through the exhaust valve, and the high-pressure gauge will show a drop in the pressure reading. A leaking exhaust valve could cause the suction pressure to begin to slowly rise. If suction pressure rises to approximately 0 psi, the intake valve is also leaking. A leaking exhaust valve needs repair.
- In the second way, connect a gauge manifold across the compressor. Front seat the discharge service valve stem by turning it all the way in. If possible, turn the compressor shaft by hand several turns to build up head pressure. If it is not possible to hand crank the compressor, briefly cycle on the compressor, taking care not to create excessive head pressure. Gauge pressure that fluctuates considerably indicates a leaky exhaust valve. If pressure merely increases and does not drop back much, the exhaust valve is not leaking. Shut down the compressor and observe the high-side pressure measurement. If it drops, the exhaust valve is leaking.

The inability of a compressor to produce a high vacuum indicates an intake valve leak. However, the vacuum produced is maintained after the compressor is shut off, but only if the exhaust valve is holding and not leaky.

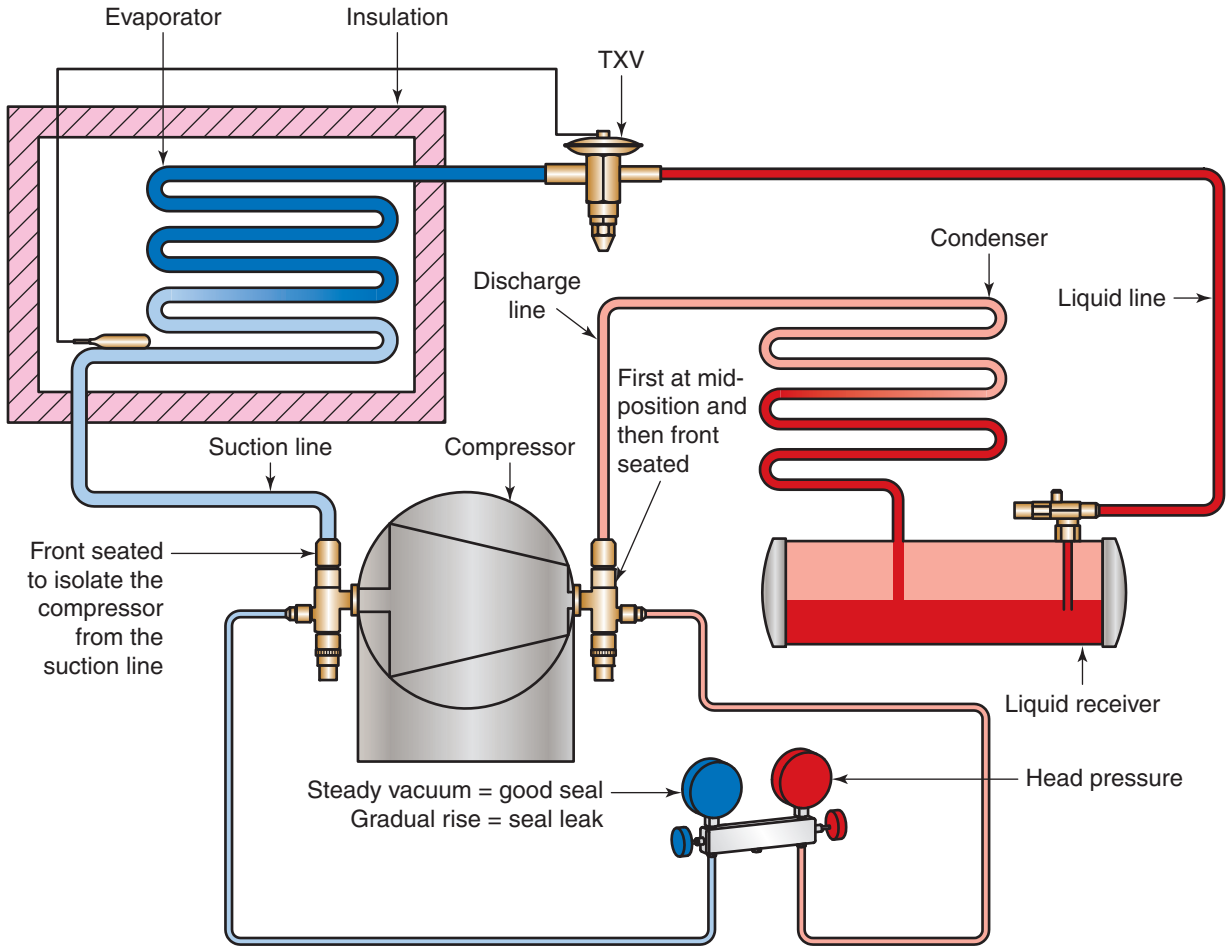
Inability of a compressor to produce a high vacuum may also be due to other factors. These include too thick a gasket or worn piston and rings. Lack of oil will also result in poor pumping ability. Review a manufacturer's specification sheets to determine what pressure levels a compressor should be able to maintain. These pressure values will vary, especially in regard to a compressor's intended temperature range and cooling capacity.

Crankshaft Seal Leak Detection

The following test is used to determine whether a crankshaft seal of an open-drive compressor is leaking:

1. Connect the gauge manifold as shown in **Figure 54-8**. Be sure that both gauge manifold valves are turned all the way in, isolating each gauge from the central chamber.
2. Front seat the suction service valve by turning it all the way in.
3. For now, adjust the discharge service valve to mid-position.
4. Cycle on the compressor's motor to pump as high a vacuum as possible on the crankcase of the compressor.
5. Turn the discharge service valve all the way in to front seat it. Keep the compressor running.

Copyright Goodheart-Willcox Co., Inc. 2017



Goodheart-Willcox Publisher

Figure 54-8. Testing a compressor for low-side leaks is done by determining the best vacuum the compressor can create. If air or vapor is entering the compressor, the high pressure will increase.

6. Monitor the measurement of head pressure as indicated on the high-pressure gauge for a while.

If there is a low-side leak, the measurement of pressure will gradually increase as the compressor continues to run. This indicates that gas or air is being drawn in on the compressor low side through the crankshaft seal. However, if pressure levels off and remains steady, then the crankshaft seal is not leaking.

Traces of oil on a crankshaft seal or on the floor underneath the compressor indicate a seal leak. Leak detectors may also be used to check for a seal leak. To perform this check properly, the crankcase pressure must be over 0 psig. Also use your ears to listen for any gas movement to locate leaks.

54.4.2 Checking Hermetic Compressors

Two types of hermetic compressors are used in commercial refrigeration:

- Hermetic (welded) compressors.
- Semi-hermetic (bolted) compressors.

Hermetic compressors may or may not have service valves. Semi-hermetic compressors usually have service valves. Semi-hermetic compressors may be tested, removed, and overhauled. They are then retested and installed in a manner similar to an open-drive compressor. The motor that is built into the housing is usually tested and reconditioned at the same time.

Although semi-hermetic compressors may be remanufactured, the HVACR technician should consider the cost to do so, including the downtime of the unit while the compressor is out for repair. It is often

Copyright Goodheart-Willcox Co., Inc. 2017

more cost effective to replace a compressor than to repair it, depending on the age and condition of the compressor.

Small welded compressors very seldom have service valves. Similar valves must be installed in these systems. One method of doing this is to use a piercing valve, **Figure 54-9**. Refer back to Chapter 10, *Equipment and Instruments for Refrigerant Handling and Service*, for information on installing these valves.

The condition of oil in hermetic compressors is very important. It should be tested to determine its acid level. The presence of acid in oil indicates that the oil is breaking down. It is reacting with the moisture and refrigerant it has contacted. The formation of acid often causes breaks in motor winding insulation causing localized hot spots in the motor windings. Checking can be done by removing an oil sample and using an oil test kit, **Figure 54-10**.

Most commercial compressors have an oil sump and oil drain to permit sampling and removal of compressor oil. Hermetic compressors will require the use of an approved refrigerant and oil recovery machine to remove, sample, and replace oil.

Sealed Unit Parts Co., Inc.

Figure 54-9. This piercing valve includes inserts for different diameter tubing.

Pro Tip

Acidic Compressor Oil

An oil sample is easily drained from semi-hermetic compressors. However, hermetic compressors usually require removing the compressor and draining some oil out of the suction line opening.

If the oil is acidic, the compressor should be thoroughly inspected. The motor windings should be checked for shorts and grounds. Motor winding failures may cause the compressor oil to become acidic. This is an indication that a motor failure is imminent and the compressor should be replaced.

Courtesy of Sporlan Division - Parker Hannifin Corporation

Figure 54-10. Kit used for testing refrigerant oil acidity.

Compressors require electrical power with specific characteristics. One of the first things technicians should check is whether the motor is operating with the correct voltage and current. Compare the electrical properties listed on the compressor's motor nameplate with the values measured. A variety of instruments will be necessary for measurement in order to acquire a full knowledge of a compressor's electrical characteristics, including voltmeters, ammeters, wattmeters, and power factor meters.

Voltage supplied to a compressor's motor must be no more than 10% below the motor's rated voltage and no more than 20% over. For instance, a 120 V motor should have a minimum voltage of 108 V and a maximum voltage of 144 V. This voltage should be read while the motor is running, not during starting or stopping when the level may temporarily drift.

The correct amount of current is vital to good operation. An in-line ammeter should never be connected across the line (in parallel). It must always be put in series with the electrical device being checked by interrupting one wire only in the circuit. However, whenever possible, avoid disturbing the wiring by using a clamp-on ammeter, instead of an in-line ammeter.

Carefully check external wiring and electrical controls for correct operation before assuming motor fault. First, turn off and lock out power to reduce your risk of electrical shock and injury. An ohmmeter is

Copyright Goodheart-Willcox Co., Inc. 2017

often used to check continuity in these de-energized circuits. Check each circuit separately. Disconnect if there is a chance of parallel circuits.

Motor capacitors should be checked with a capacitor tester. Review text and procedures in Chapter 17, *Servicing Electric Motors and Controls*. Do not use older, unreliable methods of testing capacitors, such as shorting after charging. Such methods are inaccurate and dangerous.

Three main problems to check in a compressor's motor are open circuits, shorted windings, and grounded (shorted-to-ground) windings. For open circuits, the motor should be cool or at least not very hot, else internal overload devices may be open, giving a false open (infinity, ∞) reading. Normal winding resistance readings are usually low values, often in the single or very low double digits. Check manufacturer specification sheets for exact values. For shorted windings, compare ohmmeter readings with motor manufacturer resistance values. These are usually low values.

For grounded (shorted-to-ground) windings, conduct a preliminary resistance measurement test using an ohmmeter. These readings should be extremely high, such as infinity (∞). If this reading is lower than this, conduct a motor winding insulation test using a megohmmeter. Insulation breaks can be checked accurately only with this high-voltage tester. Handle carefully to avoid shocks. Review Chapter 17, *Servicing Electric Motors and Controls*, for additional information.

Companies report that many compressors that are returned and labeled as "faulty motor" actually have good motors. This false diagnosis indicates the need for careful checking. Always double check and record your readings for motor winding continuity, checks for shorts to ground, and current draw. **Figure 54-11** contains a list of typical motor and circuit troubles, their causes, and their remedies.

54.4.3 Checking Air-Cooled Condensers

Condenser capacity is the amount of heat a condenser can reject. The more heat a condenser can reject, the higher its capacity. Condenser capacity can rise or lower by changing a number of factors relating to the condenser.

Air-cooled condensers must have sufficient surface area to allow vapor refrigerant to expel heat into ambient air. In general, the more surface area a condenser has, the more heat it can expel from its refrigerant at a given rate of flow in a given period of time. For instance, heat rejection will be reduced in a condenser that contains more liquid refrigerant than normal. This is because the liquid refrigerant will be occupying surface area that should be occupied by vapor refrigerant. Reducing the surface area reduces the heat rejection, which reduces condenser capacity.

Another factor that may reduce a condenser's heat rejection is if the normal airflow around it is reduced. An air-cooled condenser relies on air to act as a medium that will carry away the rejected heat. If the medium does not carry away the heat, the condenser will not be able to reject as much heat as it normally could, reducing condenser capacity.

A third factor that reduces condenser capacity is when the temperature of the air is above normal. The lower the temperature of ambient air, the easier it is to reject heat into it. The greater the temperature difference, the easier the exchange of heat. High ambient air temperature creates a situation where the condenser is not able to reject as much heat as it normally could. Also, when condenser temperature rises, head pressure increases. This requires the compressor to draw more current to pump to the higher pressure.

If noncondensables (such as air) get into the refrigerant-circulating part of a system, it will collect in the condenser. This air cannot condense. Also, it will be stuck in the condenser, as it will be held back by a liquid trap in the liquid receiver or the lower end of the condenser. Each psi of air pressure will increase the head pressure by 1 psi. This increase in pressure will reduce the pumping efficiency of the compressor and increase the condensing temperatures. It also occupies space that otherwise would have been occupied by vapor refrigerant to reject heat.

Excessive head pressures are very hard on a refrigeration system. High head pressure causes high compressor discharge temperatures, which will cause the formation of sludge, carbon, and acid as the oil is broken down in the system. The suction and discharge valves may also be damaged.

High head pressures may be caused by:

- Excessively low suction pressure.
- Reduced condenser heat exchange caused by high ambient temperature, a dirty condenser, reduced airflow, etc.
- Noncondensables in the system.
- Overcharge of refrigerant.

If a condenser has high head pressure and a higher than normal temperature, examine the condenser. Ensure that the condenser fans are operating properly. Remove any obstructions to condenser air passageways. Clean the tubes and fins of any dirt or film. Some air-cooled condensers may be cleaned with a vacuum cleaner. However, more often technicians

Hermetic Compressor Service Chart	
Problems and Causes	**Remedies**
Compressor will not start—no hum.	
1. Open line circuit.	1. Check wiring, fuses, and receptacle.
2. Protector open.	2. Wait for reset—check current.
3. Control contacts open.	3. Check control, check pressures.
4. Open circuit in stator.	4. Replace stator or compressor.
Compressor will not start—hums intermittently (cycling on protector).	
1. Improperly wired.	1. Check wiring against diagram.
2. Low line voltage.	2. Check main line voltage, determine location of voltage drop.
3. Open starting capacitor.	3. Replace starting capacitor.
4. Relay contacts not closing.	4. Check by operating manually. Replace relay if defective.
5. Open circuit in starting winding.	5. Check stator leads. If leads are all right, replace compressor.
6. Stator winding grounded (normally will blow fuse).	6. Check stator leads. If leads are all right, replace compressor.
7. High discharge pressure.	7. Eliminate cause of excessive pressure. Make sure discharge shutoff and receiver valves are open.
8. Tight compressor.	8. Check oil level—correct binding condition, if possible. If not, replace compressor.
9. Weak starting capacitor or one weak capacitor of a set.	9. Replace capacitor.
Compressor starts, motor will not get off starting winding.	
1. Low line voltage.	1. Bring up voltage.
2. Improperly wired.	2. Check wiring against diagram.
3. Defective relay.	3. Check operation—replace relay if defective.
4. Running capacitor shorted.	4. Check by disconnecting running capacitor.
5. Starting and running windings shorted.	5. Check resistances. Replay compressor if defective.
6. Starting capacitor weak or one of a set open.	6. Check capacitance—replace if defective.
7. High discharge pressure.	7. Check discharge shutoff valves. Check pressure.
8. Tight compressor.	8. Check oil level. Check binding. Replace compressor if necessary.
Compressor starts and runs but cycles on protector.	
1. Low line voltage.	1. Bring up voltage.
2. Additional current passing through protector.	2. Check for added fan motors or pumps connected to wrong side of protector.
3. Suction pressure too high.	3. Check compressor for proper application.
4. Discharge pressure too high.	4. Check ventilation, restrictions, and overcharge.
5. Protector weak.	5. Check current—replace protector if defective.

Goodheart-Willcox Publisher

Figure 54-11. Refer to this chart for guidance in troubleshooting hermetic compressors. (*continued*)

6. Running capacitor defective.	6. Check capacitance—replace if defective.
7. Stator partially shorted or grounded.	7. Check resistances; check for ground—replace if defective.
8. Inadequate motor cooling.	8. Correct cooling system.
9. Compressor tight.	9. Check oil level. Check for binding condition.
10. Unbalanced line (three-phase).	10. Check voltage of each phase. If not equal, correct condition of unbalance.
11. Discharge valve leaking or broken.	11. Replace valve plate.
Starting capacitors burnout.	
1. Short cycling.	1. Reduce number of starts to 20 or less per hour.
2. Prolonged operation on starting winding.	2. Reduce starting load (install crankcase pressure regulator), increase voltage if low—replace relay if defective.
3. Relay contacts sticking.	3. Clean contacts or replace relay.
4. Improper relay or incorrect relay setting.	4. Replace relay.
5. Improper capacitor.	5. Check parts list for proper capacitor (mfd.) rating and voltage.
6. Capacitor voltage rating too low.	6. Install capacitors with recommended voltage rating.
7. Capacitor terminals shorted by water.	7. Install capacitors so terminal will not get wet.
Running capacitors burnout.	
1. Excessive line voltage.	1. Reduce line voltage to not over 10% above rating of motor.
2. High line voltage and light load.	2. Reduce voltage if over 10% excessive.
3. Capacitor voltage rating too low.	3. Install capacitors with recommended voltage rating.
4. Capacitor terminals shorted by water.	4. Install capacitors so terminals will not get wet.
Relays burnout.	
1. Low line voltage.	1. Increase voltage to not less than 10% under compressor motor rating.
2. Excessive line voltage.	2. Reduce voltage to maximum of 10% above motor rating.
3. Incorrect running capacitor.	3. Replace running capacitor with correct mfd. capacitance.
4. Short cycling.	4. Reduce number of starts per hour.
5. Relay vibrating.	5. Mount relay rigidly.
6. Incorrect relay.	6. Use relay recommended for specific motor compressor.

use a high-pressure jet of air, mechanical scrubbing, or pressurized water with detergent, **Figure 54-12**.

Safety Note

Eye Protection

Whenever operating pressurized gas or liquid equipment, be certain to wear goggles. Also, some form of eye protection is recommended when scrubbing or scraping surfaces that may chip or break off pieces.

Determining Head Pressure for an Air-Cooled Condenser

One of the most important pieces of information necessary for checking an air-cooled condenser is the proper value of a system's head pressure. A few steps are necessary in determining this value:

1. Measure and record the temperature of the ambient air around the condenser: _____ °F/_____ °C.
2. Add 30°F or 35°F (16.6°C or 19.4°C) to the value of the ambient air temperature: _____ °F/ _____ °C. This new value is the temperature at which the refrigerant condenses inside of the condenser. Note that if the condenser is high efficiency or microchannel, check with manufacturer literature to determine if the 30°F to 35°F temperature difference between condensing and ambient should be different.
3. Refer to the pressure-temperature (P/T) chart for the refrigerant used in this system. Corresponding values for common refrigerants can be found in the pressure-temperature charts in Chapter 9, *Introduction to Refrigerants* and in the *Appendix*.
4. Find the pressure value that corresponds with the temperature value calculated in the previous step: _____ psi. This pressure value is the proper head pressure for your system. Ideally, the refrigeration system will have this head pressure.

A variety of issues could cause head pressure to be higher than the value found corresponding in a P/T chart. For instance, noncondensables may be in the refrigerant circuit. Noncondensables in a refrigeration system become trapped in the condenser, where they occupy surface area space. As mentioned earlier in this

SpeedClean

Figure 54-12. Cleaning condenser tubes and fins maximizes heat exchange for improved system efficiency.

Copyright Goodheart-Willcox Co., Inc. 2017

chapter, the less condenser surface area, the less heat can be rejected from the condenser. This results in a higher condensing temperature and a corresponding higher head pressure. (In a fixed volume, as pressure rises, temperature also rises.)

Another cause of higher head pressure could be clogged or obstructed air inlets and outlets. Both air inlets and air outlets must be free and clear of any debris or blockages. If air passageways are not clean and open, air movement is reduced. Less air movement means less heat is carried away from the condenser, meaning less heat can be rejected from the condenser. A reduction in heat rejection raises the temperature and pressure in the condenser.

Other factors affecting head pressure include incorrect refrigerant charges. An overcharge would cause high head pressure, as more liquid refrigerant would occupy condenser surface area and reduce heat rejection. An undercharge of refrigerant would result in a lower than normal head pressure.

Most commercial air-cooled condensers use forced convection. They have one or more fans for moving air through the condenser. Larger fans are either belt-driven or directly driven with a coupling. Fans, motors, and belts need regular maintenance and service.

Refrigeration systems with special arrangements and controls can maintain good head pressure when outdoor air-cooled condensers are exposed to colder temperatures, from 50°F (10°C) down to –10°F (–23°C). These include pressure-regulating valves, split condenser arrangements, air louver controls, electric heaters, and fan speed control and cycling. This information is explained in Chapter 21, *Heat Exchangers* and Chapter 22, *Refrigerant Flow Components*.

Service of outdoor air-cooled condensers depends on the types of head pressure control used. In all cases, condenser operation can be checked by blocking the condenser air inlet or outlet with cardboard. This will raise head pressure. Removing the cardboard will lower head pressure. This will quickly allow the HVACR technician to achieve the cut-in and cut-out pressure to confirm that the head pressure control is operating correctly. Use the following procedures according to type.

Troubleshooting Outdoor Condensers

Outdoor condensers may have electrical or mechanical failures. They often suffer from restricted airflow due to debris. Rooftop units can become clogged with bird nests and leaves. Ground units may be clogged with grass clippings and flower pollen. A close inspection often shows that outdoor condensers require cleaning.

1. First check the fan assembly for mechanical faults, such as a loose fan, bent blades, broken shroud, or worn belts and bearings.
2. Use a voltmeter to check for electrical power to the fan motor.
3. Use a clamp-on ammeter to measure starting current draw and running current draw.
   - Starting current measurement: _____ A.
   - Running current measurement: _____ A.
4. Compare these measurements with the manufacturer's specifications on the motor label.
   - Starting current specification: _____ A.
   - Running current specification: _____ A.
5. After taking measurements, shut off and lock out power, **Figure 54-13**.
6. Check the motor windings for shorts, opens, and shorts-to-ground using an ohmmeter. If ground readings seem suspiciously low, test for shorts-to-ground with a megohmmeter.
7. Check for continuity using an ohmmeter across any high-temperature cut-out controls. If the cut-out is stuck open, replace it.

Goodheart-Willcox Publisher

Figure 54-13. Shutting off and locking out power protects technicians from electrical dangers.

Copyright Goodheart-Willcox Co., Inc. 2017

Troubleshooting Outdoor Condenser Louvers

1. Check louver and power element operation by blocking condenser airflow to see if the louvers will operate automatically.
2. If the louvers do not open after inlet airflow is blocked, inspect the louvers and all related mechanical parts. Debris may be blocking the free movement of the louvers. Part of the linkage may be broken or disconnected.
3. If the mechanical parts appear to be in good condition, then the power element, which is operated by head pressure, may be faulty. If possible, use gauges or a temperature survey to confirm that refrigerant is making it to the power element. Look for kinks in the refrigerant tubing running to the power element. Eliminate other possible causes of louver failure before replacing a power element.

54.4.4 Checking Water-Cooled Condensers

Water removes heat from metal surfaces about 15 times more rapidly than air can. This means that a water-cooled condenser of a given size can reject 15 times more heat than an air-cooled condenser of the same size. Therefore, water-cooled condensers can be built much smaller than air-cooled condensers. Also, since available water is often colder than ambient air, water-cooled condenser's temperature and pressure can be lower than those values of an air-cooled condenser of comparable capacity.

The temperature of the cooling water rises as it flows through the condenser. This temperature rise is expected as the heat absorbed from high-side refrigerant is not intended to change the phase of the cooling water. The temperature rise of water as it travels through a condenser should be limited. Water flow should be adjusted so temperature does not exceed a 15°F rise.

Determining Head Pressure for a Water-Cooled Condenser

There are only a few easy steps in calculating head pressure for a refrigeration system using a water-cooled condenser. Remember that the system must be running during measurements for these conditions and values to hold true.

1. Measure the temperature of the condenser water at the water outlet: _____ °F/_____ °C.
2. Add 10°F to 15°F (6°C to 8°C) to the measured value of the water temperature: _____ °F/_____ °C. This calculated temperature is what the condensing refrigerant temperature should be.
3. Refer to the pressure-temperature (P/T) chart for the refrigerant used in this system. Corresponding values for common refrigerants can be found in the pressure-temperature charts in Chapter 9, *Introduction to Refrigerants* and in the *Appendix*.
4. Find the pressure value that corresponds with the temperature value calculated in an earlier step: _____ psi. This pressure value is the proper head pressure for this refrigeration system.
5. With the compressor still running, measure head pressure using a high-pressure gauge connected to the discharge service valve: _____ psi.
6. Compare the calculated head pressure and the measured head pressure. If the measured head pressure exceeds the calculated value by more than 5 psi, stop the compressor.
7. Recover the unit's refrigerant, evacuate the system, and recharge the specified amount of refrigerant according to the manufacturer. While the system's charge is recovered and the condenser drained of water, see if scale or buildup is present within the condenser. This could be reducing heat transfer and causing a corresponding increase in head pressure.
8. After recharging the system and returning water valves to the normal position, return the system to normal operation for several minutes.
9. Measure and record pressure and temperatures to verify that the system is operating within normal parameters.

Leak Testing a Water-Cooled Condenser

1. Check water flow by placing a flowmeter at the water inlet to the condenser. Compare the water flow rate to the manufacturer's required minimum flow rate.
2. Check for signs of scale build-up. Water leaks usually result in a build-up of lime and calcium

Copyright Goodheart-Willcox Co., Inc. 2017

deposits around the water tubing, which can be easily detected.
3. Check for obvious signs of water leakage and cracked lines or burst fittings in the water plumbing.
4. Shut down the system, close off the water supply, and replace or clean any water inlet filters or screens.
5. Replace any damaged or leaking plumbing sections and fittings.

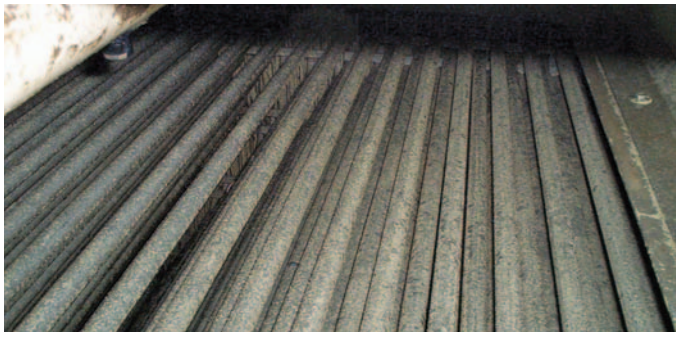
A common water-cooled condenser problem is the formation of scale deposits from water on the tubing walls. Minerals normally found in solution in water are drawn to the walls of the condenser tubing. These materials include carbonate, sulfate, lime, and iron. This process occurs because of the attraction of opposite charges of the minerals and the tubing. These deposits then act as an insulating layer, reducing the exchange of heat. Scale build-up is also a problem in cooling towers as it develops on the exterior of tubing, as shown in **Figure 54-14**.

All water-cooled heat exchangers should be included in a monthly maintenance plan depending on the type and usage of the system. Biodegradable treatments and mechanical brushes are used to periodically flush and clean heat exchangers and cooling towers. Cooling towers are first cleaned with a high-pressure washer and biodispersement product, which loosens dirt and debris for removal. The bacteria level of the cooling water should be checked. If bacteria is present, the coils must be disinfected with a chlorine-based solution to kill off bacteria.

Removing Scale Deposits from Water-Cooled Condenser Water Tubes

Before beginning this procedure, survey the system. Drain the water from the condenser's water circuit and valve off the proper pipes. Next, determine the best way to remove refrigerant from the condenser. This may include pumping down the charge into the liquid receiver or recovering the charge into a cylinder.

1. Remove all debris from filters and water catch basins.
2. Clean all exterior surfaces with a biodegradable detergent and high-pressure water.
3. Check all standing water for bacteria and pH levels.
4. Use an approved and certified cleaning company for mechanical wire-brush cleaning of heat exchangers and acid washing of scale and lime build-up.



Scale Free International

Figure 54-14. Scale build-up on the surface of cooling tower coils.

Regular maintenance of water-cooled condensers includes cleaning a system and preventing the buildup of scale. An acid-based solution is used on scale build-up in open water systems, such as cooling towers and evaporative condensers. The use of non-biodegradable materials is strictly controlled and harmful to the environment. Observe all EPA regulations when using or disposing of hazardous chemicals.

Safety Note

Poisonous Chemical Cleaners

When handling cleaners, be aware of any special labels or warnings. Some can be poisonous. Wear goggles, rubber gloves, and a rubber bib apron. Storage and handling of hazardous materials is strictly controlled by DOT and EPA regulations. Working with these substances should be done by certified technicians only. For this reason, cleaning of heat exchangers and cooling towers is normally handled by licensed and insured hazardous waste contractors.

Caution

Legionnaires' Disease (Legionella)

Untreated standing water has been linked to numerous outbreaks of Legionnaires' disease. The disease results in severe respiratory illness and even death. Legionnaires' disease is so named due to an outbreak in 1979 at an American Legion Conference in Philadelphia, Pennsylvania, where 29 members died and 182 people suffered pneumonia-like illnesses. Bacterial contamination in cooling tower water was suspected of transferring the disease to the airstream of the conference center, sickening those who were in attendance. As a result of numerous outbreaks, cooling tower water cleanliness is of utmost priority to a safe and healthy building environment.

Careless mixes of acid and water can ruin copper piping and steel structures. Some technicians do use

Copyright Goodheart-Willcox Co., Inc. 2017

acids to descale, but it must be done rapidly. It must be cleaned as quickly as possible. Remember to wear goggles and rubber gloves. This task is best left for a certified technician.

A clogged or scaled water-cooled condenser can be recognized by checking the liquid line temperatures of the refrigerant. A corroded water-cooled condenser will have a hotter than normal liquid line. This holds true provided the refrigerant amount is correct and other troubles just mentioned are not found. Temperature and pressure in the condenser will be considerably higher than expected, as the waste heat is not removed from the condenser. Eliminate all other possible causes for excessive head pressure, such as overcharge and restrictions. When these possibilities have been eliminated, a badly corroded or dirty condenser is probably the cause.

Soft scale deposits are deposits that can easily be removed from some water-cooled condensers with a power-driven wire brush. This can usually be done without removing the condenser from the system. However, the water circuit must be closed and the unit shut down.

Pro Tip

Water-Cooled Condenser Gasket Replacement

The inlet and outlet of the water supply to a water-cooled condenser use gaskets to seal the connections. It is good practice to use new gaskets and tighten assembly joints to specification when servicing a water-cooled condenser.

There are "scale-free" systems that effectively eliminate the scaling process that causes deposits. Electronic scale treatment systems expose an electrolyte rod to the water to use as a positive ground. This process, in turn, picks up the electrical energy from the water. It is grounded to the outside of the condenser. Thus, the inside tubing is kept free from scale. This electrical energy also causes existing scale or deposits to go back into solution. They are then carried through the system and discarded.

There are two common signs that indicate troubles with water circulation in water-cooled condensers. One is the lack of cooling in the condensing unit. The other is too great a consumption of water.

Restricted Water Flow

If the water flow is inadequate, the cause might be one of the following:

- Leaking valve.
- Clogged screen.
- Chattering valve.
- Valve that is incorrectly adjusted.
- Sediment-bound valve.
- Leaking bellows.

In addition to these possible problems, leaking of the water-cooling system may also be the cause. Hard piped water lines sometimes flex and break at their joints, causing a leak. Some water-cooled systems use a length of rubber or plastic hose between sections of the water pipe. This hose is run along the wall and the condensing unit water lines. It eliminates the transmission of the condensing unit vibration into the building's plumbing system. It also prevents damage to tubes caused by this vibration.

Occasionally, someone may partially or completely shut off the water supply. This happens when a hand-operated valve installed in the system is closed. Always put signs near the shutoff valves, warning of the effect on the unit if these valves are closed.

If the water circulation is stopped, the refrigeration system will start to short cycle. Because water is not removing the heat, the condenser heats up, which also causes head pressure to rise. As head pressure rises, a high-pressure switch on the high side opens, stopping the compressor. Once the compressor has stopped, head pressure drops rapidly. This closes the high-pressure switch and allows the compressor to turn on again. Though the high-pressure switch is the control that is causing the system to short cycle, the root cause is the lack of water that allows heat and pressure to rise.

Short cycling will continue unless the lack of water is remedied. Such a condition is a severe strain on the compressor's motor. Furthermore, it does not provide satisfactory refrigeration.

Excess Water Flow

Excess water flow will result in lower condenser temperature and pressure. It is possible that excess water flow could cause reduced system efficiency. If anything, it results in excessive water usage. Depending on system setup, this could increase the cost of water and wastewater. Three common causes of this condition include:

- Water pressure too high.
- Water valve leaking.
- Water valve incorrectly adjusted.

Water pressure may be measured by a flowmeter. High water pressure to a system is seldom found, unless the water supply pressure is uncontrolled. If high water pressure is found in one system, it may be true for all the systems in that locality. If the local water pressure is too high for a manufacturer's specification, a restrictor or water pressure regulator may be

Copyright Goodheart-Willcox Co., Inc. 2017

required to reduce the flow rate available to the water valve. Excess water flow is often due to either a leaking valve or a valve opened too far.

A further indication of excess water flow is a continuous flow of water during the Off cycle. Check for signs of scale build-up and water puddles around the valve that would indicate a leak. A leaking water valve is often caused by foreign matter between the valve and seat. This material can usually be dislodged by flushing the valve. The flushing may be done by opening the valve and manually cleaning and flushing water through the valve.

Tracing Water Circuit Troubles

If there are water circuit problems, the fault may be the water valve or some other part of the water circulating system. The exact source of the trouble must be located. Doing so will require disconnecting the water tubing joints along the system.

If possible, close the water inlet valve. Have a nearby bucket ready to minimize spillage. Then crack the water inlet valve open just a little to permit a small amount of water flow. Place the bucket under the joint to be opened. Crack open the joint to see if a steady stream of water flows to this point. Repeat this process down the line until the source of the restriction is found.

Disconnecting the water outlet pipe will show whether the water is flowing as far as this point. If it is, the connection should be resealed. The other end of the pipe must be disconnected from the wall pipe. If water does not flow up to this point, the trouble is probably in the drain pipe.

To determine whether water is coming as far as the water valve, disconnect the water valve's inlet pipe connection. If water flows through the pipe, either the water valve or the condenser is the problem. To check these sources, reseal the inlet pipe to the water valve and disconnect the water valve's outlet pipe going to the condenser.

If the water flows through the water valve but not through the condenser, the condenser water tubes will need to be replaced or cleaned. If the water does not flow through the water valve, the water valve must be disconnected and repaired or replaced.

A very noisy condition that is easily recognized is ***water hammer***, which is a single, distinct thump (rap) heard in the pipes just as a valve closes. Generally, this condition can be corrected by adding a T-fitting with a short, vertical pipe in the water line just upstream from the valve. It provides an air column that helps absorb the shock of the sudden stopping of water flow. Another method of reducing the surge of water is to install an expansion tank. This is a pressure vessel that allows for increased water volume and eliminates or reduces water hammering.

54.5 Checking Liquid Lines

The primary purpose of a liquid line is to deliver a steady stream of subcooled, high-pressure liquid refrigerant from a condenser or liquid receiver to an evaporator. However, it can also contain various inline components for specific purposes. Filter-driers clean and remove moisture from refrigerant. Sight glasses can show bubbles or vapor in the liquid refrigerant. Moisture indicators show the moisture content of the refrigerant. Hand and solenoid valves regulate flow for different operations.

While each component along a liquid line can improve system control and operation, they also provide another opportunity for a leak, a clog, or other failure. Components along the liquid line that should be inspected include the following:

- Hand shutoff valves.
- Sight glass.
- Moisture indicator.
- Inlet screen.
- Filter-drier (or dehydrator).
- Solenoid valves.

Each mechanical joint or brazed connection is a potential leak. Test all joints for leaks. Each kink, pinch, or buckled piece of tubing could be an unintentional pressure drop. When diagnosing refrigeration system problems, determine if each component has the proper capacity.

The liquid line should be the same size as the liquid receiver service valve connection. Check to be sure that reducer fittings have not been used. See Chapter 51, *Commercial Refrigeration Component Selection*, for recommended liquid line sizes. Many large units use various sizes of liquid lines.

Check the temperature of the liquid line. Perform a ***temperature survey*** of the liquid line. This involves taking and recording temperature measurements at different locations and comparing them. Good measurement points include before and after any in-line components (valves, filter-driers, sight glasses, etc.) and on each side of any other tubing connections.

A liquid line should be close to room temperature along its full length. A measurable temperature drop between the inlet and outlet of any component along the liquid line indicates a pressure drop. The more the temperature drop, the more the pressure drop. The pressure drop could be caused by a clog or other restriction. Sweating and even frosting may be seen on

Copyright Goodheart-Willcox Co., Inc. 2017

the component causing the pressure drop. The pressure drop evaporates liquid refrigerant, which then absorbs heat. This cools the pressure drop component and causes sweating or frosting. This may also cause bubbles in the sight glass.

54.6 Checking Thermostatic Expansion Valves (TXVs)

A TXV problem may be diagnosed by observing affects on other parts of a refrigeration system. A problem with a TXV will manifest changes in the evaporator that can be seen, heard, and sensed by measuring temperature and pressure. The formation of frost on the evaporator and sometimes also on the suction line may be due to one of the following causes:

- The TXV needle may be leaking.
- The TXV's sensing bulb may be attached loosely to suction line, improperly located, or not properly insulated.
- Dirt or debris may be stuck in the valve and holding it open.
- The TXV's inlet screen may be clogged.
- The TXV may be adjusted for too little superheat.
- An external equalizer may be needed.
- The valve may have been repaired with the incorrect thermal bulb charge.
- The valve body may have been replaced with an incorrectly sized orifice.

Systematically check everything. Rule out the possible causes one by one. Use all pressure and temperature measurements and the sights and sounds of the system as you continue your diagnosis.

Before attempting to readjust a thermostatic expansion valve, check how its sensing bulb is mounted. A small detail like the location and attachment of a sensing bulb could have dramatic effects on a TXV's operation. Using the wrong kind of strap or placing the sensing bulb away from its proper place could result in erratic metering and improper refrigeration. A sensing bulb that has not been wrapped and insulated may form frost or sense the temperature of ambient air instead of suction line temperature.

The size of the suction line tubing will determine where the sensing bulb is placed along the tubing. A bulb placed too near a bend or turn of tubing may produce false signals from collected oil inside the tubing. A sensing bulb placed along a dirty length of tubing may not be able to sense heat as well as along a clean surface. Review sensing bulb mounting guidelines in Chapter 20, *Metering Devices*, and Chapter 52, *Installing Commercial Systems*.

If a TXV problem cannot be remedied, the valve may be internally worn or leaking. A leaking needle or valve in a TXV cannot be repaired. Replace the entire TXV.

A starved evaporator cannot adequately refrigerate its conditioned space and frosts unevenly or sweats improperly. This problem may be due to the following:

- Clogged inlet screen in the TXV, which may produce little or no refrigeration.
- Loss of refrigerant from a TXV's sensing bulb, which will give erratic (undependable) refrigeration.
- Frozen moisture in the TXV. A refrigeration system may produce good refrigeration for a while and then no refrigeration. Refrigeration stops after the moisture freezes in the valve's orifice. Refrigeration returns after the ice melts. Melting may happen during the Off cycle, or the TXV may need to be manually warmed.
- Wax from the oil accumulating in the TXV. The presence of wax means that the oil used was intended for a different temperature range. Otherwise, it may have been improperly prepared for refrigeration service. After the refrigerant and oil in the system are recovered, the system must be flushed, drawn into a vacuum, and charged with new oil and refrigerant.
- Needle stuck shut. (This is a rare occurrence.)
- Under-capacity valve orifice. It is usually recommended that a new valve be installed when an expansion valve gives trouble.

Sweating or frosting on the suction line beyond the sensing bulb indicates too much refrigerant flow. This condition may be caused by:

- A loose connection between the sensing bulb and the suction line.
- Warm airflow over a sensing bulb that is not insulated.
- Pressure drop in the evaporator is too great.
- TXV needle stuck open or unable to close fully.
- Undersized evaporator.
- Thermal bulb has wrong charge.
- TXV orifice is too large.

If a sensing bulb is loose, incorrectly mounted, or in a warm airstream, remove it. Clean the sensing bulb and the area where the sensing bulb will be mounted. Firmly secure the sensing bulb with the proper strap and insulate it to prevent ambient air from affecting TXV operation.

Copyright Goodheart-Willcox Co., Inc. 2017

An oversized TXV should be replaced with one of the correct size. When a needle is stuck open, the best remedy is to replace the valve. Only rarely one finds the following problems:

- An undersized evaporator.
- A TXV diaphragm and bulb with the wrong charge (replace).
- Too great a pressure drop across the evaporator (replace the evaporator).

54.7 Checking Electronic Expansion Valves (EEVs)

Electronic expansion valves (EEVs) operate much like thermostatic expansion valves. However, the plunger pin, which controls refrigerant flow through the valve, is usually operated by a small electric motor, rather than mechanical pressure from a diaphragm. An EEV requires several main components for operation:

- A stepper motor that moves the plunger.
- An electronic temperature sensor that senses temperature.
- A pressure transducer that provides the controller with pressure levels for controlling superheat. Not all EEVs use a pressure transducer.
- A controller that processes the sensor data and controls the stepper motor.

Figure 54-15 illustrates the wiring diagram for a typical EEV system. In this example, two temperature-sensing thermistors are used to monitor evaporator inlet and outlet temperatures. A pressure sensor is also placed at the outlet of the evaporator for regulating superheat and pressure control.

An EEV is selected based on system refrigerant type, superheat required, and tubing diameter. Electronic control of EEVs results in fast reaction time for valve regulation and high system efficiency.

An EEV is connected to a controller that monitors refrigerant temperature by use of a small temperature sensor, as shown in **Figure 54-16**. Like a TXV's sensing bulb, an EEV's temperature sensor should be mounted firmly on straight tubing and insulated properly to obtain accurate readings. A controller receives temperature and pressure information from the sensors and sends out a signal to the EEV to open or close the valve orifice. **Figure 54-17** illustrates a typical controller with a digital readout.

Servicing EEVs requires knowledge of its controller. Most EEVs are highly durable and some faults may be a result of electronic failures. Controllers usually have a self-diagnostic function. Trouble codes are specific to each manufacturer. The service technician must determine if the problem is the controller or the valve.

Figure 54-18 shows one type of instrument used to test the step motor of an EEV. This tool is used to test continuity across the motor windings and actuate the valve from open to close and all points in between.

Similar to other expansion valves, moisture and contaminants may clog the orifice of an EEV. One

Service Call Scenario

54A: Walk-In Cooler—Lack of Cooling

Customer Complaint: Lack of Cooling

Possible Causes: Restricted TXV, loss of charge in the TXV thermal bulb, malfunctioning TXV.

Description of Problem: Mr. DiMaggio, the owner of a delicatessen, has reported that his walk-in cooler is no longer cooling. Prior to arriving at the jobsite, the technician, Remi, reviews the work order. Upon arriving at the building, she identifies herself to Mr. DiMaggio and listens carefully to his comments.

Testing: Remi visually observes the system and installs the gauge manifold to read the system's pressures. The pressures indicate that the evaporator is being starved of refrigerant. Remi further notices that the TXV metering device is partially frosted at the outlet. Her diagnosis is a restriction at the TXV as well as moisture in the system. The fine-meshed screen may also be clogged, resulting in the moisture creating ice and causing a restriction of refrigerant flow. Remi informs Mr. DiMaggio of the issues and offers solutions and the costs for such. Mr. DiMaggio agrees to have Remi perform the needed service.

Solution: Remi recovers the refrigerant. Next, she installs the TXV and the filter-drier. She evacuates and recharges the system to the manufacturer's specifications. Remi starts the unit and checks the pressures and temperatures. All of the readings are acceptable and the system is now cooling. Remi provides Mr. DiMaggio with the bill and informs him that a follow-up call will occur.

Safety: Always wear the proper eye and hand protection when charging or recovering refrigerant. Most refrigerants require charging in the liquid state and can cause serious injuries if one is not protected.

advantage of EEVs is that they may be easily forced into a full open position to allow passage of any foreign particles.

54.8 Checking Evaporator Pressure Regulators (EPRs)

Firstly, it is important to remember that evaporator pressure regulators (EPRs) are called by many different names in the HVACR industry. It is important to be familiar with all of these names so misunderstandings can be avoided on the job. A brief list of other EPR names is as follows:

- Two-temperature valve.
- Holdback valve.
- Open on rise of inlet pressure (ORI) valve.
- Constant pressure valve.

As explained in Chapter 22, *Refrigerant Flow Components* and Chapter 49, *Commercial Refrigeration System Configurations*, EPRs are automatic. Each EPR maintains a higher pressure in an evaporator in a multiple-evaporator system. This pressure is higher than suction line pressure and is used to keep this evaporator at a higher temperature than the other evaporators. In a fixed volume, such as an evaporator, pressure and temperature rise and fall together.

Common troubles with EPRs include:

- Leaky valve.
- Valve stuck shut.
- Valve out of adjustment.
- Frost accumulation on bellows.
- Clogged inlet screen.

If an EPR is leaking, its evaporator will be too cold and operating below its preset temperature. There will be danger of freezing. Cold temperatures may also be due to other causes, including adjusting the EPR too low or problems with the refrigerant metering device. To determine the cause of the problem, check to see if the EPR has been adjusted recently by inspecting previous HVACR technician reports, if available. If the EPR has not been adjusted, the needle is probably leaking.

It is rare to have an EPR become stuck shut. It is easily recognized by a lack of cooling in its evaporator. There will be no refrigerant flowing through the EPR. To check refrigerant flow, check the pressure drop across the valve.

If the valve is suspected of being stuck shut, recover the refrigerant and replace the valve. By closing certain service valves and solenoid, less of the system will need to be opened to atmosphere for service. After replacing the EPR, pull a vacuum on the part of the system that was opened for service. Recharge the recovered refrigerant. Put the system back into operation. Observe EPR operation and any measureable system variables.

Some EPRs have inlet screens. A clogged screen is a likely cause of a higher than normal conditioned space temperature, as it stops the flow of refrigerant and allows heat to accumulate. Symptoms will be similar to the EPR being stuck shut.

Frost can accumulate on the bellows if the EPR is located in or near a freezing compartment. The valve should be relocated out of the freezing compartment.

An EPR having a gauge connection makes adjustment simple. Adjusting the EPR allows the technician to determine if the valve is leaking or out of adjustment.

Some EPRs operate thermostatically and have the same troubles as thermostatic expansion valves (TXVs). These include:

- Loss of charge from its thermostatic element.
- Frost accumulation on the bellows.
- Poor contact between the sensing bulb and the evaporator.

Copyright Goodheart-Willcox Co., Inc. 2017

- Pinched capillary tube.
- Improper adjustment.

54.9 Checking Hot-Gas Valves

Components used to control hot gas vary with a system's application and demand. Hot gas can be used to defrost evaporators or be redirected into the suction line for capacity control.

Some hot-gas lines are regulated by a standard solenoid valve that simply opens and closes when needed. Others use a standard solenoid valve and also some type of flow-regulating valve. These flow regulation valves often look and operate in the same way as specific control valves that are commonly used as an HVACR system's refrigerant metering device. These include automatic expansion valves (AXVs), thermostatic expansion valves (TXVs), and electronic expansion valves (EEVs). For larger flow applications, a refrigeration system may use a pilot-operated solenoid valve.

Checking a refrigeration system's hot-gas valves involves identifying each valve used to control the flow of hot gas, understanding how each valve operates, and recognizing the symptoms that manifest if a hot-gas valve malfunctions.

If an evaporator with hot-gas defrost is not defrosting, check the defrost timer. If it is not running, determine the problem and repair or replace. If the defrost timer is working properly, turn the timer to the On position. The compressor should cycle on. If the compressor is not running, jump the proper defrost timer terminals to see if the compressor operates. To do this, review manufacturer literature. Otherwise, check defrost timer operation.

Once the compressor is running and the defrost timer is operating, check the hot-gas line. If it does not become warm, check the hot-gas valves. If the hot-gas line uses a solenoid valve, perform a simple temperature survey. See if the solenoid valve's inlet and outlet tubes are cold or hot. If one side is hot and the other cold, the solenoid valve is still closed.

If a hot-gas solenoid valve is sticking, gently rap the body of the valve. Note whether or not this action allows hot gas to flow. Check the electrical supply to the solenoid valve with a voltmeter. This will show whether there is power to the solenoid valve. If there is no power, review manufacturer literature and jump its contacts on its control device. If power is applied to a solenoid valve and it remains stuck, the solenoid valve must be replaced.

If a defrost timer is faulty, check its contacts. If they are corroded, replace them. If a solenoid coil is faulty, replace it. To determine a defrost timer's motor condition, disconnect wires after shutting off the power. Then check for open circuit or grounds.

For flow-regulating hot-gas valves, diagnose and repair problems that are specific to that type of hot-gas control valve: AXV, TXV, or EEV. Refer to earlier sections of this chapter and review each relevant refrigerant metering device section in Chapter 20, *Metering Devices*. Also review the different aspects of hot-gas systems covered in Chapter 21, *Heat Exchangers*, Chapter 22, *Refrigerant Flow Components*, and Chapter 49, *Commercial Refrigeration System Configurations*.

54.10 Checking Solenoid Valves

Solenoid valves develop both electrical and refrigerant troubles. Gently rapping a stuck solenoid valve may help it to become unstuck. The electrical connections may be dirty or loose. If so, the coil may not create enough electromagnetism to actuate the valve. Usually, the valve should be mounted with the coil on top and the valve level. If not, they may stick or chatter. Solenoid valves will sometimes develop a leaky needle and seat. In this case, the valve must be replaced.

54.11 Checking Evaporators

Dry (direct-expansion) evaporators must contain the proper amount of liquid refrigerant at the proper vapor pressure to provide their designed cooling. Air or water being cooled must flow in and out of the evaporators efficiently. Evaporators must be leakproof and properly sized. These conditions should be checked. Evaporators must also be regularly cleaned for good heat transfer.

Airflow through an evaporator can be checked with an anemometer. This instrument is also called an *air velocity meter*. Refer to Chapter 27, *Air Movement and Measurement* and Chapter 30, *Ventilation System Service* for additional information on using this instrument. If the air outlet or inlet is too small, airflow will be reduced, which can lead to inadequate cooling and abnormal system temperature and pressure readings. Air temperatures at the inlet and outlet can also be checked. The air temperature will usually drop about 15°F (8°C) as it passes through the evaporator. Check manufacturer literature for individual evaporators and their applied use.

Ideally, refrigerant pressure at the evaporator inlet (just after the refrigerant metering device) and at the evaporator outlet should be measured. This will show any pressure drop across the evaporator.

Copyright Goodheart-Willcox Co., Inc. 2017

Service Call Scenario

54B: Beverage Cooler—No Cooling

Customer Complaint: No Cooling

Possible Causes: Plugged filter-drier, closed TXV, kinked liquid line, plugged metering device.

Description of Problem: Ms. Ohara, the owner of a small pub, has reported that her beverage cooler is no longer cooling. Prior to arriving at the jobsite, David, the technician, reviews the work order. Upon arriving at the pub, he identifies himself to Ms. Ohara and listens carefully to her comments.

Testing: David installs the gauge manifold to read the system's pressures. He then visually inspects the entire system. David notes that the system is a pump-down system and that the compressor appears to be starting and stopping quickly. He checks to see if the evaporator is receiving refrigerant. He then checks the liquid line solenoid valve for resistance. It reads infinite ohms. David concludes the cause is an open solenoid coil. David informs Ms. Ohara of the issues and offers solutions and the costs for such. Ms. Ohara agrees to have David perform the needed service.

Solution: David shuts the system's electrical power off and then removes and installs a new solenoid coil. He then restores the electrical power to the system and checks all operations. The unit is now operating properly and the pressures and temperatures are within normal readings. The system is now cooling. David provides Ms. Ohara with the bill and informs her that a follow-up will occur.

Safety: Remember to disconnect the electrical power source when replacing electrical components. Some components operate at high voltages that can cause serious injury. Follow the correct procedures when lockout devices are required.

Many service technicians only check low-side pressure at the suction service valve. While this may be the suction pressure, it will not reveal any restrictions or pressure drops along the suction line. Evaporator pressure may be higher due to a clogged filter-drier or kinked refrigerant line.

The best superheat setting is reached when a TXV's bulb temperature varies the least while the unit is running to prevent hunting of the valve. Location of the liquid in the evaporator can also be determined this way. Evaporator temperature should also be checked. The superheat setting of a TXV can be checked using spring-loaded, clip-on thermometer clamps mounted on the evaporator tubing, **Figure 54-19**.

Taking pressure and temperature measurements on an evaporator often reveal symptoms that are not the fault of the evaporator, but rather the system control devices. TXV, EPR, and hot-gas defrost valve operation all contribute to the appearance and condition of an evaporator. Use evaporator pressure and temperature measurements to diagnose which components are causing the evaporator to respond as it is.

Frost accumulation acts as insulation and also tends to reduce the airflow. Accumulation near the TXV usually means too great a superheat adjustment along with low suction pressures. Spotty frost usually means uneven airflow over the evaporator. Otherwise, it may indicate that some defrosting elements are not working.

Ritchie Engineering Co., Inc. – YELLOW JACKET Products Division

Figure 54-19. Superheat/subcooling calculators and other instruments often include thermistor clamps for taking temperature measurements.

Pro Tip

Leak Testing an Evaporator

When checking an evaporator for refrigerant leaks, the blower fan and the rest of the unit should be shut off. Low-side pressure should be at least 15 psig (100 kPa) when testing for leaks. System pressure levels below atmospheric pressure could allow air infiltration into the refrigerant circuit through any system leaks.

54.12 Checking Suction Lines

The primary purpose of a suction line is to deliver superheated, low-pressure vapor refrigerant from an evaporator to a compressor. However, a suction line can also contain various in-line components for specific purposes. An EPR maintains a higher pressure in its evaporator to regulate its temperature. A check valve prevents backflow between evaporators with different pressures. As in a liquid line, these components improve system control and operation, but they also provide another opportunity for a leak, a clog, or other system failure.

Servicing the suction line is much like servicing the liquid line. Components to inspect include:

- Hand shutoff valves.
- Vibration absorbers.
- Check valves.
- Evaporator pressure regulators (EPRs).
- Filter-driers.
- Accumulators.
- Any joints or connections.

Check each mechanical joint and brazed joint for leaks. Check the suction line for any kinks, pinches, buckles, or deformations. These reduce refrigerant flow and cause pressure drops.

Suction line size is important. If it is too small, it will cause too much pressure drop. High gas velocities will cause noise. A small suction line can reduce a compressor's capacity and increase its power usage by forcing it to pump a higher volume of refrigerant vapor to maintain the desired temperature in the evaporator. The suction line should be the same size as the suction service valve connection or the suction line connection on the compressor.

On multiple-evaporator systems, the suction line for each evaporator may be smaller than the main suction line. For example, the most remote evaporator may have a 1/2″ (12.7 mm) OD suction line. Each evaporator closer to the compressor would have a larger suction line, as follows: 5/8″ (15.875 mm) OD, 1″ (25.4 mm) OD, 1 1/2″ (38.1 mm) OD. The suction line connected to the compressor may be 2″ (50.8 mm) OD. See Chapter 51, *Commercial Refrigeration Component Selection*.

In a multiple-evaporator system, pressure drop should be checked by installing a compound gauge at the most remote evaporator and another compound gauge at the compressor. Record these low-side

Service Call Scenario

54C: Walk-In Freezer—No Cooling

Customer Complaint: No Cooling

Possible Causes: Defective heater element, open defrost limit switch, faulty defrost timer.

Description of Problem: Ms. Rossi, owner of a small restaurant, has reported that her walk-in freezer is no longer cooling. She is quite concerned as she has thousands of dollars of frozen meats stored there. Prior to arriving at the jobsite, the technician, Tony, reviews the work order. Upon arriving at the restaurant, Tony identifies himself to Ms. Rossi and listens carefully to her comments.

Testing: Tony installs the gauge manifold to read the system's pressures. He visually observes the system's operation. While inspecting the evaporator, he notes that it is completely covered with ice build-up. Tony next checks the defrost timer and sees that the defrost contacts are stuck open. The contacts will not close in order to allow the unit to defrost automatically. Tony bypasses the contacts to make certain the electric heaters become energized and that there are no open components within the defrost circuit. He observes that the electric heaters do heat up, which confirms that the defrost timer is faulty. Tony informs Ms. Rossi of the issue and offers the solution and the cost for such. Ms. Rossi agrees to have Tony perform the needed service.

Solution: Tony installs a new defrost timer. He again initiates defrost to confirm that the cooler is automatically going in and out of defrost mode as it should. The system's evaporator is now thawed and all system operations are now working properly with normal pressures and temperatures. Tony provides Ms. Rossi with the bill and informs her that a follow-up call will occur.

Safety: When working on walk-in freezers, wear protective clothing such as gloves, eye protection, and warm clothing. Walk-in freezers can be extremely cold and can cause frostbite

Copyright Goodheart-Willcox Co., Inc. 2017

pressures when the compressor is running. The difference between these two pressure measurements is the ***suction line pressure drop***. It should be approximately 2 psi (14 kPa). If the pressure drop is more than 2 psi (14 kPa), the refrigerant line sizes may need to be increased or some sort of restriction in the line may be causing a pressure drop.

When checking suction line pressure drop, the pressure drop across EPRs should also be checked. Their pressure drops are separate from the suction line pressure drop. For suction line pressure drop, measure pressure just past the EPR on the suction line side. This will be past the evaporator and in the suction line. Compare this value with a pressure measurement at the compressor from the suction service valve.

Pro Tip

Suction Line Pressure Drop

Suction line pressure drop should not be excessive. However, before replacing any suction line with larger diameter tubing, try to determine if the pressure drop is caused by a restriction, rather than undersized tubing. Look for any kinked or deformed tubing that may be reducing pressure. Check any filter-driers or other in-line components with a temperature drop between its inlet and outlet. Use an infrared thermometer for an initial examination. This temperature drop may indicate a pressure drop from a clog or other restriction. Doing a temperature and pressure survey can help in finding the real cause of a suction line pressure drop and avoid wasted labor and parts.

Copyright Goodheart-Willcox Co., Inc. 2017

Chapter Review

Summary

- When troubleshooting an electrical circuit, thoroughly review any wiring diagrams. When checking voltage drops and current draw, exercise extreme caution as power must be on. When checking resistance or continuity, turn off and lock out power. Motor sounds may help in determining a problem.
- Mechanical trouble on external motors includes misalignment, excessive end play, and faults in the bearings and pulleys. Check sheave wear with a wear gauge.
- Open-drive compressor problems include faulty valves that click, seals that leak refrigerant and oil, excess oil that chugs, and noisy, damaged mechanical parts.
- The condition of the refrigerant oil in hermetic compressors should be checked for its level of acidity. Early detection allows technicians to replace the oil, install new filter-driers, and prevent compressor failure.
- Condenser capacity is the amount of heat a condenser can reject. The more heat a condenser can reject, the higher its capacity. Air-cooled condensers need to have unobstructed airflow passageways, clean tubes and fins, properly operating fans, and properly calibrated head pressure control devices.
- A common problem in water-cooled condensers is the formation of mineral deposits within the water circuit that inhibits heat exchange, raises head pressure, and reduces system efficiency. Cleaning solutions and equipment can often remove mineral deposits, though condenser replacement is necessary in extreme cases.
- Reduced water flow through water-cooled condensers can result from leaking valves, clogs, poorly calibrated controls, or faulty controls. Excessive water flow results from water pressure being too high, leaking valves, or improperly calibrated valves.
- Components along a liquid line to inspect include shutoff valves, sight glasses, moisture indicators, inlet screens, filter-driers, solenoid valves, and all tubing joints and connections. These and any pinched or buckled length of tubing can cause a clog or pressure drop.
- Problems with a TXV are usually evident by how they affect the evaporator. Frost on evaporator tubing is commonly caused by a leaking TXV, a poorly installed sensing bulb, or a clogged inlet screen.
- As with TXVs, EEV problems affect the evaporator. Troubleshoot an EEV as you would troubleshoot a TXV, but also use any diagnostic codes and features available on an EEV's controller.
- Common EPR problems include leaking valves, poor calibration, frost accumulation on bellows, clogged inlet screens, and being stuck shut. Troubleshoot using pressure and temperature surveys.
- A hot-gas valve may be a standard solenoid valve or some type of flow-regulating valve, resembling some type of expansion valve (TXV, AXV, or EEV). Systems may use one or more solenoid and flow-regulating valve to control the flow of hot gas. When a hot-gas function is not operating properly, use a temperature survey to determine if and where hot gas is flowing. Check system controls for proper operation.
- Solenoid valves are electrically operated valves that open and close. Operation can be checked mechanically and electrically. Depending on their use, solenoid valves may also be checked using temperature and pressure surveys.
- Evaporators need to be clean and have unobstructed airflow passageways. Frost accumulation, lack of cooling, and other problems associated with evaporators are often caused by problems from controls devices, such as refrigerant metering devices (expansion valves), EPRs, and hot-gas defrost valves.
- Components along a suction line to inspect include shutoff valves, check valves, EPRs, inlet screens, filter-driers, and accumulators. These and any pinched or buckled length of tubing can cause a clog or pressure drop. A simple temperature survey can indicate a pressure drop.

Review Questions

Answer the following questions using the information in this chapter.

1. Electrical wiring to a particular refrigeration unit must be sized large enough for proper _____.
   A. current
   B. pressure
   C. viscosity
   D. voltage
2. To check continuity on a system's electrical circuit, turn off and lock out the power before using a(n) _____.
   A. ammeter
   B. gauge manifold
   C. ohmmeter or continuity tester
   D. voltmeter
3. When an external motor is operating properly, it will emit _____.
   A. erratic squeals
   B. a low, steady hum
   C. a melodic screeching
   D. rotor chattering
4. When an open-drive compressor has faulty valves or faulty seals, it will most likely cause _____.
   A. compressor inefficiency
   B. high head pressure
   C. low suction pressure
   D. short cycling
5. When testing across a hermetic compressor's motor windings, a false open circuit measurement may be caused by a(n) _____.
   A. contactor with pitted contacts
   B. faulty unit controller
   C. good current relay
   D. overheated internal overload device
6. When testing a hermetic compressor's motor for grounded windings (shorted-to-ground), measurements on good windings would show _____.
   A. 0 Ω
   B. 5–25 Ω
   C. 500–1000 Ω
   D. extremely high resistance (infinity, ∞)
7. Condenser capacity is the _____.
   A. amount of heat a condenser can reject
   B. condenser's inner surface area
   C. high pressure limit a condenser can withstand
   D. high temperature limit a condenser can withstand
8. Common causes of reduced capacity in air-cooled condensers include the following, *except* _____.
   A. high ambient temperature
   B. low ambient temperature
   C. noncondensables trapped in the condenser
   D. reduced airflow
9. Common causes of high head pressure in air-cooled condensers include the following, *except* a(n) _____.
   A. noncondensables trapped in the condenser
   B. overcharge of refrigerant
   C. reduced condenser heat exchange
   D. undercharge of refrigerant
10. A common problem found in water-cooled condensers that reduces heat exchange is the formation of mineral deposits _____.
    A. in the electrical circuit
    B. in the refrigerant circuit
    C. in the water circuit
    D. on the outside of the compressor
11. Inadequate water flow through a water-cooled condenser may be caused by the following, *except* a water valve _____.
    A. connected to high water pressure
    B. stuck shut
    C. with a clogged inlet screen
    D. with leaking bellows
12. Common indications of a pressure drop across an in-line component in the liquid line can include the following, *except* _____.
    A. frosting
    B. having higher temperature than the liquid line
    C. sweating
    D. a temperature drop between the component's inlet and outlet
13. The HVACR problem that a leaking TXV unable to close fully is most likely to cause is _____.
    A. corrosion in a water-cooled condenser
    B. high head pressure
    C. noncondensables in the condenser
    D. short cycling
14. When there is a problem with a TXV, symptoms will most often manifest changes that can be seen, heard, or sensed by temperature and pressure in the _____.
    A. accumulator
    B. compressor
    C. evaporator
    D. liquid receiver

Copyright Goodheart-Willcox Co., Inc. 2017

15. The following reasons explain why a TXV may be operating incorrectly, *except* because its sensing bulb is _____.
    A. hanging loose in mid air
    B. installed with the wrong type of strap
    C. properly insulated
    D. secured at the wrong angle along the tubing
16. Common industry names used to refer to EPRs include the following, *except* _____.
    A. constant pressure valves
    B. holdback valves
    C. low ambient control valves
    D. two temperature valves
17. When troubleshooting an electronic expansion valve (EEV), a technician should be familiar with the following, *except* _____.
    A. any self-diagnostic functions
    B. any trouble codes
    C. an EEV's controller
    D. sensing bulb and diaphragm condition
18. Hot-gas valves that can vary and regulate the flow of hot gas include the following types, *except* _____.
    A. AXV
    B. EEV
    C. solenoid valve
    D. TXV
19. If a commercial refrigeration system's suction line tubing is too small, it can cause the following, *except* _____.
    A. high gas velocities
    B. reduced compressor capacity
    C. too little pressure drop
    D. too much pressure drop
20. When servicing a suction line, inspect the following, *except* _____.
    A. accumulators
    B. any joints or connections
    C. sight glasses
    D. valves

Learning Objectives

Information in this chapter will enable you to:

- Properly pump down or move the refrigerant charge for system service.
- Perform atmospheric balancing (pressure equalizing) before opening a system to atmosphere for service.
- Safely remove a compressor from a system for replacement.
- Safely replace an external electric motor.
- Safely service a refrigeration system with a motor burnout in a hermetic compressor.
- Add refrigerant oil to a refrigerant system using several different methods.
- Safely remove, repair, and install air-cooled and water-cooled condensers.
- Diagnose and repair or replace water valves.
- Perform basic cooling tower maintenance.
- Diagnose and repair liquid line problems.
- Remove, repair, and install forced-air evaporators.
- Remove, repair, and install expansion valves.
- Adjust the setting of a thermostatic expansion valve (TXV).
- Diagnose, repair, install, and adjust evaporator pressure regulators (EPRs) and hot-gas valves.
- Remove and replace service valves and solenoid valves.

Review of Key Concepts

Reviewing these concepts from earlier chapters will help you understand new concepts presented in this chapter:

- An important part of HVACR system service is isolating parts for service using refrigerant recovery or system pump down. (Chapter 11)
- Properly evacuating a system before charging promotes optimal operation and reduces the risk of equipment failure. (Chapter 11)
- Service for external motors deals with electrical or mechanical problems. (Chapter 17)
- Motor failure and erratic system performance may be due to the motor control system. (Chapter 17)
- Understanding the operation of refrigerant metering devices is necessary in servicing an HVACR system. (Chapter 20)
- Understanding the use and operation of various refrigerant flow components is necessary in servicing an HVACR system. (Chapter 19)
- Service procedures for domestic refrigeration appliances address many of the same problems found in commercial refrigeration systems. (Chapter 26)

Introduction

The servicing of commercial refrigeration systems is much like working on domestic systems. However, in commercial refrigeration, multiple evaporators on a single suction line is common. Also, a single suction line may flow into one or several compressors in parallel. Since commercial refrigeration condensers operate throughout the year, they use some method of head pressure control, such as fan cycling, variable frequency drives, louver opening and closing, pressure-regulating valves (low-ambient controls), split condenser arrangements, and electric heaters. Unloading and defrosting subsystems add to service complications.

Copyright Goodheart-Willcox Co., Inc. 2017

55.1 System Service Fundamentals

In most communities, local refrigeration code determines the servicing of large commercial systems. Major repairs or changes to a commercial system can be done by only licensed contractors. When completed, their work must be checked by the local community refrigeration inspector. Plumbing and electrical service work should be performed by licensed plumbers and electrical contractors.

When part of a commercial refrigeration system needs service and will be inoperable for a time, empty the contents of the conditioned space cabinet. If this is not possible, move all the contents to one side and cover them. Spread a drop cloth around and under any components to be serviced. This will catch any moisture or other fluids, which will minimize cleanup, avoid property damage, and prevent personal hazards.

Care should be taken when disassembling interior and exterior parts of the unit's cabinet. Chipping or cracking of enamel surfaces may necessitate replacing a complete panel. Do not soil enamel finishes with oil or grease.

Tools and materials should be in a safe place to prevent injury from tripping. Always provide good lighting. Internal parts of a machine must be kept as chemically clean as possible. Moisture can freeze in low temperature passages. Filter-driers and strainers should be checked regularly. Dirt and debris may clog screens and cause wearing of metering devices, control valves, compressor valves, and valve seats.

Opening a Refrigerant Circuit for Service

When opening any part of a system to remove or service components, follow these general steps:

1. Pump down or recover the refrigerant from the part to be opened.
2. Isolate parts to be opened from the rest of the system by closing certain service or shutoff valves.
3. Balance pressures in parts of the system just evacuated to 0 psi to prevent ambient air infiltration.
4. Clean and dry joints to be opened.
5. Immediately plug all refrigerant openings as soon as they are opened.

55.1.1 Isolating Part of a System for Service

When a system's refrigerant circuit must be opened for service, refrigerant must be removed from the part of the system that will be opened to atmosphere. In many cases, the refrigerant charge can be pumped down into the liquid receiver. However, if there is no place within a refrigeration system to store its refrigerant charge, the charge must be removed from the system and stored in a recovery cylinder.

Refrigerant is pumped down into the liquid receiver by first installing a gauge manifold in the system. The service valves are properly adjusted depending on the system. Finally, the compressor is operated.

Recovery of refrigerant from any part of a system requires a low pressure to draw out the refrigerant from the part to be dismantled. This is done in order to evaporate the refrigerant from it. The low pressure evaporates and then draws out the refrigerant, **Figure 55-1**.

The pressure in the part of the system to be opened to atmosphere must be equalized to 0 psig or slightly higher by bypassing a small amount of vapor refrigerant into it. This process is called ***atmospheric balancing***. It may also be known as *pressure equalizing* or *balancing pressures*. How this is done depends on the refrigeration system, the part of it needing service, and the instruments and equipment available.

Often, a refrigerant charge is pumped down into the liquid receiver for low-side service. In this case, a technician can bypass refrigerant vapor from the high

Goodheart-Willcox Publisher

Figure 55-1. An HVACR system in a slight vacuum after refrigerant recovery.

Copyright Goodheart-Willcox Co., Inc. 2017

side through the gauge manifold into the low side for atmospheric balancing, **Figure 55-2**.

If a refrigerant charge was recovered from a system and stored in a cylinder, a small amount of refrigerant vapor could be valved from the recovery cylinder through the gauge manifold and into the low side or high side of the system as needed.

Atmospheric balancing prevents air and particles from rushing into the system when opened. Balancing pressure is very important. If the system were left in vacuum when opened for service, contaminants and noncondensables would infiltrate the refrigerant circuit. Such unwanted contamination could cause a variety of problems.

General steps to follow when isolating a system component:

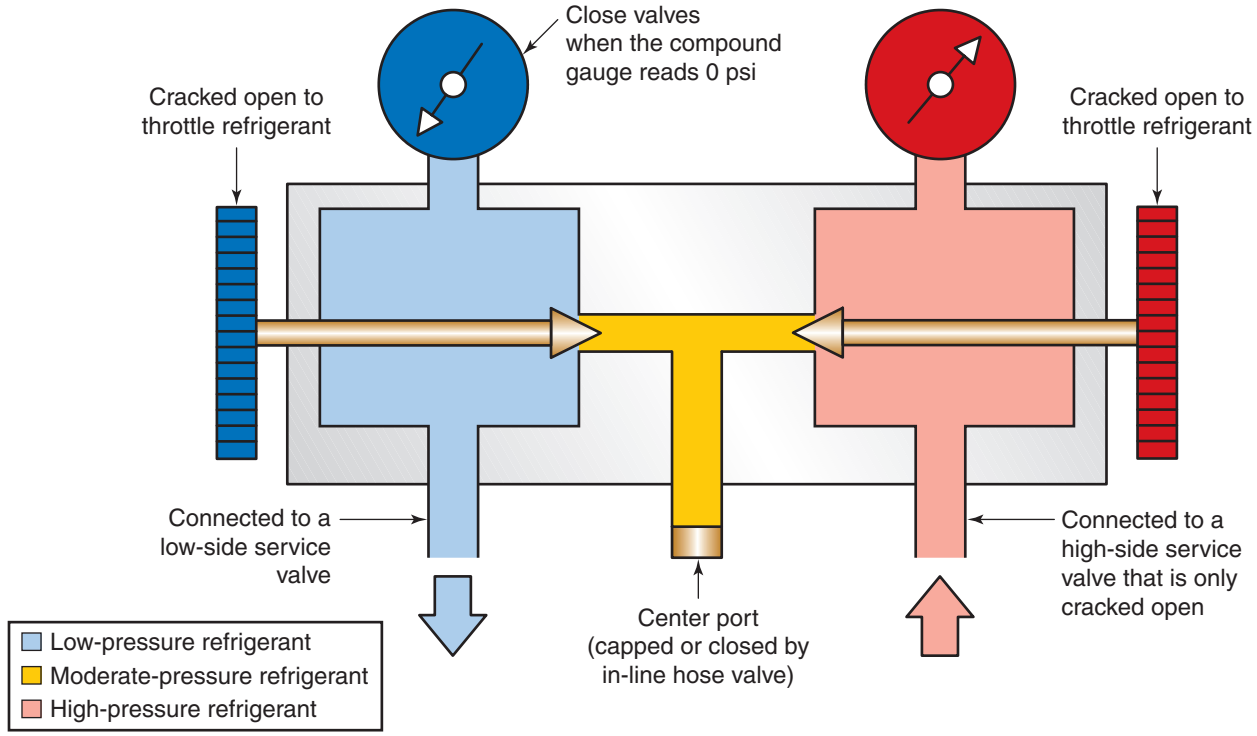
1. To begin refrigerant recovery, front seat the inlet service valve to the part to be serviced.
2. Run the compressor until the gauge shows 0 psig or a slight vacuum. At that point, stop the compressor.
3. Front seat the outlet service valve to the part to be serviced.
4. Gently crack open the inlet service valve until the gauge reads zero. At zero, front seat the inlet service valve to the part.
5. Clean and dry the joints surrounding the part to be serviced.
6. Remove the part and plug any openings immediately. Always plug all refrigerant openings immediately after removing the part. This is necessary in order to keep out dirt and moisture.

For example, if a technician must remove a compressor, evaporator, or TXV, the refrigerant should be stored in the liquid receiver. The liquid receiver service valve is closed. The compressor is run until no liquid refrigerant is in the liquid line, evaporator, or suction lines. If there is no place to store the refrigerant in the system, the refrigerant must be removed from the system and stored in a recovery cylinder.

Pro Tip

Isolation Valve Options

When isolating sections of a refrigerant circuit, close the valves that make the most sense. Minimize the amount of tubing and components that must be emptied. The best valve to close may be the liquid receiver service valve. However, if the system has liquid line manifold valves feeding individual evaporators, then these could be closed, so the entire liquid line would not need to be emptied. Instead of manifold valves, a system may have a liquid line solenoid valve. Isolating the least amount of the refrigerant circuit saves time. Evaluate the system and determine which valve or valves are best to close for system isolation.



Goodheart-Willcox Publisher

Figure 55-2. Atmospheric balancing is done through the gauge manifold and minimizes contamination of a system's refrigerant circuit. This diagram shows how a pumped down system bypasses refrigerant vapor from the high side into the low side.

Copyright Goodheart-Willcox Co., Inc. 2017

For any procedure dealing with pressurized fluids, wear goggles and always leave a gauge manifold connected to the system until the system is opened. The pressure in the system must be known.

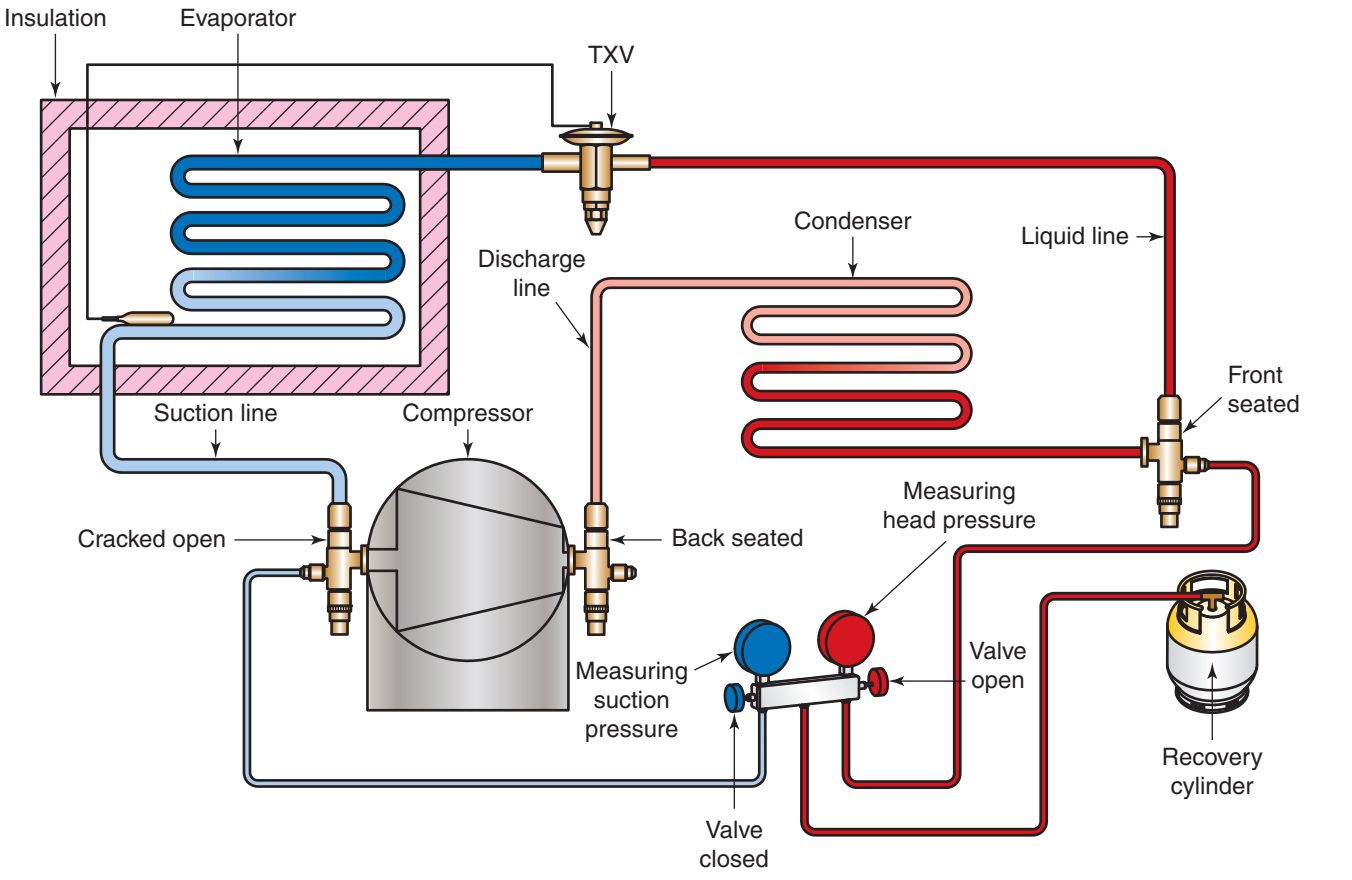
When performing service on isolated sections of a refrigerant circuit that uses an open-drive compressor, the compressor can be used to pump down or recover the charge. How this is done depends on the system and the service valves available. See **Figure 55-3** for a typical arrangement. Purge hoses as previously described.

The compound gauge is used to measure suction to indicate the refrigerant charge remaining in the system. The high-pressure gauge is connected to a liquid line service valve. It measures head pressure. Connecting to the liquid line allows the compressor to pump subcooled liquid refrigerant into the recovery cylinder. This is highly preferable to connecting at the discharge service valve at the compressor outlet.

Refrigerant exiting the compressor is both in vapor form and superheated. This would be high-pressure and high-temperature vapor. Recovering from the liquid line takes advantage of refrigerant being in liquid form, which will save time. Also, the refrigerant is already subcooled, having gone through the condenser. It is still recommended to partially submerge the recovery cylinder into an ice bath. This helps to keep cylinder pressure and temperature in check during the recovery process, **Figure 55-4**.

Review the system wiring diagram. There may be different safety controls that need to be ***jumpered*** to prevent them from cycling off the system. This simply involves connecting a jumper wire in parallel with a device. Usually this is just across a control's two terminals. Controls to jumper may include low and high pressure switches, temperature switches, and other devices. Be sure to monitor pressure and other variables in case a problem develops with these safety devices jumpered.

With hoses purged and all connections tightened, cycle on the compressor. Monitor pressure levels. With the recovery cylinder partially submerged in an ice



Goodheart-Willcox Publisher

Figure 55-3. The compressor is recovering the refrigerant and storing it in a recovery cylinder. The low-side manifold valve is closed, and the high-side valve is open. The suction service valve is cracked open off the back seat to monitor suction pressure. The discharge service valve is back seated. A service valve along the liquid line is front seated to block the flow of refrigerant and direct it through the gauge manifold and into the recovery cylinder.

Ritchie Engineering Co., Inc. – YELLOW JACKET Products Division

Figure 55-4. Submerging a recovery cylinder in an ice bath will help to protect the cylinder from the high pressures and temperatures that develop during recovery.

bath, head pressure should not rise to dangerous levels. Be familiar with normal operation head pressure levels and compare to measurements. As the recovery process continues, suction pressure should drop gradually as the refrigerant circuit is emptied.

After a constant low suction pressure has been maintained for at least two minutes, cycle off the compressor. Listen closely to compressor operation for a chugging sound, which indicates oil pumping. Never allow the compressor to pump oil. These hydraulic pressures could cause serious damage to the compressor and hoses. Cycle off the compressor if such noises are heard.

Close relevant valves to isolate sections of the refrigerant circuit. The more isolation the better, in case of accidental infiltration or other incident. Before opening any part of the refrigerant circuit for service, raise pressure in that section to just above atmospheric pressure (0 psig). If a refrigerant circuit in vacuum is opened to atmosphere, noncondensables and contaminants would be drawn inside. To prevent this, perform atmospheric balancing by gently cracking open the low-side manifold valve until the compound gauge indicates 1 psig. Barely opening this valve for a short time bypasses just enough refrigerant vapor from the recovery cylinder into the system to balance the pressure throughout. The isolated section of the system may now be opened and serviced. After removal of any parts, immediately plug the refrigerant openings.

Pro Tip

Compensating for High Head Pressure during Recovery

Excessive head pressures may be reduced by cooling the recovery cylinder, such as immersing the cylinder in an ice water bath, **Figure 55-4**. High head pressure may also be avoided by running the compressor intermittently. By operating the compressor for intervals interrupted by short rest periods, high head pressure can gradually drop through the corresponding high heat dissipating into ambient air or an ice bath.

Caution

Using Heat to Reduce Recovery Time

To quicken the recovery, cautiously apply heat to parts of the system under suction. This is any point past the service valve isolating the high side from the low side. Apply heat using a heat lamp or warm water. Applying heat to a refrigeration system during refrigerant recovery should be done with extreme care and caution. Never use a torch, as it may melt the fuse plugs and brazed joints. Never allow any part or spot to become too warm to touch with the hand.

Refrigerant to be returned to a system after service may be stored temporarily. It may also be stored temporarily for distillation if facilities are available for such processes. A clean refrigerant cylinder should be used for storing a recovered refrigerant charge. Remember that the refrigerant will always have an oil content. Some large companies save all refrigerant, redistill it, and process it for further use. This is good practice from the standpoint of both economy and ecology.

Federal laws govern chemical substance disposal. Refrigerant disposal is strictly classified by the following regulations:

- The United States Resources Conservation and Recovery Act (RCRA).
- United States EPA regulations.
- United States Department of Transportation (DOT) regulations.

Large quantities of refrigerants must be stored in steel drums and moved to registered waste disposal sites. See Chapter 9, *Introduction to Refrigerants* for further details concerning refrigerants containing CFCs.

55.1.2 Reassembling Refrigeration Systems

After repairs have been made and the parts tested, a refrigeration system must be properly reassembled. Four fundamentals must be followed when installing parts of a refrigeration system:

Copyright Goodheart-Willcox Co., Inc. 2017

- Clean and dry each part to be put into the system.
- Evacuate that part of the system that has been opened, using the proper equipment.
- Test for leaks.
- Reintroduce refrigerant to evacuated sections.
- Return all valves and controls to normal settings.
- Start and adjust the unit.

It is difficult to assemble a refrigeration system in the field without foreign materials entering a system. It is almost impossible to keep dirt and moisture out of a system. Filter-driers should be installed to remove any matter that does enter the refrigerant circuit. These devices are installed in both the liquid line and suction line of a system.

A service call should be made within the next day or two after repair. The operating pressures and the general condition of the refrigeration system should be checked. If at all possible, connect temperature and pressure recorders into the system for 24 hours.

55.2 Servicing Motors and Compressors

Since electric motors provide the torque necessary for many compressors in the HVACR industry, it is natural that motor and compressor service go hand in hand. Aspects of motor and compressor service are electrical and mechanical. When field repair is not feasible, replacement is necessary.

Removing Open-Drive Compressors

To remove an open-drive compressor, follow this procedure:

1. Install a gauge manifold on the compressor service valves using hoses with quick-connect fittings to minimize refrigerant losses. The middle port of the manifold is used for recovery, evacuation, or charging.
2. Carefully test for leaks.
3. Turn the suction service valve all the way in, closing off the suction line.
4. Start the compressor. Let it run for only a few seconds, in order to prevent oil pumping. Oil in the crankcase may bubble vigorously as the refrigerant boils out. Pumping of oil should be avoided. It is indicated by a pounding noise in the compressor.
5. After starting and stopping the unit two or three times, it may finally be run continuously. Run the unit for a few minutes after a constant vacuum is reached on the compound gauge before stopping the compressor.
6. Crack open the high-side manifold valve. Then gently crack open the low-side manifold valve while watching the compound gauge. When it measures just above 0 psig, close the low-side and then the high-side manifold valves. This step allows the crankcase to reach equilibrium with atmospheric pressure before opening.
7. Turn the discharge service valve stem all the way in to close off the compressor from the discharge line.
8. Shut off and lock out the electric power.
9. Close the manifold valves.
10. Clean the joints to be opened with a grease solvent. Dry the joints before opening.
11. Unbolt the suction and discharge service valves from the compressor, **Figure 55-5** *Do not remove the suction and discharge lines from the service valves*. Immediately plug all openings through which refrigerant could flow using dry rubber stoppers or tape.
12. Disconnect the bolts that hold the compressor to its base and remove its belt or unhook the drive coupling.
13. Disconnect any other connections to the compressor, such as pressure transducers, oil return lines, and other devices. If necessary, valve off or isolate these devices before disconnection. The compressor is ready now for removal.
14. Drain the oil immediately and plug compressor refrigerant openings. Blank flanges work best for plugging openings. Do not reuse old oil if it is discolored.

Removing a compressor from a large unit presents a problem, because of the compressor weight. When lifting a compressor, avoid strain caused by assuming an awkward position. Use care not to slip on oil or loose tools. Carts and small hydraulic hoists are available for moving a heavy compressor. When replacing compressors, always install an exact or compatible replacement.

Thinking Green

Motor Efficiency

When a motor fails and a direct replacement is not available, a larger motor is often substituted. Motors are most efficient when they operate at 75% to 110% of their rated load. If a motor has been upsized and frequently operates at less than 50% of its rated load, it should be replaced with the proper size motor.

Bitzer; Goodheart-Willcox Publisher; Mueller Industries, Inc.

Figure 55-5. A—Compressor with service valves removed. B—Blank flange used to close compressor valve opening while compressor is being moved. C—Service valve gaskets.

To keep the crankshaft seal from being abused, never rest the compressor weight on the flywheel. Always place the compressor on a block so that the flywheel hangs free. If possible, remove the flywheel before removing the compressor. Any undue strain on the flywheel may damage the crankshaft and the crankshaft seal. The flywheel can be removed with a universal flywheel puller. A little heat to the flywheel hub helps while the wheel puller is drawn snug.

Crankshaft seals may leak if a compressor has been idle for a long time. Turn the compressor over by hand a few times. This allows oil to seep between the rubbing metal surfaces. Also, put an ounce of special refrigerant detergent oils into the crankcase. This will help eliminate this problem.

55.2.1 Servicing External Motors

Motors used on open-drive compressors in commercial systems vary in size. They may be anywhere from 1/12 hp (62 W) for fans to 15 hp (11 kW) for compressors. Air-conditioning systems require motors of 1/3 hp (48 W) to 25 hp (18 kW). These motors are connected to 120 V/240 V single-phase, 240 V three-phase, or 480 V three-phase lines.

In addition to compressor motors, commercial refrigeration systems use external motors for other purposes, such as for fans, water pumps, and mixers in ice cream machines.

Motor Lubrication

Adequate lubrication of a motor's bearings is necessary. Normally motors should be oiled twice each year. Use electric motor oil (SAE 30). Too much oil is as bad as too little oil. Most motors are equipped with overflow openings. These openings eliminate most of the effects of excess oil. Many lubricants are now available in aerosol cans. Larger motors may use grease for lubrication. Refer to manufacturer's literature for a specific motor's lubrication requirements.

Motor Cleanliness

Thoroughly clean a motor occasionally using a vacuum, brush, and damp cloth to remove dust, dirt, and grease accumulations. Most motors are air cooled. Vents should be kept clean to allow for proper airflow. Contacts and wires should be checked for cracking, pitting, or loose connections.

Removing Electric Motors

To remove an electric motor, check for a fuse or circuit breaker in the system. Disconnect and lock out the power circuit. Disconnect the power line and remove the wires from the motor terminals. Label the

Copyright Goodheart-Willcox Co., Inc. 2017

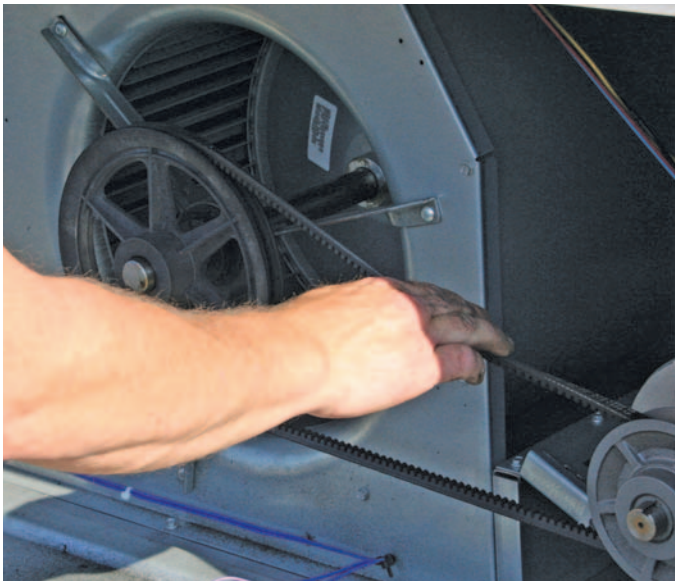
terminals for easier assembly later. Loosen hold-down bolts that attach the motor to its base.

If a motor is part of a belt-driven unit, remove the belt from the flywheel first. Then remove the belt from the pulley. The motor can then be lifted out. Do not allow the fan to hit the condenser or catch on the belt. Use a puller to remove the pulley from the motor shaft after loosening the lock screw. An example of a belt-driven unit is an open-drive compressor or a large motor running a fan using a belt drive.

Fan motors are sometimes difficult to remove. It is best to loosen and remove the fan. Generally, the fan hub is locked in place on the motor shaft with an Allen setscrew. Check pulleys for signs of wear. Worn pulleys may be the root of the problem and can ruin replacement belts, requiring callbacks. The belts used in driving fans should be checked regularly for cracks, worn spots, and warping. Always replace a belt with the same groove configuration if signs of wear are shown, **Figure 55-6**.

55.2.2 Servicing Hermetic Motor Burnouts

A *burnout* is a condition in which the insulation of an electric motor deteriorates due to overheating. This may occur in any motor but is of particular interest in bolted assembly (semi-hermetic) and welded (hermetic) compressors. The warmest spot in a hermetic compressor is usually the motor windings due to high current draw. High current draw is often a result of high head pressure in the system. The high-pressure cut-out or high-temperature overload may be cycling off such a compressor. A restricted condenser, a large heat load on the evaporator, or a high-side restriction may all result in a high-pressure cut-out and motor overheating. In time, the condition could lead to a burnout and a motor winding short. The breakdown of motor windings causes contamination or burning of the refrigerant oil. Such oil becomes acidic. This can also make the refrigerant toxic and change its condition. See Chapter 26, *Service and Repair of Domestic Refrigerators and Freezers* for earlier coverage of burnouts.



Goodheart-Willcox Publisher

Figure 55-6. A belt used to transfer the motion produced by an external motor must be in good condition for proper system operation.

To prevent acid formation, a refrigeration system must be kept free of moisture and contaminants. Condensers should be regularly cleaned and checked for obstruction-free airways to prevent high head pressure. To detect acid formation, check the system regularly:

- Use a sight glass with moisture indicator to monitor moisture levels.
- Take an oil sample often, and test it with an oil test kit. The oil sample must be kept sealed until tested, **Figure 55-7**.

If a burnout occurs, a hermetic compressor must be replaced. In large systems equipped with shutoff valves, it may be possible to save the refrigerant. If possible, filter or recycle such refrigerant before storing in a recovery cylinder.

Safety Note

Burnout Cleanup Safety

When working with a burned out hermetic compressor, wear goggles and rubber gloves. Work in ventilated space. The oil may be acidic and cause serious burns. Do not get any on your skin. The fumes may also be irritating and toxic.

While a burned out hermetic compressor needs to be replaced, the rest of the refrigeration system can be reconditioned by flushing it with nitrogen. Use a refrigerant recovery machine to triple evacuate to 500 microns to ensure that all contamination and moisture have been removed from the system. Install a ***burnout filter-drier*** in the suction line and another in the liquid line, **Figure 55-8**. Burnout filter-driers are designed for use after burnouts. Note that they should be removed later after cleanup. Test for leaks and evacuate again. Charge the system.

Connect the electrical wires. Never solder leads to compressor terminals. The glass may crack or the terminal may come loose, causing a leak.

Start the system and check operation. Operate the system for a half hour and sample the oil using an oil

Copyright Goodheart-Willcox Co., Inc. 2017

Refrigeration Technologies

Figure 55-7. Kit for testing refrigerant oil acidity.

Emerson Climate Technologies

Figure 55-8. Special filters are installed in suction lines to protect compressors after a burnout.

test kit. Replace the filter-drier if the oil sample is discolored or shows an acid trace.

Burnout filter-driers should always be used after a hermetic compressor has a motor burnout. Contaminants in a system may cause serious damage. Small solid particles act as an abrasive. They will wear down the needles and seats of refrigerant controls, valves, and also the valve seats, bearings, and pistons of compressors. These particles may also wear through a hermetic compressor's motor insulation and could cause another burnout. After cleanup, remove the burnout filter-driers from the system.

Removing Hermetic Compressors

If the motor is definitely faulty in a hermetic compressor, the compressor must be removed and replaced. Perform the steps of the removal procedure as follows:

1. Open the main circuit switch and lock out the power in the open position. Tag the switch to inform others why the switch is locked open.
2. Recover the refrigerant charge, as described previously. Close any valves to isolate the compressor as much as possible.
3. Disconnect the wires from the compressor. Label these or use a color code to prevent later confusion.
4. Clean the outside of the compressor.
5. Disconnect the compressor refrigerant lines. The type of disconnect depends on the compressor housing assembly. If removable, unbolt the service valves from the compressor housing. If the suction and discharge service valves are brazed fittings, open the brazed joints by heating or cutting the lines. Always wear goggles.
6. Plug the refrigerant openings.
7. Disconnect any other connections to the compressor as necessary.
8. Remove the compressor. Be careful not to tilt it, else oil could spill out. Avoid lifting if it is heavy by using a lifting machine (tripod or fork lift).

55.2.3 Adding Oil to a Refrigeration System

Remember when adding refrigerant to a refrigeration system that some of the oil will be dissolved in the refrigerant. If a unit becomes noisy (grinding or banging sound) soon after the refrigerant is added,

Copyright Goodheart-Willcox Co., Inc. 2017

refrigerant oil should be added. A compressor that runs too warm or is noisy may lack oil.

Caution

Moisture-Free Lubricant

Remember that refrigerant oil and all the oil transfer equipment must be clean and dry. When adding oil to a system, always use oil from an unopened container. Even if an oil container was only temporarily opened and then covered again with a cap, the oil will have drawn in some moisture. Adding this oil to a refrigeration system will create problems later on.

Refrigerant oil must meet several requirements. The oil must be the proper viscosity for the compressor. It must be compatible with the refrigerant in the system. The oil must be designed to work properly in the low-side temperature range. If several available oils meet this requirement, select the one with the lowest wax content. At low temperatures, wax can precipitate out of the refrigerant and clog orifices. A low wax content is preferable over a high wax content.

There are several ways to add refrigerant oil to a refrigeration system.

- The most rapid method of adding oil uses the system's compressor. Attach tubing equipped with a hand valve to the middle opening of the gauge manifold. Evacuate the tubing. Then immerse it in a clean, dry container of refrigerant oil. Run the compressor. Draw a vacuum on the crankcase by turning the suction service valve all the way in. Oil will be drawn into the crankcase. It is important that some of the oil in the glass container be left there. This is so the filling tube is always immersed in the oil. Otherwise, air will be drawn into the system. Glass containers are used in order to observe how much oil has been added. Oil should always be metered into a system slowly (a couple of ounces at a time). The system should be run for a couple of minutes and observed for noises, which could indicate that more oil is needed. When the proper amount of oil has been added, shut the hand valve, open the suction service valve, and observe compressor operation. This method can also be done with small containers, **Figure 55-9**.
- Another method of adding oil to a system is to evacuate the crankcase, equalize pressure to 0 psig, remove the oil fill plug from the crankcase housing, and directly add the oil. Replace the oil fill plug and then evacuate the compressor. Be sure to differentiate properly between the oil fill plug and oil drain plug.
- Oil can also be forced into a system by putting the oil into a service cylinder first. Draw oil into the service cylinder by first evacuating the cylinder. With the oil in the cylinder, build up a pressure in the cylinder with refrigerant vapor through the gauge manifold. The cylinder's lower valve is then connected to the center port of the gauge manifold. Open the low-side manifold valve and service cylinder valve. The oil is drawn from the cylinder into the compressor.
- Special pumps are available to manually pump oil into a compressor. Some of these pumps can even add oil into a system pushing against high-side pressure, **Figure 55-10**.

Ritchie Engineering Co., Inc. – YELLOW JACKET Products Division

Figure 55-9. These calibrated vessels allow a specific amount of oil to be added to a refrigeration system at a time.

Some compressor oil circulates around the system with the refrigerant. Therefore, oil must be added to the compressor if refrigerant lines are over 30′ (9.14 m) long. This includes both suction and liquid lines. Add about 3 fl. oz. (0.088 L) of oil for each 10′ (3.05 m) of tubing installed.

A suction line filter-drier must be installed if oil is added to a system. The oil additives may react and make sludge. Refrigerants can be successfully dried with a drier in either the liquid or suction line.

Copyright Goodheart-Willcox Co., Inc. 2017

Ritchie Engineering Co., Inc. – YELLOW JACKET Products Division

Figure 55-10. This pump allows a technician to add oil while the compressor is operating.

Caution

Oil Overcharge

Exercise extreme care when adding oil to a refrigeration system. If an HVACR system has too much oil, the compressor could be damaged by pumping liquid oil.

55.3 Servicing Condensers

Condenser service procedures depend on the type of condenser. In all cases, heat transfer surfaces must be clean. This is true for surfaces in contact with the refrigerant and for surfaces in contact with the cooling air or water. Jets of air may be used as a blowing agent. They are used to clean the condenser or drain lines, **Figure 55-11**.

If there is air in the refrigerant circuit, use a recovery machine to recover the refrigerant charge and evacuate the condenser while the compressor is stopped. Take precautions against freezing when working on water coolers and water chillers.

Remember that the purpose of a condenser is to remove heat. A condenser will fail to do its job efficiently if the heat transfer surfaces are covered with an insulating film of dirt or grime. The heat removing medium (air or water) must also be at correct temperature and volume.

DiversiTech Corporation

Figure 55-11. This pressurized air gun blows condensate drain lines clean.

55.3.1 Servicing Air-Cooled Condensers

Over time, the fins and tubes of air-cooled condensers accumulate a film of dirt and grime. This inhibits heat transfer, reduces system efficiency, increases head pressure, and can lead to various other problems. Regular cleanings are essential for optimal performance, **Figure 55-12**.

Goodway Technologies Corp.

Figure 55-12. A pressurized cleaning solution is sprayed over condenser coils to remove accumulated grime.

Copyright Goodheart-Willcox Co., Inc. 2017

Code Alert

Condenser Cleaning Permits

Check local and state codes to see which permits (if any) are needed to wash out condenser coils.

Removing Air-Cooled Condensers

A condenser may need replacing due to leaks or other problems. If so, it must be removed from the installation. Before removal, liquid refrigerant must be recovered from the condenser or pumped down into the liquid receiver. Also, the pressure must be balanced or equalized by adjusting to atmospheric level.

After pumping down the system into the liquid receiver, close the valve between the condenser and the liquid receiver. Then equalize the condenser to atmospheric pressure. Always wear goggles when working with pressurized vessels. Residual oil in the condenser should be drained and measured upon removal.

If there is no shutoff valve between the condenser and the liquid receiver, refrigerant should be removed by using a recovery machine. The amount of oil removed should be measured and noted for replacement into the system when the condenser has been repaired or replaced.

To remove a condenser, first clean the condenser as well as possible. Brushes, vacuum cleaner, air jets, carbon dioxide, and nitrogen jets may be used.

Most air-cooled condensers are housed in a protective shroud. This shroud also serves as an air duct. On some of the larger units, these sheet metal parts are heavy. Handle with care. Gloves and safety shoes are recommended. Most air-cooled condenser housings have an access door, which needs to be removed to service the condenser fan. **Figure 55-13** shows a condenser fan with the access door removed. Be sure to save removed fasteners in a container for easy organization.

Fans, fan brackets, belts, and motors may need to be removed on some units. These parts should be labeled, cleaned, and stored for reuse. Be sure the fan blades are not nicked or bent. This may put them out of balance and decrease their efficiency or cause disturbing noises. If electrical connections are removed, label them. Use masking tape and a marker or wire tags, **Figure 55-14**.

Always clean tubing connections before disconnecting the condenser from the rest of the system. Immediately plug the refrigerant openings. This keeps the internal refrigerant passages clean and prevents oil spills when moving the condenser.

Exercise care to avoid damaging condenser fins. Wood or cardboard protectors taped over the corners of the fins will provide protection. Because fins can be sharp, always use gloves when lifting or carrying a condenser.

Repairing Air-Cooled Condensers

A leak in a commercial condenser can often be repaired. First, clean the condenser. Then remove refrigerant from the condenser in the most convenient manner available. Flush the inside of the refrigerant tubes with nitrogen. If a brazed joint is leaking, clean the outside of the joint. With the charge removed from

Copyright Goodheart-Willcox Co., Inc. 2017

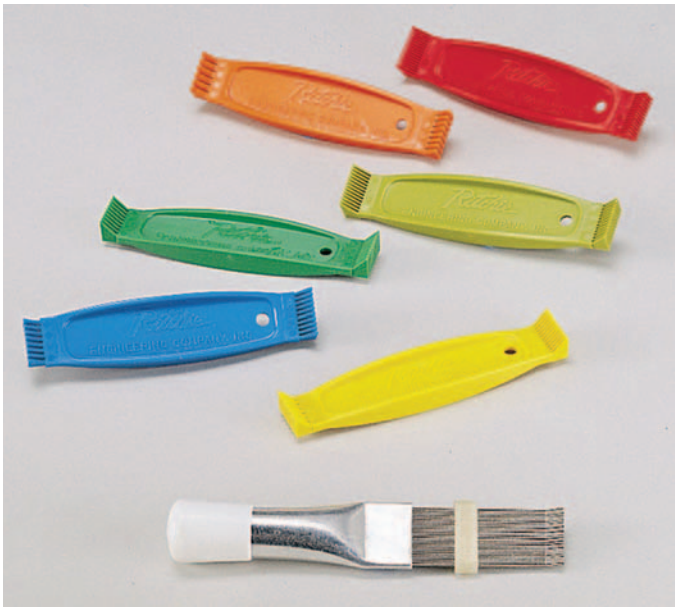
the condenser, set up low-pressure flowing nitrogen through the condenser. Apply flux to the joint, heat it, and take it apart. Clean the brazed area to get a smooth surface. Apply flux to the male part of the joint. Then assemble and support the joint. Braze the joint according to best practices and using the proper brazing filler material. Remove excess flux from the outside of joint.

If a tube is cracked, remove the damaged part and replace with new tubing section. Braze the new part in place. Inspect fittings (and flares, if used). These connections must be in good condition. Bent fins may be straightened using a ***fin comb***, **Figure 55-15**.

To test a repaired condenser, connect a pressure gauge to the condenser and plug one end of the condenser. Connect a nitrogen cylinder to the other end. Build up a pressure in the condenser, observe the pressure gauge for any measured drop, and test for leaks using soap bubbles. If nitrogen is unavailable, build up pressure in a condenser using system refrigerant. Use an electronic leak detector that can sense the type of refrigerant in the system. If refrigerant is used for leak detection, it must be recovered after the test is complete.

Another method used in some repair shops is the "dunk test." The condenser ends are sealed with brazed caps and a service valve is added. The condenser is pressurized with nitrogen, and the condenser is submerged in a tub of water. Bubbles reveal the location of any leaks.

A condenser leak is usually located using one of the following detection methods:



Ritchie Engineering Co., Inc. – YELLOW JACKET Products Division

Figure 55-15. Fin combs used to straighten condenser and evaporator fins.

- Bubble test.
- Electronic leak detector.
- Water immersion test.

55.3.2 Servicing Water-Cooled Condensers

Water-cooled condensers may either have a problem with the cooling water flow in the water loop or a leak in the refrigerant piping. The most common problem is scale buildup or restrictions in the water loop. A technician should first check the pressure drop across the condenser and ensure that it is within the manufacturer's specification. Increased head pressure is often a sign that the water flow rate is too low or scale buildup in the water circuit is inhibiting heat transfer.

If the problem is in the refrigerant circuit, the entire water-cooled condenser may need to be replaced. It is important to shut down and lock out all electrical service to the system prior to opening the water circuit. Water on the floor and on the unit is conductive and may cause an electrical shock.

Cleaning Water-Cooled Condensers

The most common problem with water-cooled condensers is a lack of maintenance. Depending on its usage, a water-cooled condenser should be cleaned at least annually. Water-cooled condensers eventually build up scale and lime from minerals in the water. The amount of minerals in the water varies by geographic location and water source. Systems that use ground well water require water treatment, such as water softeners and additional filters to remove minerals. The accumulation of scale in the water tubes over time reduces heat transfer from the refrigerant to the water. This results in higher head pressures and a reduction in system efficiency.

After shutting down and locking out electrical power, close the water supply valve and drain any remaining water. Remove any strainers and filters. Flush and clean the valves, strainers, and replace any cartridge filters. Straight tube condensers often have access ports that may be opened to allow the insertion of brushes through each tube. Mechanical brushes or manual brushes are rotated inside each tube to remove any scaling. The tubes are then flushed to remove the debris. Coiled water-cooled condensers can also be cleaned by using cleaning agents and water jets, **Figure 55-16**.

Chemical cleaning of water-cooled condensers is usually performed by technicians trained and certified in this work. All EPA guidelines for use and removal of hazardous wastes must be followed. Many chemical treatments are caustic and require the use of rubber gloves, protective clothing, and eyewear.

Goodway Technologies Corp.

Figure 55-16. This worker is cleaning a shell-and-tube condenser. The flexible shaft on the power cleaner rotates at high speed inside a nylon casing and high-pressure water helps the cleaning brush loosen deposits.

Removing Water-Cooled Condensers

A leaking water-cooled condenser should be removed and repaired or replaced. Removing a water-cooled condenser is similar to removing an air-cooled condenser. However, the water line must be disconnected. To do this, first close off the water supply. Then disconnect the water lines and drain all the water from the condenser to prevent any freezing of moisture within. Consider further flushing with low-pressure flowing nitrogen if this is available. Any remaining moisture could freeze, expand, and cause damage during recovery of refrigerant. Removal of any remaining moisture may be done by blowing out the coils with air, nitrogen, or carbon dioxide. Do not exceed a 60 psig (415 kPa) pressure, else the system may be damaged.

The water drain valves should be left open. This will allow drainage of residual water in the piping. Be sure the drain plug of the circulating pump is removed and left loose. If a pressure-operated water valve is used, leave it installed in the system, if possible. This is necessary because of its refrigerant tubing connection.

Once the water circuit is emptied of moisture, recover the refrigerant from the condenser and isolate the condenser from the rest of the refrigerant circuit. Survey the system for the most convenient valves to close.

Clean the outside of the condenser, wipe away the water, and clean the condenser connections. Dry the connections thoroughly. If the connections are mechanical, use wrenches of proper size. After disconnecting the refrigerant circuit, promptly cover the openings using good plugs to prevent water entering the system during cleaning. Either synthetic rubber expanding plugs or flared plugs are recommended.

If the condenser is heavy, use a lifting device. When a lifting device is not available, have two or more individuals work together to move the condenser.

Repairing Water-Cooled Condensers and Liquid Receivers

When a water-cooled condenser or liquid receiver malfunctions, replacing the unit is usually cheaper than repairing it. Welding or brazing is sometimes used to repair leaks, but this work should only be done by a pressure vessel certified welder. Depending on the cost, a condenser may be sent out for remanufacturing or repair. After being repaired, the vessel must be tested and certified prior to reuse.

Liquid receivers in most commercial systems serve as refrigerant storage cylinders. They usually have a welded steel shell. A shell-and-coil condenser often functions as both a condenser and a liquid receiver.

The water coil built into shell-and-coil condenser-receivers may develop a leak. Under certain conditions there is a corrosive action of the water and refrigerant. Eventually, the copper tubing used to carry the water may corrode. The leaking tube lets refrigerant from the system into the cooling water. This type of leak may be found by using an electronic refrigerant leak detector to check for the presence of refrigerant at the water drain. Leaks sometimes occur at the joints where the water-cooling coil attaches to the liquid receiver. Such damage may be due to abuse or to corrosive action. In either case, the condenser should be replaced with a new one.

Large liquid receivers are equipped with safety release valves. Liquid receiver repair should be attempted only with permission of local inspectors.

Servicing Water Valves

Water-cooled condensers rely on the proper operation of a water valve for proper heat transfer, **Figure 55-17**. Such systems often require attention because of incorrect water flow. This trouble is sometimes due to the water valve or to the screens in the water circuit. See Chapter 33, *Commercial Air-Conditioning Systems* for additional details on water valves.

A water valve is supposed to provide water to a condenser only while the system is cycled on with the

Copyright Goodheart-Willcox Co., Inc. 2017

Danfoss

Figure 55-17. Water valves are available in different sizes and styles.

compressor running. A water valve should stop water flow when the compressor cycles off. The following are some common problems with water valves:

- Inadequate water flow.
- Excessive water flow.
- Constant water flow (that does not stop when the unit is cycled off).

Inadequate water flow will not remove as much heat as it should. This can cause head pressure to rise. High head pressure can cause several cascading problems.

Excessive water flow can be wasteful and expensive for the system owner. It may be the result of an improperly sized water valve that allows too much flow. A properly sized valve may be calibrated for too much flow. Always check the pressure drop across the water-cooled condenser to make sure that the water flow rate matches the manufacturer's recommendation.

Constant water flow is also wasteful and expensive; however, it can also obscure the presence of other problems, such as noncondensables trapped in the condenser. Constant water flow can also negate the effectiveness of a hot-gas defrost function, increasing the time and decreasing system efficiency. A water valve will only operate correctly if installation is correctly made. Supply water must be clean.

Removing Water Valves

Before disconnecting a water valve from the water circuit, shut off the water supply. This is done using a hand valve. If no replacement valve is immediately available, temporarily connect the water system without a replacement. If necessary, water flow can be regulated temporarily with a hand shutoff valve.

To remove an electrical solenoid water valve from a system, open the switch that controls the circuit to the motor. Remove the water valve wires from the motor circuit. If these wires are soldered and taped, they must be unsoldered or cut. Most use slip-on connections, as this is quick and convenient.

Some pressure-operated water valves are difficult to remove from a system because the valve is connected to the high side of the condensing unit. The pressure tube for these valves may be connected into the compressor cylinder head or the compressor discharge tubing. However, some manufacturers connect this tube into the liquid line. Sometimes this tube has a hand shutoff valve. If so, removal of the valve is simple.

Removing a Pressure-Operated Water Valve

If a pressure-operated water valve is connected to the cylinder head of a compressor, follow the steps of this procedure. Since this involves dealing with pressurized fluids, be sure to wear goggles for eye protection.

1. Install a gauge manifold across the suction service valve and discharge service valve.
2. Turn the suction service valve all the way in.
3. Run the compressor until the pressure in the crankcase reaches 0 psi. Listen for a chugging sound that would indicate oil pumping, which sometimes occurs before 0 psi is reached. Immediately turn off the compressor if oil pumping occurs.
4. Heat the water valve line and the water valve bellows carefully with a heat lamp. Do this for three or four minutes until both are quite warm to the touch. This operation will move the liquid refrigerant that has condensed in this tube and valve back into the condensing unit. Then, only a small amount of high-pressure vapor will be left in this tube.
5. Turn the discharge service valve all the way in to block off the discharge line.
6. Open both low-side and high-side manifold valves. This bypasses the high pressure in the manifold and water valve refrigerant line into the low side.

Copyright Goodheart-Willcox Co., Inc. 2017

7. Clean the joints to be opened.
8. Disconnect the pressure tube from the water valve.
9. Immediately plug the refrigerant pressure tubing openings.
10. Gently heat the water valve again. Often, some liquid refrigerant becomes oil-bound within the water valve's bellows chamber. It releases with explosive force a few minutes after the valve is opened to the atmosphere. Heating will drive it out.

Safety Note

High-Pressure Oil

Be very careful not to point the refrigerant openings toward anyone. There is danger of being hit by the refrigerant. It is best to wrap the refrigerant openings with several layers of heavy toweling. The toweling will absorb any refrigerant being thrown from the mechanism.

11. Shut off the water supply.
12. Disconnect the water valve from the water line. Replace it with a new valve or connect the water lines directly. Now the old water valve is ready to be dismantled and repaired.

Some water valves permit removing the valve body without disturbing the refrigerant connections. To disconnect one of these valves, shut off the water. Disconnect the valve body from the water lines and bellows body.

Thermostatic water valves or motorized water valves are easily removed. Only electrical connections need to be broken and the water circuit closed.

Repairing Water Valves

It is usually better to replace a worn water valve than to repair it. Sometimes, however, a water valve only needs cleaning. A muriatic acid solution and wire brushes work best. Use the same precautions as when cleaning the water tubes of a condenser. If a valve has rubber or plastic seals, it should be replaced.

Occasionally, a packing gland is used to seal the joint. This is done where the valve stem passes into the valve body proper. The packing is usually composed of graphite, lead, and other materials. If the packing nut is turned all the way down and this joint still leaks, replace the packing.

Electric water valves may have faulty electrical coils (either shorted or with an open circuit). Replace the coil using one with the same electrical properties (voltage and wattage). Thermostatic water valves may lose the element charge. If so, replace the valve.

Installing and Adjusting Water Valves

After cleaning and repairing a pressure-operated water valve, test and adjust it. Only after testing and adjusting a water valve should a system be returned to service. If the maximum water supply temperature is 75°F (24°C), adjust the valve to open at the pressures shown in **Figure 55-18**. If the water inlet temperature is not 75°F, adjust valve to its correct opening pressure. Refer to **Figure 55-19**.

A pressure-operated water valve should also be tested for leaks while it is being adjusted using a portable air cylinder. To do this, connect an air pressure line to the valve's water inlet. The pressure-operating bellows controls the water flow. To test it, connect another air line and a pressure gauge to this fitting. No air should flow through the water valve until correct control bellows pressure is reached. Adjustment may be made to obtain this condition.

After installing a water valve, check it for leaks (both water and refrigerant), outlet water temperature, water flow, and head pressure.

55.3.3 Servicing Cooling Towers

Evaporative condensers and cooling towers collect deposits from the cooling water. These deposits must be removed periodically, else they will act as insulation. Deposits may be reduced by using water softening chemicals. Such chemicals can be bought from wholesale supply companies.

Chemicals in water are measured by a pH factor. The scale of pH is from 1 to 14. A solution that is acidic is indicated at 1 pH through 7 pH. A solution that is alkaline (base) is indicated at 8 pH through 14 pH. Chemicals may be added to the water to create a pH of 7 or 8 in the water.

The water temperature is important when testing for pH (acidity or alkalinity). The warmer the water, the more active the reaction to probes or color testers.

Water Valve Opening Pressures

Refrigerant	Pressure	
R-22	144 psig	1097 kPa
R-134a	92 psig	735 kPa
R-404A	182 psig	1355 kPa
R-717	152 psig	1152 kPa

Values based on water temperature of 75°F (24°C).

Goodheart-Willcox Publisher

Figure 55-19. Table of head pressures for systems with various refrigerants at various inlet water temperatures.

It is best to test the water between 70°F (21°C) and 80°F (27°C). Water near boiling is about 15% more active. Very cold water (near freezing) will give readings about 5% below the true value.

Chemicals may be used to lessen algae, mold, and slime growth. Deposits can be removed by scraping or by using a weak acid solution. This should be followed by a soda solution rinse and wash.

In addition to scale deposits, cooling tower basins can fill with slime, mud, algae, and bacterial colonies. Such contaminants can foul up components and reduce efficiency. Remove these as quickly as possible, **Figure 55-20**. Also, air passageways should be washed to eliminate blockages and maximize airflow, **Figure 55-21**.

Cooling towers need regular maintenance. Once a year, repair corrosion spots. It is good practice to do the following monthly:

Goodway Technologies Corp.

Figure 55-20. Technician vacuuming contaminants out of a cooling tower.

Goodway Technologies Corp.

Figure 55-21. Technician pressure washing the air passageways of this cooling tower.

- Inspect fan and motor bearings and oil sleeve.
- Grease (with water inhibitor) fan coil ball bearing.
- Inspect belt tightness and alignment and adjust, if necessary.
- Clean the strainer.
- Clean and flush the water pump.
- Inspect water level and adjust float, if necessary.
- Inspect spray nozzles and clean, if necessary.
- Inspect water level bleed; it must be working.
- Inspect air inlet screens and clean, if necessary.
- Inspect water for algae, leaves, or other particles.

55.4 Servicing Liquid Lines

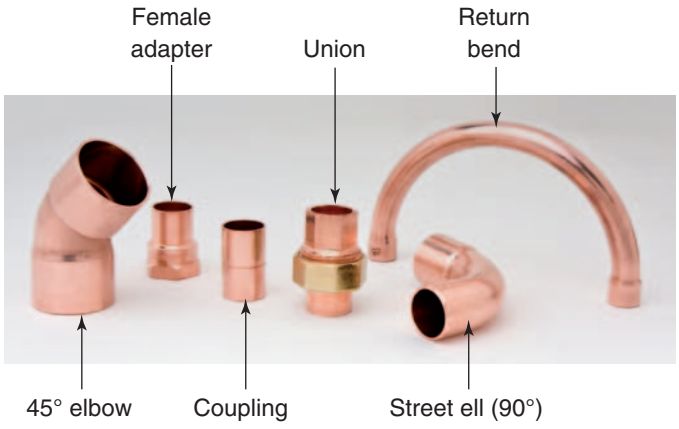
Refrigerant lines are typically made of copper tubing called air conditioning and refrigeration (ACR) tubing. ACR tubing is dehydrated and sealed with gaseous nitrogen by the manufacturer to keep the tubing dry and clean until it is used. Commercial refrigeration

Copyright Goodheart-Willcox Co., Inc. 2017

systems mostly use hard-drawn ACR tubing, although soft ACR tubing is used in some applications as well.

Soft ACR tubing and hard-drawn ACR tubing are available in different wall thicknesses, primarily K and L. Soft ACR tubing comes in rolls of 25′, 50′, and 100′ while hard-drawn ACR tubing is sold in straight lengths of 10′ and 20′. Hard-drawn ACR tubing cannot be bent or shaped, so any changes in tubing direction must be accomplished using brazed fittings. See **Figure 55-22**.

To differentiate from plumbing and other types of piping in nominal sizes, ACR tubing size is designated by the actual outside diameter of the tubing. See Chapter 8, *Working with Tubing and Piping*, for additional information about copper tubing and tubing sizes.



Mueller Industries, Inc.

Figure 55-22. Straight lengths of hard-drawn ACR tubing are connected with different types of fittings to achieve the desired tubing arrangement. All elbows and bends must be long radius.

Pro Tip

Tubing Sizes

While both the plumbing trade and the HVACR trade use copper tubing, the method of specifying tubing size is different between the trades. The plumbing trade specifies tubing size based on inside diameter, and the HVACR trade specifies tubing size based on outside diameter. This distinction prevents tubing intended for plumbing from being used in HVACR applications. Copper tubing intended for plumbing may have traces of processing oils that are incompatible with refrigerant oils.

Code Alert

Refrigerant Line Support

The manner in which refrigerant lines must be secured is specified by local building codes. The codes specify the materials that can be used, the support intervals required, and any shielding that is required around concealed tubing or tubing penetrating walls, floors, and ceilings of a building.

When servicing liquid lines, inspect the condition of the entire length of a liquid line. It must be protected from abrasion and abuse as objects are moved. The tubing should be well supported along its full length. While inspecting liquid lines, check the liquid line filter-drier, sight glass, and moisture indicator. Ensure that the sight glass and moisture indicator are installed between the filter-drier and refrigerant metering device. This is important for several reasons.

First, this arrangement allows the filter-drier to absorb moisture before it reaches the moisture indicator. If the filter-drier is full and cannot absorb any more moisture, the moisture indicator will show a rising level of moisture. A technician will know then to replace the filter-drier.

Another reason to install the sight glass between the filter-drier and refrigerant metering device is that this arrangement allows the sight glass to indicate possible unintentional pressure drops along the liquid line. For instance, if a liquid line filter-drier is clogged or restricted in some way, bubbles will appear in the sight glass. The system may have an adequate refrigerant charge, but the pressure drop caused by the restriction will cause bubbles to appear in the sight glass. Confirm the location of the pressure drop by performing a high-side temperature survey. This involves taking temperature measurements across the length of the liquid line and its in-line components. A temperature drop will confirm the source of the pressure drop and the location of the restriction.

Be mindful of the temperature of the liquid line. During system operation, a liquid line should be filled with warm liquid refrigerant. If a liquid line is not just warm but hot, it may contain refrigerant vapor. This could occur due to several different causes. In any case, it should be investigated.

Note that hot gas circulating through a liquid line could cause several different problems. For example, if driers are heated while in a refrigerant circuit, they will release moisture back into the circulating refrigerant. This could occur when refrigerant vapor is in the liquid line, due to a system undercharge or a dirty condenser or inoperable condenser fan. In any case, the hot-gas vapor circulating through the liquid line heats the drier, causing it to release moisture back into the refrigerant.

After addressing the cause of vapor in the liquid line, install a new filter-drier in the liquid line if the moisture indicator signals an unsafe or increasing amount of moisture in the refrigerant circuit.

If a liquid line has been evacuated or emptied of liquid refrigerant, take care when admitting liquid

Copyright Goodheart-Willcox Co., Inc. 2017

refrigerant into a liquid line through the liquid receiver service valve. Always open the valve slowly. A sudden rush of liquid may damage the screen or pack the desiccant in a filter-drier so firmly that it will clog.

55.5 Servicing Evaporators

Like air-cooled condensers, air-cooling evaporators usually consist of finned tubing passageways through which refrigerant flows to exchange heat. While condensers expel heat, evaporators absorb heat. Condensers and evaporators need to be clean and free of obstructions inside and outside to have optimal heat transfer.

55.5.1 Removing Evaporators

When removing an evaporator, first install a gauge manifold and test for leaks. Before opening the system, pump down or recover the refrigerant charge. However, before pumping down the system or recovering the charge, identify any in-line components that may interfere with the process. These may include evaporator pressure regulators, solenoid valves, shutoff valves, hot-gas valves, or pressure or temperature safety devices. Ensure that any valves along the suction line remain open so the refrigerant removal process continues unhindered. Ensure that any hot-gas bypass valves remain closed to prevent wasting time and effort pumping more than necessary. Be sure that any of the solenoid valves for hot-gas bypass are closed.

To pump down the system, close the liquid receiver service valve (LRSV) and run the compressor. As the compressor runs, watch the compound gauge to see when atmospheric pressure (0 psig) or a constant vacuum has been produced. At this point, begin feeling the relative temperature of the liquid line and evaporator. Continue running the compressor until the evaporator and liquid line are warm.

Unusual noises heard from the compressor indicate that it is being starved of oil. If that occurs, immediately stop the process and recover the remaining refrigerant using an approved recovery machine.

To speed up the pump down operation, heat the evaporator carefully with a heat lamp or heat gun set on low. Never allow the evaporator to get more than warm to the touch. When the compound gauge has a low pressure measurement and the evaporator and liquid line are warm, all the liquid refrigerant has been removed.

Warming the evaporator and liquid line and obtaining a vacuum ensures that as much refrigerant as possible has been pumped down into the liquid receiver. Before opening the system, perform atmospheric balancing. To balance the pressure in the evaporator to atmospheric pressure, a technician may bypass a small amount of high-side vapor through the gauge manifold into the evaporator. Make sure the center port of the gauge manifold is covered or valved off with an in-line hose. Turn both the discharge service valve and the suction service valve so they are just cracked open off the back seated position. Observe the compound gauge as you crack open the high-side manifold valve and then the low-side valve. Vapor from the high side will flow into the low side. Close the manifold valves when the compound gauge reads atmospheric pressure. Front seat both service valves and remove the evaporator. Plug all refrigerant circuit openings.

Multiple-evaporator systems may have hand shutoff valves for each evaporator. If so, use these valves instead of the compressor service valves. Close the liquid line service valve first. Then pump refrigerant out of the evaporators. Be sure there is 0 psi or slightly more in the evaporator. Close the suction line hand valve, and the evaporator is ready for removal.

Shut off the electric power to the evaporator fan and liquid line solenoid valve, if these are present. Remove the casing or shroud of the evaporator carefully. If electric defrost elements are mounted in or on the evaporator, disconnect them.

Clean and dry the suction line where it is connected to the evaporator. Also clean the inlet connection. Then, unfasten the suction line and liquid line from the evaporator. Plug the openings with appropriate fittings.

55.5.2 Repairing Evaporators

Evaporator repairs are usually limited to the following tasks:

- Repairing leaks.
- Repairing or replacing fittings.
- Straightening fins.
- Replacing defrosting elements.
- Repairing or replacing hangers.
- Repairing or replacing fins or motors.

Where leaks occur, completely dismantle leaking component and clean the surfaces. If it is a brazing repair, follow the procedural steps explained in Chapter 8, *Working with Tubing and Piping*. Always anneal an old tube before flaring it. Fins can be straightened using a fin comb.

Electrical defrosting elements should be checked for continuity. Terminals, insulation, and isolating parts should be inspected also. Rusty or bent hangers and abused hanger assembly bolts should be replaced. Check for the following:

- Fan and motor vibration.
- Tightness of the fan on the motor shaft.

Copyright Goodheart-Willcox Co., Inc. 2017

- Motor end play.
- Motor bearing wear.
- Condition of lubricant.

Small faulty motors should be replaced. Larger motors can be rebuilt. See Chapter 17, *Servicing Electric Motors and Controls*.

All parts should be cleaned before assembly. The evaporator is usually assembled on the job. If leaks have been repaired, the evaporator should be leak tested before it is installed.

55.5.3 Installing Evaporators

If the evaporator has been removed, the following reassembly procedure should be followed to ensure proper operation. Bolt the evaporator back into place and level it. Using a towel, wipe dry the surfaces of lines and evaporator before removing seals. Then remove the plugs on the refrigerant openings. Attach the refrigerant tubes to the unit. Be careful that no moisture enters the lines during these operations.

Install a thermostatic expansion valve (TXV). Connect a vacuum pump and evacuate all parts of the system that had been opened to atmosphere. These may include the evaporator, suction line, and compressor, if not isolated. Evacuate the evaporator a second time. Charge the evaporator and other parts in vacuum with a small amount of refrigerant to between 5 psig and 25 psig (35 kPa and 170 kPa). Test for leaks using an electronic leak detector. Complete the charge and test again for leaks.

When pulling a vacuum on an evaporator, heat it to a fairly high temperature as it is being evacuated to ensure that it is completely dehydrated. It should be heated to 175°F to 200°F (79°C to 93°C). This drives out any moisture that may be present. Heat lamps work well for this purpose.

After installing an evaporator and testing for leaks, install any defrost unit and its electrical connection, if used in this application. Install the fan and motor. The electrical connections should be tight and moisture-proof. Test the operation of the defrost unit and the fan. Assemble the casing or shroud. Start the unit and check for normal operation.

55.6 Servicing Valves

Valves function to control the flow of fluids through a system. Different types are used in different applications. While some simply open and close, others vary how much they open to provide modulating flow. Understanding a valve's purpose and operation is necessary for troubleshooting and servicing any refrigeration system.

55.6.1 Servicing Expansion Valves

The operation of different expansion valves is described in Chapter 20, *Metering Devices*. All types of refrigerant controls may be found in commercial systems. Systems having a self-contained hermetic unit may be serviced as described in Chapter 26, *Service and Repair of Domestic Refrigerators and Freezers*. However, multiple-evaporator systems and larger commercial units have other features that a service technician must understand.

Removing Expansion Valves

A faulty expansion valve should be removed and replaced with one in good condition. The troublesome valve may then be checked in a shop equipped for this purpose. In this way the trouble can be accurately determined.

When removing an expansion valve, as much refrigerant as possible should be pumped down or recovered before opening the refrigerant circuit. Close any valves located between the liquid line and the expansion valve. These may include a liquid line solenoid valve, manifold valves, or any shutoff valves.

In multiple-evaporator systems, individual shutoff valves can isolate the evaporators and reduce the amount of refrigerant pumped down or recovered. When installing a replacement expansion valve, be sure to mount and insulate its sensing bulb properly. Ensure that a replacement TXV has compatible properties, such as its superheat range/setting, valve orifice size, equalization connection, and refrigerant type.

Repairing Clogged Expansion Valve Screens

A clogged screen in an expansion valve's inlet may be easily detected. Indications are poor refrigeration, sweating or frosting only near the TXV, and the absence of the sound of refrigerant circulating. A clog will result in the starving of the evaporator. The compressor will pump out much of the refrigerant from the evaporator, leaving only low-pressure vapor or a slight vacuum. No liquid refrigerant should remain on the low side.

Removing an expansion valve having a clogged screen requires removing as much refrigerant from the lines to be opened as possible. The liquid line may be carefully heated with a heat lamp. This drives the liquid refrigerant back to the nearest shutoff valve. This valve then is closed.

The evaporator should already be evacuated of liquid refrigerant due to the clog allowing the compressor to draw a low pressure. A lack of liquid refrigerant is indicated by a warm evaporator. If an evaporator is not warm and has some pressure in it, run the compressor until pressure is at atmospheric pressure.

Copyright Goodheart-Willcox Co., Inc. 2017

Valves along the suction line may be closed if low-side pressure is at atmospheric pressure. If evaporator pressure is below atmospheric pressure, bypass just enough vapor refrigerant from the high side to the low side through the gauge manifold to bring evaporator pressure up to atmospheric pressure. After cleaning and drying the connections, the system may be opened to remove the screen.

Some TXVs have their inlet screens installed within their inlet tubing. These require the liquid line to be disconnected from the TXV in order to access the inlet screen. Other TXVs are built with inlet screens attached to a bolt that may be easily removed without having to disconnect the liquid line, **Figure 55-23**. Review TXV manufacturer literature before opening the refrigerant circuit.

Clean the screen or replace it with a new one. Fine-mesh copper or stainless steel screens are cleaned well with air pressure and safe solvent. However, the best way is to replace the screen and any gaskets supplied in a TXV repair kit. Never install an expansion valve into service without an inlet screen between the liquid line and the valve.

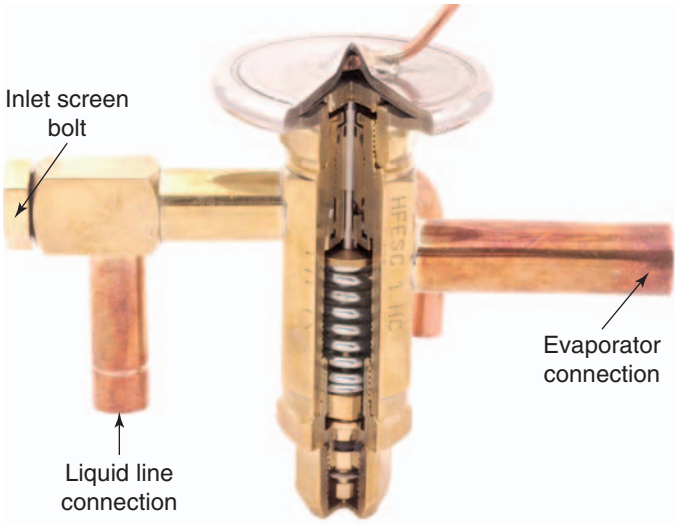
Install the new or cleaned screen and reassemble the components. Then evacuate the part of the system that was open to atmosphere. Test for leaks. Return the evaporator to normal operation by opening the closed valves.

Adjusting Thermostatic Expansion Valves (TXVs)

A TXV's sensing bulb should be secured to the suction line tubing. This is done at the point where it attaches to the evaporator, though not on a joint or any location where there will not be maximum surface area contact.

In service, a thermostatic expansion valve may be adjusted as follows:

1. While the compressor is cycled on, determine the temperature of the evaporator by measuring low-side pressure and converting the value using a P/T chart.
2. Adjust the TXV to allow more or less refrigerant into the evaporator based on evaporator superheat settings and measurements. **Figure 55-24** shows the internal components of a thermostatic



Emerson Climate Technologies

Figure 55-23. This TXV has an inlet screen that can be removed without opening the liquid line connection.

expansion valve. This TXV's adjustment screw is located on the bottom.

3. If the suction line frosts up, adjust the TXV to reduce the refrigerant flow. Superheat settings are generally based on the temperature range used for a conditioned space. Medium-temperature refrigeration uses 6°F to 8°F, and low-temperature refrigeration uses 3°F to 4°F.

Servicing Electronic Expansion Valves (EEVs)

The motor section of an EEV is often hermetically sealed and may not always be serviced. **Figure 55-25** illustrates a typical electronic expansion valve body, wiring, circuitry, and spare parts. The valve body and pin of an electronic expansion valve may be serviced similar to mechanical valves. Calibration of the valve is required following service of an electronic expansion valve. Review manufacturer literature for possible service procedures and diagnostic troubleshooting using an EEV's control unit, **Figure 55-26**.

Danfoss

Figure 55-26. Manufacturer diagnostic codes on control units can reduce troubleshooting time.

55.6.2 Servicing Evaporator Pressure Regulators (EPRs)

EPRs are commonly used on multiple-evaporator systems to regulate one evaporator to a different temperature than the other evaporators piped in parallel. If an EPR has been tampered with, it may need to be readjusted. Always use a pressure gauge when adjusting an EPR's setting. Refer to a P/T chart with the system refrigerant for the proper pressure and corresponding temperature. A thermometer may be used to help monitor and correct evaporator temperature during the adjustment. The adjustment nut should not be turned more than a half-turn at a time. A 15-minute

Copyright Goodheart-Willcox Co., Inc. 2017

interval of system operation should pass between each adjustment. This permits the evaporator to completely respond to the new pressure.

Many EPRs have an access port on their inlet tubing connecting to the evaporator. This allows a technician to connect a pressure gauge to verify corresponding pressure and temperature values during system operation and EPR calibration. Pressure readings would show evaporator pressure, not suction line pressure. However, an access port is not available on all EPRs.

When installing an EPR, install a shutoff valve on its outlet to the suction line. This will allow the evaporator to be isolated from the other evaporators in a multiple-evaporator system. This shutoff valve should have an access port, which will allow a technician to use a pressure gauge to measure suction line pressure. Having a shutoff valve with an access port installed between each EPR and the suction line will make maintenance and service work easier.

55.6.3 Replacing Hot-Gas Valves

When replacing a hot-gas valve, a technician must examine and thoroughly understand the particular refrigeration system being serviced. A hot-gas valve bridges the high side and low side. The technician will need to determine how best to evacuate refrigerant from different parts of the system and determine which valves can be used to reduce the size of the refrigerant circuit that will have to be opened to atmosphere. This may be a challenge, as hot-gas valves can connect to the low side at several different places, such as between an expansion valve's distributor and the evaporator or several places along the suction line.

To replace a hot-gas valve, refrigerant must be pumped down or recovered from the system. Then balance the pressures, either by bypassing a small amount of vapor through a gauge manifold or adding a low-pressure amount of nitrogen, depending on the type of joint around the hot-gas valve. Remove the valve, plugging refrigerant openings as soon as they are opened. Install a new valve. Test the system for leaks. Evacuate the part of the system opened to atmosphere. Recharge the system or allow refrigerant back into the part of the system serviced.

55.6.4 Replacing Service Valves

Occasionally a service valve stem will break or its threads will be stripped. Often the valve must be replaced. The location of the valve and the type of refrigeration system will determine the replacement service valve, **Figure 55-27**.

Mueller Industries, Inc.

Figure 55-27. Compressor service valves vary in size and build.

If it is a suction service valve, pump down or recover all refrigerant from the evaporator (unless the evaporator has hand shutoff valves), then balance the pressure.

To remove a discharge service valve or a liquid receiver service valve, first recover the entire refrigerant charge from the system. Close any service valves and shutoff valves to isolate as much of the system as possible from where it will be opened to atmosphere. In the part of the system to be opened for service, equalize the pressure to atmosphere.

Most open-drive compressors use bolt-on service valves. These may be unbolted and replaced with new valves and new gaskets. Some liquid receiver service valves are also removable. However, hermetic compressors may have service valves welded to the compressor dome, which may not be removed from the unit. If the entire valve cannot be replaced, it is often possible to replace the valve stem, valve seat, and packing gland.

55.6.5 Replacing Solenoid Valves

If a solenoid valve is being replaced, it is important that the solenoid be of the proper voltage and amperage rating. Otherwise, the coil may burn out. A 120 V valve cannot be connected to a 240 V circuit. The valve must also be able to withstand the pressure of the refrigerant in that part of the system, **Figure 55-28**.

To remove a solenoid valve from the system, isolate the smallest amount of the refrigerant circuit as possible and use the same pump-down or recovery procedure as previously described. Balance pressures before opening the system and plug refrigerant openings as quickly as possible.

55.7 Reconditioning Equipment after a Flood

Refrigeration equipment that has been exposed to flooding must be carefully reconditioned before attempting start-up. Clean and dry the entire outside of the

equipment. Use a detergent and bacteria cleanser. Replace all open motors or have them completely reworked.

Replace all external electrical parts. If attempting to clean and reuse them, an electric insulation leak inhibitor must be used.

Replace capacitors, relays, overload devices, and limit switches. Clean compressor terminals and spray with electrical insulation leak inhibitor. Check the electrical system completely with an ohmmeter. Check especially for grounds.

Chapter Review

Summary

- When servicing a system, be mindful of preventing personal and product harm. Always perform atmospheric balancing (pressure equalizing) before opening any part of a system. Monitor pressures throughout service procedures.
- Before opening a system's refrigerant circuit, shut as many valves as possible to isolate and reduce the amount of the system opened to atmosphere. Always clean and dry any joints that will be opened. Immediately plug refrigerant openings.
- When recovering refrigerant, immerse the recovery cylinder in an ice water bath to prevent high head pressure and temperature and to reduce recovery time. Gently warming parts of the refrigerant circuit also reduces recovery time.
- When reassembling a refrigeration system, clean and dry every part being installed. Pull a vacuum on any part of the system that has been opened to atmosphere before recharging with refrigerant.
- Proper lubrication of motor bearings is important. While overflow openings may allow excess oil to drain off, only add the necessary amount of lubricant. Keep motor parts clean and free of dust and dirt.
- A motor burnout involves the deteriorating of motor winding insulation due to overheating. In a hermetic or semi-hermetic compressor, a burnout can lead to the formation of acid in the refrigerant circuit that can ruin many system parts.
- Accumulated dirt and grime on the fins and tubes of air-cooled condensers must be cleaned off to maximize heat transfer potential.
- To remove or replace an air-cooled condenser, the refrigerant charge must be pumped down into the liquid receiver or recovered into a recovery cylinder. Condenser pressure must be balanced with atmosphere before opening the system.
- When removing a water-cooled condenser, the water circuit must be shut off, disconnected, and drained. To ensure a complete removal of water, blow out the water passageways using nitrogen, air, or carbon dioxide.
- Inadequate flow through a water valve reduces heat exchange and increases head pressure in a water-cooled condenser. Excessive water flow is costly and wasteful. Constant water flow is costly, wasteful, and counterproductive for hot-gas defrost functions.
- When replacing a water valve, begin by shutting off the water supply. Motorized and solenoid water valves have wiring to disconnect. A pressure water valve has refrigerant connections to undo. After replacing a water valve, check it for leaks, outlet water temperature, water flow, and head pressure.
- Evaporative condensers and cooling towers must be cleaned to eliminate heat-insulating deposits. Regular maintenance of cooling towers includes checking belt condition, water level, air passageways, pumps, strainer cleanliness, and fan and motor bearings and lubrication.
- Liquid line tubing must be supported and protected from damage along its entire length. When admitting liquid refrigerant back into a liquid line, slowly open the liquid receiver service valve. Use temperature surveys to locate unintentional pressure drops caused by restrictions.
- Indications of a clogged expansion valve include poor refrigeration, sweating or frosting only near the TXV, and the absence of the sound of circulating refrigerant. Its inlet screen may be installed inside the inlet piping or on a removable bolt.
- An EEV should be calibrated after service. Review manufacturer literature for how to use an EEV's controller for service and diagnostics.
- Temperature and pressure readings help when setting an EPR. Allow 15 minutes of operation for the temperature response to stabilize after each adjustment.
- When servicing or replacing hot-gas valves, thoroughly examine the system to see how best to isolate the part of the system to open to atmosphere for service.
- When replacing service valves, examine the system for options. In some cases, the entire refrigerant charge may need to be recovered. When replacing solenoid valves, find a valve with compatible voltage, current, and pressure ratings.

Review Questions

Answer the following questions using the information in this chapter.

1. In order to prevent noncondensables and contaminants from entering a refrigerant circuit, just before opening a system to atmosphere for service, a technician should _____.
   A. balance pressure with atmospheric pressure
   B. disconnect the gauge manifold
   C. increase pressure to at least 225 psi
   D. reduce pressure into a vacuum
2. A common method for reducing recovery time and preventing the development of high head pressure during recovery is to _____.
   A. immerse the recovery cylinder in an ice water bath
   B. run cold water over the condenser
   C. run cold water over the evaporator
   D. use a torch to gently warm the recovery cylinder
3. When pumping down a system, the best way to deal with safety controls that could cycle off the compressor is to _____.
   A. attempt to adjust their settings out of range
   B. completely disconnect them from the circuit
   C. connect a jumper wire across its terminals
   D. physically hold all the controls in the closed position
4. If an open-drive compressor is set down with its weight on its attached flywheel, a leak could develop at the _____.
   A. compressor head
   B. crankshaft seal
   C. inlet valve
   D. service valve packing
5. A motor burnout in a hermetic compressor will result in the development of a(n) _____ condition.
   A. acidic
   B. adiabatic
   C. alkaline
   D. azeotropic
6. When a motor burnout occurs, aside from the hermetic compressor, the rest of the refrigeration system can usually be reconditioned by flushing it with _____.
   A. ammonia
   B. butane
   C. muriatic solution
   D. nitrogen
7. Before adding refrigerant oil to a refrigeration system, ensure that the oil meets the following guidelines, *except* _____.
   A. able to work in the low-side temperature range
   B. compatible with the refrigerant
   C. has a high wax content
   D. proper viscosity for the compressor
8. Common methods of adding refrigerant oil to a refrigeration system include the following methods, *except* _____.
   A. drawing oil into the suction service valve through tubing immersed in an oil-filled container
   B. dumping it into the liquid receiver service valve while the compressor is operating
   C. injecting oil manually using a hand pump
   D. pouring oil into the compressor crankcase after balancing pressure with atmosphere
9. If a compressor makes a grinding or banging sound after refrigerant has been added, _____.
   A. add more refrigerant
   B. add refrigerant oil
   C. remove refrigerant oil
   D. repeatedly strike the compressor with a rubber mallet
10. When removing an installed water-cooled condenser, first empty the condenser of _____ and then remove the _____.
    A. oil; desiccant
    B. oil; water
    C. refrigerant; water
    D. water; refrigerant
11. Chemicals are added to cooling tower water to address the following problems, *except* _____.
    A. algae
    B. conductivity
    C. mold
    D. slime

Copyright Goodheart-Willcox Co., Inc. 2017

12. Along the liquid line, when a _____ is heated, it can release moisture back into the refrigerant.
    A. filter-drier
    B. shutoff valve
    C. sight glass
    D. solenoid valve
13. Indications of an expansion valve having a clogged inlet screen include the following, *except* _____.
    A. the absence of the sound of refrigerant circulating
    B. excessive refrigeration
    C. poor refrigeration
    D. sweating or frosting only near the expansion valve
14. When adjusting the setting of an EPR, wait approximately _____ of operation time to allow the new evaporator temperature to stabilize before additional adjustments.
    A. 10 seconds
    B. 1 minute
    C. 3 minutes
    D. 15 minutes
15. An access port on an EPR's inlet tubing can be used to measure _____ pressure.
    A. evaporator
    B. head
    C. liquid line
    D. suction

Appendix A: Service Information

A.1 Review of Abbreviations and Symbols

US Customary Units

°F = degrees Fahrenheit
°R = degrees Rankine = degrees Fahrenheit absolute
Btu = British thermal unit
Btu/hr = British thermal units per hour
cfm = cubic feet per minute
fpm = feet per minute
ft = foot or feet = ′
ft^2 = square foot
ft^3 = cubic foot
ft-lb = foot-pound
hp = horsepower
in = inches = ″
in. Hg = inches of mercury
in^2 = square inch
in^3 = cubic inch
lb = pound
lb/ft^3 = pounds per cubic foot
psi = pounds per square inch
psia = pounds per square inch, absolute
psig = pounds per square inch, gauge
qt = quart
ton = ton of refrigeration effect

SI Metric Units

°C = degrees Celsius
cm = centimeter
cm^2 = square centimeter
cm^3 = cubic centimeter
g = gram
J = joule
K = kelvin
kg = kilogram
kJ = kilojoule
kPa = kilopascal
kW = kilowatt
L = liter
m = meter
m^2 = square meter
m^3 = cubic meter
mm = millimeter
MW = megawatt
N = newton
Pa = pascal
W = watt

Miscellaneous Abbreviations and Symbols

π = 3.1416 (a constant used in determining the area of a circle)
Δ = delta = difference
∞ = infinity
A = area
c = specific heat
D = diameter
h = specific enthalpy (Btu/lb or kJ/kg)
H = total enthalpy
hr = hour(s)
Hz = hertz
in. WC = inches of water column
k = gas constant
m = mass
p = pressure
Q = heat energy
r = radius of circle
rh = relative humidity
sec = second(s)
RT = reference temperature
V = volume

Appendix B: Troubleshooting Charts

Troubleshooting Charts

Four different troubleshooting charts are included here for study. They cover domestic hermetic refrigeration, domestic and light commercial refrigeration, industrial refrigeration, and flake ice machines. Most troubleshooting charts, and all of these examples, are based on the assumption that the equipment was previously operable.

The hermetic refrigeration system troubleshooting chart is designed for use with hermetic refrigeration systems, like the type used in self-contained refrigerators. Note the general introductory procedures and the system electrical check used if the compressor will not run. The hermetic refrigeration system diagnosis shown in this section is for a self-contained commercial food storage unit.

The domestic and light commercial systems troubleshooting chart is used to diagnose refrigerated display cases, coolers, and walk-in freezers. The introductory section provides additional explanations for some of the possible causes and repairs listed in the chart.

The industrial refrigeration troubleshooting and service chart is used to diagnose industrial refrigeration equipment, like warehouse cold storage systems. It is assumed that only experienced, qualified persons would use this chart, and that the refrigeration equipment has been operational. It is written only for industrial refrigeration systems using open-drive reciprocating compressors.

The flake ice machine service procedure and troubleshooting chart includes an explanation of the sequence of operation and system schematic.

B.1 Hermetic Refrigeration System Diagnosis

1. General

   Each complaint is followed by probable causes and suggested repairs. To isolate the possible cause, proceed in a systematic manner to determine the faulty component. This guide does not cover all possible troubles and deficiencies that may occur under conditions of operation.

2. Electrical check

   A. Compressor does not run.

   1. Check power at outlet receptacle. Your compressor is designed to operate (see serial no. and data plate) on 115-60-1 with a voltage range of 103.5–126.5. Your 240/220-60-1 will operate within a range of ± 10%.
   2. Check thermostat for proper setting and continuity. Make sure control setting is not in an "Off" position. Continuity may be verified by following instructions on the individual compressor motor circuits.
   3. Look for obvious loose or broken wiring.
   4. Following systematically the instructions listed on the compressor motor circuitry, check the relay, overload, and, if employed, the start capacitor for continuity. Replace any components found faulty with the recommended service parts.

Troubleshooting and Service Chart

Complaint	Possible Cause	Repair
A. Compressor will not start—no hum.	1. Line disconnect switch open. 2. Fuse removed or blown. 3. Overload protector tripped. 4. Control stuck in open position. 5. Control off due to cold location. 6. Wiring improper or loose. 7. No call from thermostat.	1. Close start or disconnect switch. 2. Replace fuse. 3. Refer to electrical diagram. 4. Repair or replace control. 5. Relocate control. 6. Check wiring against diagram. 7. Test thermostat, replace if necessary.

(*continued*)

Troubleshooting and Service Chart		
Complaint	**Possible Cause**	**Repair**
B. Compressor will not start—hums.	1. Improperly wired. 2. Low voltage to unit. 3. Starting capacitor defective. 4. Relay failing to close. 5. Compressor motor has winding open or shorted. 6. Internal mechanical trouble in compressor. 7. Run capacitor defective.	1. Check wiring against diagram. 2. Determine reason and correct. 3. Determine reason and replace. 4. Determine reason and correct, replace if necessary. 5. Replace compressor. 6. Replace compressor. 7. Replace capacitor.
C. Compressor will not start—hums but trips on overload protector.	1. Improperly wired. 2. Low voltage to unit. 3. Relay failing to open. 4. Run capacitor defective. 5. Excessively high discharge pressure. 6. Compressor motor has a winding open or shorted. 7. Internal mechanical trouble in compressor (tight). 8. Start relay and capacitor defective.	1. Check wiring against diagram. 2. Determine reason and correct. 3. Determine reason and correct, replace if necessary. 4. Determine reason and replace. 5. Check discharge shutoff, possible overcharge or insufficient cooling on condenser. 6. Replace compressor. 7. Replace compressor. 8. Replace.
D. Compressor starts and runs, but short cycles on overload protector.	1. Additional current through overload protector. 2. Low voltage to unit. 3. Overload protector defective. 4. Run capacitor defective. 5. Excessive discharge pressure. 6. Suction pressure too high. 7. Compressor too hot—return gas hot. 8. Compressor motor has a winding shorted.	1. Check wiring diagram, check for added fan motors, pumps, etc., connected to wrong side of protector. 2. Determine reason and correct. 3. Check current, replace protector. 4. Determine reason and replace. 5. Check ventilation, restrictions in cooling medium, restrictions in refrigeration system. 6. Check for possibility of misapplication. Use stronger unit. 7. Check refrigerant charge (fix leak), add if necessary. 8. Replace compressor.
E. Unit runs ok, but short cycles.	1. Overload protector. 2. Thermostat. 3. High pressure cut-out due to: a. Insufficient air. b. Overcharge. c. Air in system. 4. Low pressure cut-out due to: a. Undercharge. b. Restriction in metering device.	1. See D above. 2. Differential set too close—widen. 3a. Check air to condenser—correct. b. Reduce refrigerant charge. c. Purge. 4a. Fix leak, add refrigerant. b. Replace metering device.

(*continued*)

Troubleshooting and Service Chart		
Complaint	**Possible Cause**	**Repair**
F. Unit operates too long or continuously.	1. Shortage of refrigerant. 2. Control contacts stuck or frozen closed. 3. Refrigerated space has excessive load or poor insulation. 4. System inadequate to handle load. 5. Evaporator coil iced. 6. Restriction in refrigeration system. 7. Dirty condenser. 8. Filter dirty.	1. Fix leak, add charge. 2. Clean contacts or replace control. 3. Determine fault and correct. 4. Replace with larger system. 5. Defrost. 6. Determine location and remove. 7. Clean condenser. 8. Clean or replace.
G. Start capacitor open, shorted, or blown.	1. Relay contacts not operating properly. 2. Prolonged operation on start cycle due to: a. Low voltage to unit. b. Improper relay. c. Starting load too high. 3. Excessive short cycling. 4. Improper capacitor.	1. Check and replace. 2a. Determine reason and correct. b. Replace. c. Correct by using pump down arrangement if necessary. 3. Determine reason for short cycling (see E above) and correct. 4. Determine correct size and replace.
H. Relay defective or burned out.	1. Incorrect relay. 2. Incorrect mounting angle. 3. Line voltage too high or too low. 4. Excessive short cycling. 5. Relay being influenced by loose, vibrating mounting. 6. Incorrect run capacitor.	1. Check and replace. 2. Remount relay in correct position. 3. Determine reason and correct. 4. Determine reason (see E) and correct. 5. Remount rigidly. 6. Replace with proper capacitor.
I. Space temperature too high.	1. Control setting too high. 2. Inadequate air circulation.	1. Reset control. 2. Improve air movement.
J. Suction line frosted or sweating.	1. Evaporator fan not running. 2. Overcharge of refrigerant.	1. Determine reason and correct. 2. Correct charge.
K. Liquid line frosted or sweating.	1. Restriction in dehydrator or strainer.	1. Replace part.
L. Unit noisy.	1. Loose parts or mounting. 2. Tubing rattle. 3. Bent fan blade causing vibration. 4. Fan motor bearings worn.	1. Find and tighten. 2. Reform to be free of contact. 3. Replace blade. 4. Replace motor.

B.2 Domestic and Light Commercial Systems

The Troubleshooting and Service Chart is fairly self-explanatory; however, a discussion of some of the complaints, possible causes, and repair solutions may be of some additional assistance.

COMPLAINT "A" is Compressor will not start—no hum.

Possible causes are:

1. *Switch open.* Rather obvious, but maybe it would be wise to determine why it is open or who opened it.
2. *Fuse removed or blown.* Again, was there a reason?
3. *Overload protector tripped.* Here, too, it is not a case of waiting until the overload resets, but rather to determine why.
4. *Control stuck in open position.* Faulty contactors may be a cause, although every effort is made to provide the best quality contactors. Heed this warning: Do not use the insulated end of a screwdriver to hold the contactor in. In doing so, you run the risk of burning out a good compressor.

COMPLAINT "B" is Compressor will not start—hums and trips on overload.

1. and 2. have been discussed (see Complaint "A").
3. *Starting capacitor defective.* It says "determine reason." Possibly a start capacitor was installed with too low a voltage rating.
4. *Relay failing to close.* Is the correct one being used?
5. *Compressor has a winding open or shorted*. The repair specified says simply "replace compressor." This means if the cause indicated has been proved conclusively, only then replace the compressor. Remember that replacing the compressor is generally the most costly repair bill an owner can get. So be sure.
6. *Internal mechanical trouble in compressor*. If the service person has proved without question that none of the other possible causes are the reason for the condition, then and only then can it be mechanical trouble.

A Troubleshooting Chart of this kind is not the entire answer. There are probably a number of other reasons for the cause of each "complaint" listed, so keep in mind that application of knowledge gained through experience and common sense are as much a part of troubleshooting as the use of any chart.

COMPLAINT "C" is Compressor starts but stays on run winding.

How do you know this condition is occurring? If the amps stay higher than normal, or if you don't hear the changeover.

1. through 3. Covered previously (see Complaints "A" and "B").
4. *High head pressure*. Be sure to check all the things listed in the "repair" column.

COMPLAINT "D" is Compressor starts and runs, but short cycles on overload protector.

1. Mentioned before (see Complaint "A").
2. Low voltage to unit (or unbalanced if three-phase). In the matter of three-phase unbalance—this is an instance in which it is probably wise to call in the power company, or check with the building owner to determine what other equipment is on the source of power to cause the unbalance.
3. *Overload protector defective*. Sometimes difficult to determine. One good clue is how it looks—does it appear to have been overheated?
4. and 5. Answered previously (see Complaint "C")
6. *Suction pressure too high*. This will occur more often on refrigeration than air conditioning, especially on low temperature equipment.
7. *Compressor hot—insufficient gas cooling.* Usually a result of a low charge.

Most of the other complaints, causes, and repair suggestions are straightforward, and the best suggestion is to follow the chart.

WARNING: ELECTRICAL POWER MUST BE DISCONNECTED WHEN TERMINAL PROTECTIVE COVER IS NOT IN PLACE TO PROTECT AGAINST ELECTROCUTION OR VENTED TERMINAL.

Troubleshooting and Service Chart

Complaint	Possible Cause	Repair
A. Compressor will not start—no hum.	1. Line disconnect switch open.	1. Close start or disconnect switch.
	2. Fuse removed or blown.	2. Replace fuse.
	3. Overload protector tripped.	3. Refer to electrical section.
	4. Control stuck in open position.	4. Repair or replace control.
	5. Control off due to cold location.	5. Relocate control.
	6. Wiring improper or loose.	6. Checking wiring against diagram.
	7. Defective thermostat.	7. Test thermostat, replace if necessary.

(*continued*)

Troubleshooting and Service Chart		
Complaint	**Possible Cause**	**Repair**
B. Compressor will not start—hums and trips on overload protector.	1. Improperly wired. 2. Low voltage to unit. 3. Starting capacitor defective. 4. Relay failing to close. 5. Compressor motor has a winding open or shorted. 6. Internal mechanical trouble in compressor. 7. Liquid refrigerant in compressor. 8. Run capacitor defective.	1. Check wiring against diagram. 2. Determine reason and correct. 3. Determine reason and replace. 4. Determine reason and correct, replace if necessary. 5. Replace compressor. 6. Replace compressor. 7. Add crankcase heater and/or accumulator. 8. Replace capacitor.
C. Compressor starts, but does not switch off of start winding.	1. Improperly wired. 2. Low voltage to unit. 3. Relay failing to open. 4. Excessively high discharge pressure. 5. Compressor motor has a winding open or shorted. 6. Internal mechanical trouble in compressor (tight).	1. Check wiring against diagram. 2. Determine reason and correct. 3. Determine reason and correct, replace if necessary. 4. Check discharge shut-off valve, possible overcharge, or insufficient cooling on condenser. 5. Replace compressor. 6. Replace compressor.
D. Compressor starts and runs, but short cycles on overload protector.	1. Additional current passing through overload protector. 2. Low voltage to unit (or unbalanced if three phase). 3. Overload protector defective. 4. Run capacitor defective. 5. Excessive discharge pressure. 6. Suction pressure too high. 7. Compressor too hot—return gas hot. 8. Compressor motor has a winding shorted. 9. High superheat.	1. Check wiring diagram. Check for added fan motors, pumps, etc., connected to wrong side of protector. 2. Determine reason and correct. 3. Check current, replace protector. 4. Determine reason and replace. 5. Check ventilation, restrictions in cooling medium, restrictions in refrigeration system. 6. Check for possibility of misapplication. Use stronger unit. 7. Check refrigerant charge (fix leak), add if necessary. 8. Replace compressor. 9. Check refrigerant charge, add if necessary.
E. Unit runs OK, but short cycles on.	1. Overload protector. 2. Thermostat. 3. High-pressure cut-out due to: a. Insufficient air or water supply. b. Overcharge. c. Air in system. 4. Low-pressure cut-out due to: a. Liquid line solenoid leaking. b. Compressor valve leak. c. Undercharge. d. Restriction in expansion device.	1. See D above. 2. Differential set too close—widen. 3a. Check air or water supply to condenser—correct. b. Reduce refrigerant charge. c. Purge. 4a. Replace. b. Replace. c. Fix leak, add refrigerant. d. Replace device.

(*continued*)

Troubleshooting and Service Chart		
Complaint	**Possible Cause**	**Repair**
F. Unit operates long or continuously.	1. Shortage of refrigerant. 2. Control contacts stuck or frozen closed. 3. Refrigerated or air conditioned space has excessive load or poor insulation. 4. System inadequate to handle load. 5. Evaporator coil iced. 6. Restriction in refrigeration system. 7. Dirty condenser. 8. Filter dirty.	1. Fix leak, add charge. 2. Clean contacts or replace control. 3. Determine fault and correct. 4. Replace with larger system. 5. Defrost. 6. Determine location and remove. 7. Clean condenser. 8. Clean or replace.
G. Start capacitor open, shorted, or blown.	1. Relay contacts not operating properly. 2. Prolonged operation on start cycle due to: a. Low voltage to unit. b. Improper relay. c. Starting load too high. 3. Excessive short cycling. 4. Improper capacitor.	1. Clean contacts or replace relay if necessary. 2a. Determine reason and correct. b. Replace. c. Correct by using pump down arrangement if necessary. 3. Determine reason for short cycling (see E above) and correct. 4. Determine correct size and replace.
H. Run capacitor open, shorted, or blown.	1. Improper capacitor. 2. Excessively high line voltage (110% of rated-max).	1. Determine correct size and replace. 2. Determine reason and correct.
I. Relay defective or burned out.	1. Incorrect relay. 2. Incorrect mounting angle. 3. Line voltage too high or too low. 4. Excessive short cycling. 5. Relay being influenced by loose vibrating mounting. 6. Incorrect run capacitor.	1. Check and replace. 2. Remount relay in correct position. 3. Determine reason and correct. 4. Determine reason (see E above) and correct. 5. Remount rigidly. 6. Replace with proper capacitor.
J. Space temperature too high.	1. Control setting too high. 2. Expansion valve too small. 3. Cooling coils too small. 4. Inadequate air circulation.	1. Reset control. 2. Use larger valve. 3. Add surface or replace. 4. Improve air movement.
K. Suction line frosted or sweating.	1. Expansion valve passing excess refrigerant or is oversized. 2. Expansion valve stuck open. 3. Evaporator fan not running. 4. Overcharge of refrigerant.	1. Readjust valve or replace with smaller valve. 2. Clean valve of foreign particles, replace if necessary. 3. Determine reason and correct. 4. Correct charge.
L. Liquid line frosted or sweating.	1. Restriction in dehydrator or strainer. 2. Liquid shut-off (king valve) partially closed.	1. Replace part. 2. Open valve fully.
M. Unit noisy.	1. Loose parts or mountings. 2. Tubing rattle. 3. Bent fan blade causing vibration. 4. Fan motor bearings worn.	1. Find and tighten. 2. Reform to be free of contact. 3. Replace blade. 4. Replace motor.

B.3 Industrial Refrigeration Troubleshooting and Service Chart		
Complaint	**Possible Cause**	**Repair**
A. Compressor will not start.	1. No power to motor.	1a. Check power to and from fuses; replace fuses if necessary.
		1b. Check starter contacts, connections, overloads, and timer (if part winding start). Reset or repair as necessary.
		1c. Check power at motor terminals.
		1d. Repair wiring if damaged.
	2. Control circuit is open.	2a. Safety switches are holding circuit open. Check high pressure, oil failure, and low pressure switches. Also check oil filter pressure differential switch if supplied.
		2b. Thermostat is satisfied.
		2c. Check control circuit fuses if blown; replace.
		2d. Check wiring for open circuit.
B. Motor ″hums″ but does not start.	1. Low voltage to motor.	1a. Check incoming power for correct voltage. Call power company or inspect/repair power wiring.
	2. Motor shorted.	2a. Check at motor terminals. Repair or replace as necessary.
	3. Single phase failure in the three-phase power supply.	3a. Check power wiring circuit for component or fuse failure.
	4. Compressor is seized due to damage or liquid.	4a. Remove belts or coupling. Manually turn crankshaft to check compressor.
	5. Compressor is not unloaded.	5a. Check unloader system.
C. Compressor starts, but motor cycles off on overloads.	1. Compressor has liquid or oil in cylinders.	1a. Check compressor crankcase temperature.
		1b. Throttle suction stop valve on compressor to clear cylinders and act to prevent recurrence of liquid accumulation.
	2. Suction pressure is too high.	2a. Unload compressor when starting. Use internal unloaders if present.
		2b. Install external by-pass unloader.
	3. Motor control.	3a. Motor control located in hot ambient.
		3b. Low power voltage.
		3c. Motor overloads may be defective or weak.
		3d. Check motor control relay.
		3e. Adjust circuit breaker setting to full load amps.
	4. Bearings are ″tight″.	4a. Check motor and compressor bearings for temperature. Lubricate motor bearings.
	5. Motor is running on single phase power.	5a. Check power lines, fuses, starter, motor, etc., to determine where open circuit has occurred.
D. Compressor starts but short cycles automatically.	1. Low refrigerant charge.	1a. Check and add if necessary.
	2. Driers plugged or saturated with moisture.	2a. Replace cores.
	3. Refrigerant feed control is defective.	3a. Repair or replace.
	4. No load.	4a. To prevent short cycling, if objectionable, install pump-down circuit, anti-recycle timer or false load system.
	5. Unit is too large for load.	5a. Reduce compressor speed.
		5b. Install false load system.
	6. Suction strainer blocked or restricted.	6a. Check and clean or replace as necessary.

(*continued*)

Copyright Goodheart-Willcox Co., Inc. 2017

B.3 Industrial Refrigeration Troubleshooting and Service Chart		
Complaint	**Possible Cause**	**Repair**
E. Motor is noisy or erratic.	1. Motor bearing failure or winding failure.	1a. Check and repair as needed.
	2. If electronic start, check calibration on control elements.	2a. Adjust as necessary.
F. Compressor runs continuously but does not keep up with the load.	1. Load is too high.	1a. Speed up compressor or add compressor capacity. 1b. Reduce load.
	2. Refrigerant metering device is underfeeding, causing the compressor to run at too low a suction pressure.	2a. Check and repair liquid feed problems. 2b. Check discharge pressure and increase if low.
	3. Faulty control circuit, may be low pressure control or capacity controls.	3a. Check and repair.
	4. Compressor may have broken valve plates.	4a. Check compressor for condition of parts. This condition can usually be detected by checking compressor discharge temperature.
	5. Thermostat control is defective and keeps unit running.	5a. Check temperatures of product or space and compare with thermostat control. Replace or readjust thermostat.
	6. Defrost system on evaporator not working properly.	6a. Check and repair as needed.
	7. Suction bags in strainers are dirty and restrict gas flow.	7a. Clean or remove.
	8. Hot-gas bypass or false load valve stuck.	8a. Check and repair or replace.
G. Compressor loses excessive amount of oil.	1. High suction superheat causes oil to vaporize.	1a. Insulate suction lines. 1b. Adjust expansion valves to proper superheat. 1c. Install liquid injection (suction line desuperheating).
	2. Too low of an operating level in chiller will keep oil in vessel.	2a. Raise liquid level in flooded evaporator (R-12 systems only).
	3. Oil not returning from separator.	3a. Make sure all valves are open. 3b. Check float mechanism and clean orifice. 3c. Check and clean return line.
	4. Oil separator is too small.	4a. Check selection.
	5. Broken valves cause excessive heat in compressor and vaporization of oil.	5a. Repair compressor.
	6. ″Slugging″ of compressor with liquid refrigerant that causes excessive foam in the crankcase.	6a. ″Dry up″ suction gas to compressor by repairing evaporator. 6b. Refrigerant feed controls are overfeeding. 6c. Check suction trap level controls. 6d. Install a refrigerant liquid transfer system to return liquid to high side.
	7. System has a leak.	7a. Locate and fix leak.

(*continued*)

Copyright Goodheart-Willcox Co., Inc. 2017

B.3 Industrial Refrigeration Troubleshooting and Service Chart		
Complaint	**Possible Cause**	**Repair**
H. Noisy compressor operation.	1. Loose flywheel or coupling.	1a. Tighten.
	2. Coupling not properly aligned.	2a. Check and align if required.
	3. Loose belts.	3a. Align and tighten per specs.
		3b. Check sheeve grooves.
	4. Poor foundation or mounting.	4a. Tighten mounting bolts, grout base, or install heavier foundation.
	5. Check compressor with stethoscope if noise is internal.	5a. Open, inspect, and repair as necessary.
	6. Check for liquid or oil slugging.	6a. Eliminate liquid from suction mains.
		6b. Check crankcase oil level.
I. Low evaporator capacity.	1. Inadequate refrigerant feed to evaporators.	1a. Clean strainers and driers.
		1b. Check expansion valve superheat setting.
		1c. Check for excessive pressure drop due to change in elevation, too small of lines (suction and liquid lines). A heat exchanger may correct this.
		1d. Check expansion valve size.
	2. Expansion valve bulb in a trap.	2a. Change piping or bulb location to correct.
	3. Oil in evaporator.	3a. Warm the evaporator, drain oil, and install an oil trap to collect oil.
	4. Evaporator surface fouled.	4a. Clean.
	5. Air or product velocity is too low.	5a. Increase to rated velocity.
		5b. Coils not properly defrosting.
		5c. Check defrost time.
		5d. Check method of defrost.
	6. Brine flow through evaporator may be restricted.	6a. Chiller may be fouled or plugged.
		6b. Check circulating pumps.
		6c. Check process piping for restriction.
	7. Wrong refrigerant for system.	7a. Retrofit system with proper refrigerant.
J. Discharge pressure too high.	1. Air in condenser.	1a. Purge noncondensables.
	2. Condenser tubes fouled.	2a. Clean.
	3. Water flow is inadequate.	3a. Check water supply and pump.
		3b. Check control valve.
		3c. Check water temperature.
	4. Airflow is restricted.	4a. Check and clean:
		a. Coils
		b. Eliminators
		c. Dampers
	5. Liquid refrigerant backed up in condenser.	5a. Find source of restriction and clear.
		5b. If system is overcharged, remove refrigerant as required.
		5c. Check to make sure equalizer (vent) line is properly installed and sized.
	6. Spray nozzles on evaporator condensers plugged.	6a. Clean.

(*continued*)

Copyright Goodheart-Willcox Co., Inc. 2017

B.3 Industrial Refrigeration Troubleshooting and Service Chart		
Complaint	**Possible Cause**	**Repair**
K. Discharge pressure too low.	1. Ambient air is too cold.	1a. Install a fan cycling control system.
	2. Water quantity not being regulated properly through condenser.	2a. Install or repair water regulating valve.
	3. Refrigerant level low.	3a. Check for liquid seal, add refrigerant if necessary.
	4. Evaporator condenser fan and water switches are improperly set.	4a. Reset condenser controls.
L. Suction pressure too low.	1. Light load condition.	1a. Shut off some compressors. 1b. Unload compressors. 1c. Slow down RPM of compressor. 1d. Check process flows.
	2. Short of refrigerant.	2a. Add if necessary.
	3. Evaporators not getting enough refrigerant.	3a. Discharge pressure too low. Increase to maintain adequate refrigerant flow. 3b. Check liquid feed lines for adequate refrigerant supply. 3c. Check liquid line driers.
	4. Refrigerant metering controls are too small.	4a. Check superheat or liquid level and correct as indicated.
M. Suction pressure too high.	1. Low compressor capacity.	1a. Check compressors for possible internal damage. 1b. Check system load. 1c. Add more compressor capacity.
	2. Refrigerant charge too high.	2a. Check refrigerant charge, remove if necessary.

B.4 Flake Ice Machine Troubleshooting and Service Chart

SEQUENCE OF OPERATION

1. At start-up all thermostats are warm, electric power flows from fuse through Bin Thermostat directly to the compressor (through High- and Low-Pressure Cut-Outs as applicable) and through the warm side of the Gear Thermostat to the Gearmotor (and in parallel to the Green light).
   1a. Original pull down of Flaker may be slow, 5 to 10 minutes before ice is produced. During the last half of pull down, the suction line at the compressor will be frosted, and the sight glass will show bubbles during pull down. After ice starts to be produced, frost will leave the compressor suction line and within 5 minutes the sight glass will show clear or only a small bubble in the top, which will disappear slowly.
2. As ice begins to form, the suction line from the evaporator (location of Gear Thermostat cap tube) gets cold enough (below 32°) to trip Gear Thermostat to the cold side bypassing the Bin Thermostat (resetting for later Ice Unloading period) so power flows directly through Gear Thermostat to the Gearmotor (and Green light); no change is apparent.
   A. [On rare occasions with some particle-free waters, the water will subcool substantially below freezing, then suddenly crystallize and stall the Gearmotor (designed to withstand a stall). The evaporator will continue to get colder until the bottom (location of the Defrost Thermostat cap tube) gets below freezing, tripping the Defrost Thermostat cold, sending power to the Defrost Valve (and Red light) which sends hot refrigerant through the evaporator, releasing the Auger and Gearmotor until the bottom of the evaporator reaches about 45°, tripping the Defrost Thermostat open, and normal refrigeration restarts. Since subcooling with crystallization occurs only 2 or 3 times out of 100, it is unlikely to happen and very unlikely to repeat.]
3. During ice formation, ice is drawn to the top of the evaporator, lowering the water level, opening the float valve. When water flow is seen, it indicates ice formation even before ice appears in the bin coming from the ice tube. Water flows through the bottom of the auger and from a hole near the bottom flight into the ice chamber, cools to 32°, then freezes in thin layers on the wall of the evaporator cylinder where the auger flights remove it and spiral it upward. The ice thickens until it is a fairly dense mass as it rotates under the helical path of the deflector until it is forced into the discharge spout by the deflector. The ice then flows by gravity through the ice tube to give it velocity which spreads it in the bin.
4. When ice piles over about half the length of the 1/4″ stainless tube which holds the Bin Thermostat cap tube, the thermostat opens, shutting off power to the compressor. (Turning on the Yellow light which is connected in parallel with the thermostat). The Green light stays on as the Gear Thermostat is still cold supplying power from the fuse to the Gearmotor (and Green light) to Unload Ice from the evaporator until the freezing surface is above 32°. The Gearmotor must remain on a couple minutes to complete unloading and usually stays on 5 to 15 minutes until the suction line out of the evaporator warms to 45°. Then the Gear Thermostat trips warm, connecting the Gearmotor to the output side of the Bin Thermostat (resetting for the next start-up) shutting off the Gearmotor and Green light.
5. When the bin is full, only the Yellow light is illuminated indicating power is on and fuse okay. Only a trickle of power is used through Yellow neon-type light during flaker-off periods. Flaker may start up while a small amount of ice is still on the 1/4″ stainless steel tube. This is okay as the deflector can push ice through the ice tube creating some spread around the top of the bin until the stainless steel tube is fairly well covered again.

B.4 Flake Ice Machine Troubleshooting and Service Chart		
Trouble	**Cause**	**Remedy**
A. Flaker will not operate. No lights on in control box.	1. Line fuse blown. 2. Loose connection in control box or in power supply line.	1. Check circuits for short or ground. Replace fuse. 2. Check for power supply at controls in control box. Check connections to bin thermostat.
B. Flaker will not operate. Yellow light on, but no ice on bin thermostat.	1. Bin control set too warm in a cold room between 45° and 55°. 2. Room below 45°. 3. Bin control has lost charge.	1. Set bin thermostat colder (cw) but recheck with ice to be sure it will shut off. 2. Add heat to the room. 3. Replace bin control.
C. Condensing fan and gearmotor operate (green light on) but not the compressor.	1. Inoperative capacitors or relay. 2. Overload switch defective. 3. Loose connections or defective compressor.	1. Replace capacitors or relay. 2. Replace overload switch. 3. Check for power at compressor C-R terminals, C-S terminals. With power off, remove C connection, check ohms between C and R, also C and S.
D. Water-cooled flaker: gearmotor operates (green light on) but not the condensing fan or compressor.	1. High-pressure cut-out open; inadequate water supply. 2. Water supply okay, high-pressure cut-out won't close with condenser cool.	1. Check water supply and condenser water valve. 2. Replace defective high-pressure cut-out.
E. Compressor operating but fan off.	1. Circuit not complete. 2. Fan motor burned out.	1. Check circuit. 2. Replace motor.
F. Condenser fan operating but compressor unit operating intermittently.	1. Dirty condenser coil. 2. High or low voltage. 3. Excessive refrigerant. 4. Worn compressor.	1. Clean coil. 2. Correct to proper voltage within 10% of nameplate. 3. Remove some refrigerant, check sight glass. 4. Replace compressor.
G. Intermittent defrost, red light cycling on and off. Water level normal in float tank.	1. Water line elbow in bottom bearing in too far. 2. Defrost thermostat misadjusted, very cold supply water. 3. TXV too far open. 4. Deflector partially closed. 5. Gearmotor not running. 6. Gearmotor stalled with power on, bottom evaporator mounting screw too tight. 7. Gearmotor stalled.	1. Back out elbow 1 turn. 2. See service manual for defrost thermostat setting. Also see Abnormal Defrost Thermostat Setting in the manual. 3. Close TXV 1/4 turn, see service manual for proper setting. 4. See service manual for correct deflector setting. 5. Check power to gearmotor receptacle in bottom of control box. 6. Back off evaporator mounting screw 1 turn to see if gearmotor will operate after it cools down sufficiently for overload to cut back in. Also see #7. 7. Remove gearmotor and auger assembly and check for operation on workbench (take care not to damage auger flights). Remove bottom bearing, check for condition and check for snug but not a tight fit on bottom of auger. Check clearance between top of auger and bottom of deflector (see Flaker Mechanism Assem. Instr. #5).

B.4 Flake Ice Machine Troubleshooting and Service Chart		
Trouble	**Cause**	**Remedy**
H. Wet ice.	1. High water level. 2. Undercharge, bubble going through sight glass. 3. Misadjusted TXV.	1. Lower water level. 2. Check for leaks, add refrigerant. 3. Adjust TXV (see ″Expansion Valve Adjustment″).
I. Ice too hard.	1. Low water level. 2. Deflector incorrectly adjusted. 3. TXV closed much too far. 4. Moisture in system and TXV partially frozen shut.	1. Raise water level. 2. See deflector adjustments procedure. 3. See service manual for proper suction pressure and suction line temperature. 4. Dehydrate and recharge system.
J. No ice with gearmotor, compressor and condenser fan operating. (Red light not on, no power to defrost valve.)	1. Very low refrigerant. 2. Stuck defrost valve, defrost line warm, suction pressure above 20 pounds.	1. Repair leak, see service manual for proper charge. 2. Repair or replace defrost valve.
K. Flaker does not turn off.	1. Misadjusted bin thermostat. 2. Bin thermostat will not open when set warmest with ice on the thermostat cap tube. 3. Mislocated bin thermostat cap tube.	1. Adjust bin thermostat (ccw), check with ice on coil. 2. Replace bin thermostat. 3. Check location of 1/4″ stainless cap tube holder parallel and below ice path coming from ice tube. Check thermostat cap tube located in the 1/4″ stainless tube.
L. Flaker cycles off and on.	1. Ice falling on bin thermostat capillary tube. 2. Ice tube not on outlet spout.	1. Relocate tube. 2. Remount ice tube and check for restriction.
M. Low production.	1. High head pressure. 2. Inadequate water supply. 3. TXV misadjusted. 4. High ambient. 5. Deflector closed. 6. Low head pressure.	1a. Clean condenser. Improve water supply to water-cooled condenser. Improve ventilation. 1b. Replace head pressure control valve on remote condenser models. 2. Check and clean filters. Raise water level. 3. Adjust TXV. 4. Decrease ambient to 90°F. Max. 5. See deflector adjustments procedure. 6a. Adjust water regulating valve. 6b. Add refrigerant to remote condenser models. 6c. Refer to Remote Condenser section of Service Manual.
N. Flaker spouts coming off.	1. ID of discharge tubing too small. 2. Roll pins breaking on deflector. 3. Hose kinking.	1. Change to braided nylon tubing. 2. Readjust defrost thermostat. 3. Change to braided nylon tubing, reroute presently used tubing.

Appendix D: Electricity and Electronics

D.1 Electrical Units and Symbols			
Quantity	**Symbol**	**Unit**	**Unit Abbreviation**
Charge	*Q*	coulomb	C
Current	*I*	ampere	A
Electromotive force, voltage	*E*	volt	V
Resistance	*R*	ohm	Ω
Reactance	*X*	ohm	Ω
Impedance	*Z*	ohm	Ω
Capacitance	*C*	farad	F
Inductance	*L*	henry	H
Power	*P*	watt	W
Magnetomotive force	*F*	ampere (ampere turn)	A
Frequency	*f*	hertz	Hz

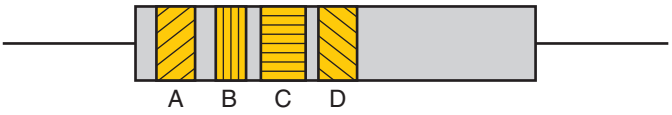
D.2 Resistor Color Codes

The color bands on a resistor indicate its resistance value.

Values Indicated by Color Coding			
Color	**Bands A and B**	**Band C**	**Band D**
Black	0	1	
Brown	1	10	
Red	2	100	
Orange	3	1,000	
Yellow	4	10,000	
Green	5	100,000	
Blue	6	1,000,000	
Violet	7		
Gray	8		
White	9		
Silver		0.01	±10
Gold		0.1	±5
No color			±20

A = First digit of the resistance value
B = Second digit of the resistance value
C = Multiplier
D = Tolerance (%)

A resistor that is color-coded orange, blue, red, and gold would have a resistance value of 36 × 100 = 3600 ohms. Since the fourth band is gold, the tolerance would be 5%. A 5% tolerance means the actual resistance can be between 3420 Ω and 3780 Ω.



D.3 Galvanic Action Sequence

Certain materials produce electricity by chemical action. This is known as galvanic action. Some materials are much more active than others. Magnesium is one of the most active, and platinum is one of the least active.

The corrosion of materials (usually metals) is often due to galvanic action. Rapid deterioration occurs at the place where galvanic action takes place. Joints where two unlike galvanic materials touch should be electrically insulated from one another in order to minimize galvanic action.

The following chart lists the galvanic action sequence for some commonly used metals. The metals listed at the top of the chart are the most active and most likely to corrode. The metals at the end of the list are least likely to corrode.

Appendix E: Heat, Temperature, and Pressure

E.1 Latent Heat Values		
Substance	Latent Heat of Vaporization	
	Btu/lb	kJ/kg
Alcohol	385	896
Ethylene glycol	344	800
Propylene glycol	393	914
R-12	72	167
R-22	101	234
R-40 (methyl chloride)	184	428
R-123	73	170
R-134a	93	216
R-401A	98	227
R-401B	99	229
R-404A	87	202
R-407C	105	245
R-409A	95	221
R-410A	117	275
R-507	86	201
R-508B	72	168
R-717 (ammonia)	589	1371
R-718 (water)	970	2257

E.2 Standard Conditions

Standard air and *standard conditions* are the same. Both conditions include pressure, temperature, and air density of 0.075 lb/ft^3 (1.2007 kg/m^3). These values are shown in the following table:

Standard Conditions		
Condition	US Customary	SI Metric
Pressure	29.92″ Hg 14.696 psia 0 psi	760 mm Hg 101.28 kPa
Temperature	69.8°F	21°C
Specific Volume	13.33 ft^3/lb	0.833 m^3/kg

E.3 Heating Value of Fuels

Fuels commonly used for heating purposes are oil, gas, coal, and wood. Burning these fuels in atmospheric air produces the heat needed.

Heating Oil

Commercial grades of heating oil have been established by ASTM International. Grade numbers are 1 through 6, although No. 3 and No. 4 are seldom used. Numbers 5 and 6 are high-viscosity oils and require preheating before use. The grade of heating oil may be determined with a special heating oil hydrometer. Heating values of fuel oils are shown in the following table:

Heating Values of Fuel Oils			
Commercial Grade	Btu/gal	A.P.I.* Gravity Range ASTM**	Average Weight per Gallon
1	137,000	45–38	6.8
2	140,000	40–30	7.1
3	140,000*		
4	141,000	32–12	7.7
5	148,000	20–8	8.1
6	152,000	18–6	8.2

*American Petroleum Institute rating

**ASTM International

Fuel Gases

The heating value of fuel gases varies greatly, depending on their composition. The heating values of common fuel gases are shown in the following table:

Heating Values of Fuel Gases	
Fuel Gas	Heat Released (Btu/ft^3)
Natural gas	1000–1100*
Manufactured gas	500–600
LP (Liquid Petroleum)	2500–3200

*Check with the local gas company.

Copyright Goodheart-Willcox Co., Inc. 2017

Coal

The heating value of coal depends on its moisture content, sulfur content, and other impurities. Heating values for coal are shown in the following table:

Heating Values of Coal	
Type of Coal	**Heat Released (Btu/lb)**
Bituminous	12,000–15,000
Anthracite	13,000–14,000

Wood

The heating value of wood is approximately 6200 Btu/lb.

E.8 Brine Freezing Temperatures

Brine is water mixed with a substance that will go into solution with the water. A brine provides a fluid that can readily flow at temperatures below 32°F (0°C).

Brines are of several types:

- Alcohol brines are usually made from ethyl alcohol.
- Salt brines are usually made with sodium chloride and/or calcium chloride. The eutectic point for a sodium chloride (common salt) solution is –6°F (–21°C). For calcium chloride, it is –60°F (–51°C).
- Glycol brines with noncorrosive properties are usually made from glycerin, ethylene glycol, or propylene glycol.

A hydrometer can be used to measure the density of a brine solution. The freezing temperature can be determined from the hydrometer reading. This is the same as measuring to determine the freezing temperature of cooling solution in automobile radiators. If the hydrometer reading indicates the solution freezing temperature is too high, it can be lowered by adding more of the antifreeze compound to the solution.

With alcohol brine, the density decreases with the lowering of the freezing temperature. This is because alcohol is lighter than water. A hydrometer with an alcohol testing scale must be used.

Freezing Temperature (°F and °C) of Various Brines

Specific Gravity	20°F (–7°C)	10°F (–12°C)	0°F (–18°C)	–10°F (–23°C)	–20°F (–29°C)	–30°F (–34°C)	–40°F (–40°C)
Alcohol (Formula No. 1)

Appendix G: EPA Certification

The final years of the twentieth century saw many changes in the refrigeration and air-conditioning industry. Among these were EPA regulations and increased opportunities for technician certification.

The depletion of the ozone has been an international concern. The threat of ozone molecules being destroyed by chlorine molecules was a major reason for the Environmental Protection Agency (EPA) to require technician certification.

The EPA currently requires technicians who service air-conditioning and refrigeration equipment that uses CFC or HCFC refrigerant to be certified. This requirement includes all persons who install, maintain, service, or repair equipment and may reasonably have the opportunity to release CFCs or HCFCs into the atmosphere. In addition, anyone who disposes of refrigerant or air-conditioning equipment must be certified.

EPA certification is achieved by successfully completing an EPA-approved test. This is required by Section 608 of the Clean Air Act. Major topics covered in certification programs include the following:

- CFC storage and handling.
- Refrigerant transportation.
- Recovery equipment and procedures.
- Basic field testing of refrigerant for purity.
- Isolation of system components to prevent venting of refrigerant.
- Leak detection, isolation of leaks, and leak repairs.
- Hazardous waste handling, storage, and disposal regulations.

Since November 14, 1994, only technicians certified by an EPA certifying agency are permitted to purchase refrigerant. Certification programs approved by the EPA are offered as seminars and workshops.

Technicians must fully understand the safety practices necessary when handling and storing refrigerants. It is the technician's responsibility to use safe practices and procedures. See **Figure G-1**.

Section 608 of the Clean Air Act charges the EPA with establishing and enforcing regulations pertaining to the refrigeration industry. These EPA regulations cover a wide scope of topics. A summary of the final regulations follows:

- Requires service practices that maximize recycling of ozone-depleting compounds, both CFCs and HCFCs, during service and disposal of air-conditioning and refrigeration equipment.
- Sets certification requirements for recycling and recovery equipment, technicians, and reclaimers.
- Restricts the sale of refrigerant to only certified technicians.
- Requires persons servicing or disposing of air-conditioning equipment to certify to the EPA that they have acquired recycling or recovery equipment and are complying with the requirements of the rule.
- Requires the repair of substantial leaks in air-conditioning and refrigeration equipment with a charge of greater than 50 lb.
- Establishes safe disposal requirements to ensure removal of refrigerants from goods that enter the waste stream with the charge intact (examples include motor vehicle air conditioners, home refrigerators, and room air conditioners).

Refrigerant Handling Safety Recommendations

1. Only fill cylinders that are currently DOT-approved for fluorocarbon refrigerants. Always inspect the cylinder for pressure rating and latest hydrostatic test date. Be sure to thoroughly check each cylinder for dents, gouges, bulges, cuts, or any other imperfections that may render it unsafe to hold refrigerant for storage or transportation.
2. It is highly recommended to read the Air-Conditioning, Heating, and Refrigeration Institute "Guideline K—Guideline for Containers for Recovered Non-flammable Fluorocarbon Refrigerants."
3. Be sure all connections are made tight before transferring refrigerant into cylinders. Be sure all closures are made tight on the cylinder immediately after filling.
4. Always use a scale when filling any cylinder. DO NOT OVERFILL.
5. CAUTION: Liquid refrigerant can cause frostbite if skin contact occurs. Be aware that the refrigerant/oil being removed from a system may contain contaminants that may be harmful to breathe or to contact with the skin. Always provide fresh air when working in enclosed areas. Avoid breathing vapors. Always wear safety glasses and gloves (cold resistant for pressurized refrigerants and rubber-type for R-11, R-113, or R-123). Avoid contact with clothing.

National Refrigerants, Inc.

The Clean Air Act—Section 608

In order to understand EPA certification testing, one must have a better understanding of Section 608 of the Clean Air Act. In 1990, the Clean Air Act (CAA) became a law. Its regulations became effective on May 14, 1993. Its goal was to increase environmental awareness, increase conservation, and reduce pollution. This section of text defines the procedures to reduce the release of chemicals into the atmosphere. In broad terms, Section 608 of the Clean Air Act does the following:

- Controls refrigerant purchase.
- Requires repair of large refrigerant leaks.
- Increases cooperation among countries in an effort to reduce emissions.
- Reduces industrial use of refrigerants.
- Discontinues the production of certain refrigerants.

Section 608 of the Clean Air Act delegates to the EPA the power to establish and enforce these regulations regarding the HVACR industry.

EPA Section 608 requires that technicians obtain certifications specific to the equipment they will be servicing or installing. This ensures that management of refrigerants is handled in a manner consistent with best practices. Any individual who performs maintenance, service, repair, or refrigerant disposal that may release refrigerants into the atmosphere is required to be certified. Apprentices are exempt from testing requirements if they are closely supervised by a certified technician.

Test prep courses are offered by EPA requirements on service practices and refrigerant reclamation. Close to 100 organizations have been approved by the EPA to provide test preparation and testing. Each testing organization is provided with an identical bank of test questions with a specific formula to create their exams and preparatory material. National providers include ESCO Institute, RSES, Video General, and Ferris State University. A complete list of preparation and testing sites can be found on the EPA website.

No new EPA certification is required for working with R-410A. However, due to the higher-pressure nature of R-410A, additional specific R-410A training is recommended.

EPA Certification Types

As of November 14, 1994, EPA-approved Section 608 certification is required to service building air-conditioning and refrigeration systems. Only certified technicians may purchase refrigerants. Technicians possessing Section 608 certification can purchase any refrigerant in containers greater than 20 pounds.

Technician certification to work on stationary refrigerant systems is regulated by the EPA Rule 608 of the Federal Register. Certification is broken down into four categories, based on the size and type of unit on which the technician will be approved to perform work. Technicians may take the exam over as many times as necessary to achieve a passing grade.

Technicians must be certified in the equipment category that they will be servicing or installing. Each of the four certification levels directly correlates to the type of service provided and the type of equipment serviced. The following are the EPA classifications for technician certification:

- Type I: small appliances.
- Type II: high-pressure or very high-pressure appliances.
- Type III: low-pressure appliances.
- Type IV: Universal certification.

The Type I, II, and III certification exams consist of 25 core questions and 25 questions specific to the type of exam taken for a total of 50 questions. The Universal certification exam consists of 25 core questions as well as 25 questions each of each Type I, II, and III for a total of 100 questions. A passing grade per section is 72% or 18 of 25 correct. Upon successful completion of the exam, the technician will receive a certificate and a patch.

A further description of the types of certification follows. It is important to remember that the type of certification indicates the type of equipment on which the technician may work. Being certified in Type I does not mean a technician can perform services on Type II or III equipment. However, a technician with Type IV certification can work on Type I, II, and III equipment.

Type I Certification: Small Appliances

Technicians are required to earn Type I certification in order to perform maintenance, service, or repair on small appliances with 5 pounds of refrigerant or less. The test consists of 25 core questions and 25 Type I specific questions, for a total of 50 multiple-choice questions.

Type I certification exams are offered in an open book or closed book format. The test may be taken online, mailed in, or proctored. The open book test score must be at least 84% correct. The proctored (closed book) test score must be at least 72%.

Those technicians passing the Type I (small appliance) examination are certified to recover refrigerant during the maintenance, service, or repair of packaged terminal air conditioners with 5 pounds or less of refrigerant. Such units can only be recovered by Type I or Universal certified technicians.

Copyright Goodheart-Willcox Co., Inc. 2017

Type II Certification: High- or Very High-Pressure Appliances

Technicians who pass the Type II test are certified to recover refrigerant during maintenance, service, or repair of high-pressure equipment. The boiling point of a refrigerant is the key to defining it as high or very high pressure. Boiling points between –58°F (–50°C) and 50°F (10°C) at atmospheric pressure are high pressure. Refrigerants with a boiling point below –58°F (–50°C) at atmospheric pressure are considered very high pressure.

High-pressure refrigerants include R-12, R-22, R-134a, R-402A, R-402B, R-404A, R-407A, R-407B, R-407C, R-410A, R-500, and R-502. Very high-pressure refrigerants include R-13, R-23, and R-503. Systems using these refrigerants can only be recovered by Type II or Universal certified technicians.

Type II certification includes the following types of equipment:

- Residential air conditioning and heat pumps.
- Commercial air-conditioning equipment.
- Chillers (other than low-pressure).
- Commercial refrigeration.
- Transport refrigeration.

The Type II certification test consists of 25 core questions and 25 Type II specific questions for a total of 50 multiple-choice questions. The test may only be taken proctored. The closed book test score must be at least 72%.

Type III Certification: Low-Pressure Appliances

Type III certification covers low-pressure appliances, which are charged with refrigerant having a boiling point above 50°F (10°C) at atmospheric pressure. Low-pressure systems typically include chillers, centrifugal compressors, and other equipment charged with R-11, R-123, and other low-pressure refrigerants.

The Type III certification test consists of 25 core questions and 25 Type III specific questions for a total of 50 multiple-choice questions. The test may only be taken proctored. The closed book test score must be at least 72%. Technicians who pass the Type III exam are certified to recover refrigerant during maintenance, service, or repair of low-pressure equipment.

Type IV Certification: Universal Certification

The Universal certification is the highest level of EPA certification. Technicians awarded Universal certification may recover refrigerant during maintenance, service, or repair of small appliances, high-pressure equipment, and low-pressure equipment. Such certification allows the technician to work on any type of air-conditioning and refrigeration equipment other than motor vehicle air conditioning.

Type IV certification encompasses the work covered under Types I, II, and III certification. The Type IV certification test consists of 25 core questions, 25 Type I questions, 25 Type II questions, and 25 Type III questions, for a total of 100 questions. The test may only be taken proctored. The closed book test score must be at least 72%.

Exam Preparation

A technician must inquire about the dates and times at which an EPA-approved testing organization will be presenting a certification exam. Testing organizations normally provide a one- or two-day course, which assists in preparing for the exam. There is usually an additional fee for this program.

Determine what to study in preparing for taking the exam. Areas of research are listed in a section later in this chapter. Keep in mind that these questions are not identical to those on the exam. After identifying weak areas, check the index to find the proper page for possible help. It is important that the material used for exam preparation be current. A review of the following chapters is recommended:

- Chapter 8, *Working with Tubing and Piping*.
- Chapter 9, *Introduction to Refrigerants*.
- Chapter 10, *Equipment and Instruments for Refrigerant Handling and Service*.
- Chapter 11, *Working with Refrigerants*.

The third step is to begin reviewing. Always keep a positive attitude throughout the studying process and during the exam. Additional information can be obtained from the EPA and local refrigeration organizations.

Studying for the tests can be divided into two parts. The first part includes studying those questions requiring what is called rote "specific" memorization. An example would be, "What term is used to describe a compressor that is contained within a sealed dome?" Questions of this type are best studied shortly before the exam. This is because they are easily forgotten since they only require simple memorization.

The second type of question is more complex. It requires the evaluation of facts and situations. It is based on a situational understanding of many items. Such questions are slower and more difficult to learn than the rote "specific" memorization questions.

A useful technique to increase retention of materials is to be quizzed by another person. Simply use the sample questions. Such review will assist in determining those areas on which to focus.

Copyright Goodheart-Willcox Co., Inc. 2017

Taking the Test

The certification exam test format will consist of multiple-choice questions. Each question will offer four possible answers. Only one of these answers is correct. Read each question and its suggested answers carefully. If a question is difficult to answer quickly, skip it and go on to the next one. Skipping these questions initially will assist in effective time management during the test. After the last question, return to those questions initially skipped. If still uncertain which answer is correct, eliminate as many incorrect answers as possible. Then, make an educated guess using those remaining choices.

If time remains, recheck all work for accuracy. It is important to remember that there is no penalty for incorrect answers. Therefore, there is no difference between leaving an answer blank or getting it wrong. Answer all questions even if it is necessary to guess at an answer.

Remember that pacing is important. Remain aware of progress throughout the exam. Bring a watch in case there is no clock in the room.

Areas for Research

To prepare for certification testing, research the subjects listed below. These are noted on the US EPA website and can be divided into core knowledge and specific certification type categories.

Core Knowledge

Ozone Depletion:

- Destruction of ozone by chlorine.
- Presence of chlorine in CFC and HCFC refrigerants.
- Identification of CFC, HCFC, and HFC refrigerants (not chemical formulas, but that R-12 is a CFC, R-22 is an HCFC, R-134a is an HFC, etc.).
- Identification of ozone-depletion potential—that CFCs have higher ozone-depletion potential (ODP) than HCFCs, which in turn have higher ODP than HFCs.
- Health and environmental effects of ozone depletion.
- Evidence of ozone depletion and role of CFCs and HCFCs.

Clean Air Act and Montreal Protocol:

- CFC phase-out date.
- Venting prohibition at servicing.
- Venting prohibition at disposal.
- Venting prohibition on substitute refrigerants in November 1995.
- Maximum penalty under the Clean Air Act.
- Montreal Protocol (international agreement to phase out production of ozone-depleting substances).

Section 608 Regulations:

- Definition and identification of high-pressure and low-pressure refrigerants.
- Definition of system-dependent vs. self-contained recovery/recycling equipment.
- Identification of equipment covered by the rule (all air-conditioning and refrigeration equipment containing CFCs or HCFCs except motor vehicle air conditioners).
- Need for third-party certification of recycling and recovery equipment manufactured after November 15, 1993.
- Standard for reclaimed refrigerant.

Substitute Refrigerants and Oils:

- Absence of "drop-in" replacements.
- Incompatibility of substitute refrigerants with many lubricants used with CFC and HCFC refrigerants and incompatibility of CFC and HCFC refrigerants with many new lubricants (includes identification of lubricants for given refrigerants, such as esters with R-134a; alkylbenzenes for HCFCs).
- Fractionation problem—tendency of different components of blends to leak at different rates.

Refrigeration:

- Refrigerant states (vapor vs. liquid) and pressures at different points of refrigeration cycle; how/when cooling occurs.
- Refrigeration gauges (color codes, ranges of different types, proper use).

Three Rs:

- Definitions of recovery, recycle, and reclaim.

Recovery Techniques:

- Need to avoid mixing refrigerants.
- Factors affecting speed of recovery (ambient temperature, size of recycling or recovery equipment, hose length and diameter).

Dehydration Evacuation:

- Need to evacuate system to eliminate air and moisture at the end of service.

Safety:

- Risks of exposure to refrigerants (oxygen deprivation, cardiac effects, frostbite, long-term hazards).
- Personal protective equipment (gloves, goggles, self-contained breathing apparatus—SCBA—in extreme cases).
- Recovery cylinders vs. disposable cylinders (ensure recovery cylinder is DOT-approved, know recovery cylinder's yellow and gray color code, never refill disposable).

Copyright Goodheart-Willcox Co., Inc. 2017

- Risks of filling cylinders more than 80% full.
- Use of nitrogen rather than oxygen or compressed air for leak detection.
- Use of pressure regulator and relief valve with nitrogen.

Shipping:

- Labels required for refrigerant cylinders (refrigerant identification, DOT classification tag).

Type I (small appliances)

Recovery Requirements:

- Definition of small appliance.
- Evacuation requirements for small appliances with and without working compressors using recovery equipment manufactured before November 15, 1993.
- Evacuation requirements for small appliances with and without working compressors using recovery equipment manufactured after November 15, 1993.

Recovery Techniques:

- Use of pressure and temperature to identify refrigerants and detect noncondensables.
- Methods to recover refrigerant from small appliances with inoperative compressors using a system-dependent or "passive" recovery device (such as heating and sharply striking the compressor, using a vacuum pump with a nonpressurized recovery container).
- Need to install both high-side and low-side access valves when recovering refrigerant from small appliances with inoperative compressors.
- Need to operate operative compressors when recovering refrigerant with a system-dependent ("passive") recovery device.
- Should remove solderless access fittings at conclusion of service.
- R-134a as likely substitute for R-12.

Safety:

- Decomposition products of refrigerants at high temperatures (HCl, HF, etc.).

Type II (high- or very high-pressure appliances)

Leak Detection:

- Signs of leakage in high-pressure systems (excessive superheat, traces of oil for hermetics).
- Need to leak test before charging or recharging equipment.
- Order of preference for leak test gases (nitrogen alone best, but nitrogen with trace quantity of R-22 is better than pure refrigerant).

Leak Repair Requirements:

- Allowable annual leak rate for commercial and industrial process refrigeration.
- Allowable annual leak rate for other appliances containing more than 50 lb of refrigerant.

Recovery Techniques:

- Recovering liquid at beginning of recovery process speeds up process.
- Other methods for reducing recovery time (chilling recovery vessel, heating appliance or vessel from which refrigerant is being recovered).
- Methods for reducing cross-contamination and emissions when recovery or recycling machine is used with a new refrigerant.
- Need to wait a few minutes after reaching required recovery vacuum to see if system pressure rises (indicating that there is still liquid refrigerant in the system or in the oil).

Recovery Requirements:

- Evacuation requirements for high-pressure appliances in each of the following situations:
  - Disposal.
  - Major vs. non-major repairs.
  - Leaky vs. non-leaky appliances.
  - Appliance (or component) containing less vs. more than 200 lb.
  - Recovery/recycling equipment built before vs. after November 15, 1993.
- Definition of "major" repairs.
- Prohibition on using system-dependent recovery equipment on systems containing more than 15 pounds of refrigerant.

Refrigeration:

- How to identify refrigerant in appliances.
- Pressure-temperature relationships of common high-pressure refrigerants (may use standard temperature-pressure chart—be aware of need to add 14.7 to translate psig to psia).
- Components of high-pressure appliances (liquid receiver, evaporator, accumulator, etc.) and state of refrigerant (vapor vs. liquid) in them.

Safety:

- Shouldn't energize hermetic compressors under vacuum.

Copyright Goodheart-Willcox Co., Inc. 2017

- Equipment room requirements under ASHRAE Standard 15 (oxygen-deprivation sensor with all refrigerants).

Type III (low-pressure appliances)

Leak Detection:

- Order of preference of leak test pressurization methods for low-pressure systems (first: hot water method or built-in system heating/pressurization device, such as Prevac; second: nitrogen).
- Signs of leakage into a low-pressure system (such as excessive purging).
- Maximum leak test pressure for low-pressure centrifugal chillers.

Leak Repair Requirements:

- Allowable annual leak rate for commercial and industrial process refrigeration.
- Allowable annual leak rate for other appliances containing more than 50 lb of refrigerant.

Recovery Techniques:

- Recovering liquid at beginning of recovery process speeds up process.
- Need to recover vapor in addition to liquid.
- Need to heat oil to 130°F (90°C) before removing it to minimize refrigerant release.
- Need to circulate or remove water from chiller during refrigerant evacuation to prevent freezing.
- High-pressure cut-out level of recovery devices used with low-pressure appliances.

Recharging Techniques:

- Need to introduce vapor before liquid to prevent freezing of water in the tubes.
- Need to charge centrifugals through evaporator charging valve.

Recovery Requirements:

- Evacuation requirements for low-pressure appliances in each of the following situations:
  - Disposal.
  - Major vs. non-major repairs.
  - Leaky vs. non-leaky appliances.
  - Appliance (or component) containing less vs. more than 200 lb.
  - Recovery/recycling equipment built before vs. after November 15, 1993.
- Definitions of "major" and "non-major" repairs.
- Allowable methods for pressurizing a low-pressure system for a non-major repair (controlled hot water and system heating/pressurization device, such as Prevac).
- Need to wait a few minutes after reaching required recovery vacuum to see if system pressure rises (indicating that there is still liquid refrigerant in the system or in the oil).

Refrigeration:

- Purpose of purge unit in low-pressure systems.
- Pressure-temperature relationships of low-pressure refrigerants.

Safety:

- Equipment room requirements under ASHRAE Standard 15 (oxygen deprivation sensor with all refrigerants).
- Under ASHRAE Standard 15, need to have equipment room refrigerant sensor for R-123.

EPA Service Requirements

In addition to implementing certification requirements for technicians, the EPA also instituted regulations for performing service on the various types of refrigeration systems. Two of the most important services regulated are refrigerant recovery procedures and leak repairs.

Recovery Procedures

The Clean Air Act requires a technician to evacuate air-conditioning and refrigeration units to specific levels. These levels ensure that discharge of refrigerant into the atmosphere will not occur. Two levels of vacuum are legally acceptable. One level is for recovery equipment manufactured prior to November 15, 1993. The other level is for recovery equipment manufactured after November 15, 1993, which has been tested and certified by an EPA organization. See **Figure G-2** for the required levels.

Recovery Procedures, Type I Certification

Recovery procedures depend on the size and type of equipment being serviced. With Type I certification, recovery devices may be divided into two types: self-contained and system-dependent recovery equipment.

A self-contained recovery unit has its own compressor to remove refrigerant from the refrigerating system. A system-dependent recovery unit depends on the compressor in the appliance or the pressure of the refrigerant in the appliance.

Copyright Goodheart-Willcox Co., Inc. 2017

For small appliances (Type I), recovery equipment must recover 90% of the refrigerant when the compressor is operating. If the compressor is not operating, 80% of the refrigerant must be recovered.

Recovery Procedures, Type II Certification

Type II certification determines recovery methods by the type of refrigerant used and the amount of the refrigerant charge in the equipment. EPA evacuation levels for Type II certification are as listed:

- R-22 appliances with less than a 200 lb of charge, when using recovery equipment manufactured after November 15, 1993—evacuation level is 0 in. Hg.
- R-22 appliances with more than a 200 lb of charge, when using recovery equipment manufactured after November 15, 1993—evacuation level is 10 in. Hg.
- Other high-pressure appliances with less than 200 lb of charge, when using recovery equipment manufactured after November 15, 1993—evacuation level is 10 in. Hg.
- Other high-pressure appliances with more than 200 lb of charge, when using recovery equipment manufactured after November 15, 1993—evacuation level is 15 in. Hg.
- Very high-pressure equipment, when using recovery equipment manufactured after November 15, 1993—evacuation level is 0 in. Hg.

Recovery Procedures, Type III Certification

For Type III certification, chillers are initially recovered using liquid recovery. The process is completed through vapor recovery. Chiller systems usually contain a large quantity of liquid refrigerant. Therefore, a liquid recovery will be faster and will recover most of the refrigerant. Specific liquid pumps are designed for recovery of low-pressure refrigerants. Do not overfill cylinders more than 80% by weight else the cylinder may burst.

Recovery methods for Type III certification are determined by the type of refrigerant used and the amount of the refrigerant charge in the equipment. The recovery requirement for low-pressure equipment, when using equipment that was manufactured after November 15, 1993, is an evacuation level of 25 mm Hg absolute (25 mm Hg absolute = 2500 microns = 29 in. Hg). Evacuation rates for recovery or recycling machines that were manufactured prior to November 15, 1993, are shown in **Figure G-2**.

Leak Repairs

An annual leak rate of 35% or more in commercial or industrial equipment with a refrigerant charge of 50 lb or more must be repaired. It is the duty of the technician to notify the equipment owner of the leak. The owner is required to repair the leak within thirty days. Units with a refrigerant charge less than 50 lb are exempt from annual leak rate requirements.

Comfort cooling equipment with a charge of over 50 lb is granted an annual leak rate of 15% of charge per year. This excludes industrial process and commercial equipment. Technicians who service such appliances must notify the equipment owner of the leak. The owner is required to repair the leak within thirty days. Note that EPA Rule 608 refers only to Type II and Type III certifications. Type I certification is exempt from these requirements.

EPA Vacuum Levels

Appliance Type	Equipment manufactured before November 15, 1993	Equipment manufactured after November 15, 1993
R-22 appliance* containing less than 200 lb of refrigerant	0 in. Hg	0 in. Hg
R-22 appliance* containing 200 lb or more of refrigerant	4 in. Hg	10 in. Hg
Other high-pressure appliance* containing less than 200 lb of refrigerant (R-12, R-500, R-502, R-114)	4 in. Hg	10 in. Hg
Other high-pressure appliance* containing 200 lb or more of refrigerant (R-12, R-500, R-502, R-114)	4 in. Hg	15 in. Hg
Very high-pressure appliance (R-13, R-503)	0 in. Hg	0 in. Hg
Low-pressure appliance (R-11, R-123)	25 in. Hg	29 in. Hg (25 mm Hg absolute)

*Or isolated component of such appliance.

Appendix H: HVACR-Related Associations and Organizations

There are numerous HVACR-related associations and organizations. Many have broad goals, while others have a more focused aim. Many offer certifications and advanced training that may benefit particular career paths within the HVACR industry. Review the following list of organizations and associations. For additional information, refer to an organization's website.

Air Conditioning Contractors of America (ACCA). A nonprofit association for the indoor environment and energy services community that promotes professional contracting, energy efficiency, and healthy, comfortable indoor environments in the HVAC trades.

Air Conditioning, Heating, & Refrigeration Institute (AHRI). A trade association that represents manufacturers of HVACR and water heating equipment, advocates on behalf of its members at all levels of government, runs an equipment certification program, and functions as a resource for industry shipment data, education and workforce information, and research.

Air Movement & Control Association International Inc. (AMCA). A nonprofit association of the world's manufacturers of fans, louvers, dampers, air curtains, air flow measurement devices, ducts, acoustic attenuators, and other air-system components, AMCA operates with the mission to advance the health, growth, and integrity of the air movement and control industry.

American Boiler Manufacturers (ABMA). A nonprofit trade organization committed to the advancement, safety, advocacy, and enhancement of the commercial, institutional, industrial, and electricity-generating boiler and combustion equipment industry that provides business connections, industry developments, and emerging trends and advocates for key issues and common interests.

American National Standards Institute (ANSI). A nonprofit organization that provides standards for a variety of manufacturing and building sectors in order to promote the voluntary consensus of standards and conformity to assessment systems.

American Society of Heating, Refrigerating and Air-Conditioning Engineers (ASHRAE). An international organization that advances the arts and sciences of heating, ventilation, air conditioning, and refrigeration by conducting research, writing standards, and providing continuing education, certifications, and various publications.

American Solar Energy Society, Inc. (ASES). A nonprofit association of solar professionals and advocates aiming to inspire an era of energy innovation and lead a transition to a sustainable energy economy through conferences, education, and publications.

Associated Builders & Contractors, Inc. (ABC). A national construction industry trade association, primarily in the industrial and commercial sectors, that provides government representation, legal advocacy, education, workforce development, information on best practices, and business development.

Carbon Monoxide Safety Association (COSA). An organization that provides training, publications, and other resources on carbon monoxide, combustion analysis, and related topics.

Cooling Technology Institute (CTI). An organization with the aim to educate, research, and increase industry interest in evaporative heat transfer systems (EHTS), cooling towers, and cooling technology. CTI also provides product certification and establishes standard testing and performance analysis for cooling towers and related equipment.

Cryogenic Society of America Inc. (CSA). A nonprofit technical society serving those interested in cryogenics and the art and science of achieving extremely low temperatures through conferences, workshops, and publications.

Heating, Air Conditioning and Refrigeration Distributors International (HARDI). An organization for distributors of HVACR equipment, parts, and supplies that provides education, conferences, and advocacy before state and federal government and regulatory bodies.

Copyright Goodheart-Willcox Co., Inc. 2017

HVAC Excellence. An organization that provides curriculum, programmatic accreditation, student outcome assessments, certification (professional, industry, government), and educator credentialing aimed at the HVACR industry.

Indoor Air Quality Association (IAQA). An organization that creates standards, funds research, provides advocacy to government agencies and NGOs, and educates through webinars, courses, videos, reporting, meetings, and publications on all issues pertaining to indoor air quality.

International Institute of Ammonia Refrigeration (IIAR). An organization that uses conferences, publications, and the sharing of knowledge and experience among manufacturers, designers, contractors, scientists, and trainers to advocate the safe, reliable, and efficient use of ammonia and other natural refrigerants in the refrigeration industry.

Mechanical Contractors Association of America (MCAA). An association of heating, air conditioning, refrigeration, plumbing, piping, and mechanical service firms that serves its members by providing educational material and programs to increase their level of technical and managerial expertise.

National Air Duct Cleaners Association (NADCA). A nonprofit association that uses standards, education, certification, marketing, and advocacy to promote the highest quality and ethical services regarding the inspection, cleaning, and restoration of HVAC systems.

National Air Filtration Association (NAFA). A nonprofit trade association representing and serving air filter and component manufacturers, sales and service companies, and HVAC and indoor air quality professionals through education, certification, publications, meetings, and technical seminars.

National Association of Home Builders (NAHB). An organization representing builders and remodelers of single-family and multifamily homes and individuals in closely related fields that provides education, produces the International Builders' Show, and advocates issues before government.

National Comfort Institute, Inc. (NCI). An organization that provides heating, air conditioning, plumbing, and electrical contractors with a focused offering of services and tools to help them improve their businesses, differentiate from others, grow, and become more profitable.

National Institute of Building Sciences (NIBS). A nonprofit, nongovernmental organization that supports advances in building science and technology to improve the built environment and brings together representatives of government, the professions, industry, labor and consumer interests, and regulatory agencies to identify and resolve problems and potential problems hampering the construction of safe, affordable housing.

North American Technician Excellence (NATE). A nonprofit program for HVACR technicians offering installation and service certification in a variety of specialty areas.

Partnership for Air-Conditioning, Heating, Refrigeration Accreditation (PAHRA). An independent, third-party organization in partnership between HVACR educators and the industry, PAHRA awards accreditation to programs that have met industry-validated standards in an effort to improve the quality of training offered and ensure competency levels.

Plumbing-Heating-Cooling Contractors Association (PHCC). An association working toward the advancement and education of the plumbing and HVACR industry for the health, safety, and comfort of society and the protection of the environment through technical training, business management practices, and legislative initiatives.

Refrigerating Engineers & Technicians Association (RETA). An organization dedicated to the professional development of industrial refrigeration operators and technicians through instructional material, certification programs, and conferences.

Refrigeration Service Engineers Society (RSES). An organization that provides comprehensive HVACR education and certification to advance proficiency of professional HVACR technicians and contractors.

Sheet Metal and Air Conditioning Contractors' National Association (SMACNA). A trade association promoting quality and excellence in the sheet metal and air-conditioning industry through voluntary standards and manuals and professional assistance in labor relations, legislation, research, safety, and business and project management.

Testing, Adjusting and Balancing Bureau (TABB). An HVAC organization providing specialty certification in indoor air quality, building commissioning, energy audit, and testing, adjusting, and balancing air duct systems.

Underwriters Laboratories Inc. (UL). An independent safety science company that promotes safe living and working environments by certifying, validating, and testing products, among other available services.

United Association (UA). An association of plumbers, fitters, welders, and service technicians representing local labor unions and providing training and certification.

Women in HVACR. An organization aimed to promote professional and personal growth of women in the HVACR industry.

Copyright Goodheart-Willcox Co., Inc. 2017

Glossary

100% shutoff. A function of a gas furnace ignition control module. When the flame rod does not detect a flame, the control module closes both the gas valve and the pilot valve. (41)

100% shutoff with continuous retry. A function of a gas furnace ignition control module. When the flame rod does not detect a flame, the control module closes both the gas valve and the pilot valve, but then it attempts to reignite the pilot after waiting for a certain period. (41)

above-atmospheric-pressure element. A type of control device that closes an electrical circuit on temperature rise. Used to control refrigeration temperature. (16)

above gap. In an oil burner, the vertical distance between the center of the nozzle and the electrode tips. (42)

abrasives. Sand-like particles, often attached to paper or cloth, used to clean, smooth, and polish surfaces. (7)

ABS (acrylonitrile-butadiene-styrene). A type of black plastic pipe appropriate for non-pressure applications such as drainage, waste, and vent piping. (8)

absolute temperature scale. A temperature scale that uses absolute zero (the temperature at which all molecular motion stops) as its starting point. Examples include Kelvin and Rankine scales. (4)

absorbant. In an absorption refrigeration system, a substance that soaks up, or absorbs, a refrigerant and lowers their combined pressure. An absorbant will absorb the refrigerant when cool and release it when heated. (34)

absorber. A surface designed to absorb visible light, infrared radiation, and ultraviolet radiation in a solar collector. The surface is painted black to maximize heat absorption. (44)

absorption. A phenomenon in which one substance (an absorbant) attracts and combines with another substance (typically a refrigerant) to form a uniform solution. This is commonly used in absorption refrigeration systems. (34)

a/c. Air conditioning. (27)

ac motor. An electric motor that runs on alternating current. (15)

access port. A small valve opening, usually with a Schrader valve core, that is used for checking pressure. While a service port is located on a service valve, an access port is standalone and does not have a service valve or manual way of controlling the flow of refrigerant through the system. (10)

access tool. A tool that allows a technician to create a point in an HVAC system's ductwork from which to inspect and clean. (30)

access valve lock. A device installed on the access valve of a service valve to prevent access to the refrigerant circuit by unauthorized individuals. Access valve locks can serve as a method of preventing refrigerant theft and huffing. Keys and tools for access should be made available only to system owners and HVACR service technicians. (32)

accumulator. A storage tank in the suction line that collects liquid refrigerant from the evaporator and suction line and prevents it from flowing further along the suction line before vaporizing. (6)

ACH_{50}. The number of air changes when indoor pressure is held at –50 Pa WRT outdoors during blower door testing. (30)

acid test kit. A kit used for testing refrigerant oil for acidity. (26)

active recovery. A refrigerant recovery method that uses a recovery machine to draw the refrigerant out of a system in either vapor or liquid form. Active recovery is quicker and more commonly used than passive recovery. (11)

active solar energy system. A solar energy system in which energy is absorbed into a collector and then transferred from the collector to be used or stored. (44)

actuator. A controlled device that changes an input energy (fluid, thermal, electrical, etc.) into mechanical motion. Solenoids, motors with gear assemblies, control valves, and other devices can act as an actuator. (16)

adaptive defrost. A defrost system that measures the time it takes to defrost a system and then uses that information to determine the interval before the next defrost cycle. (24)

adiabatic compression. The process of compressing a vapor without removing or adding heat from the vapor's surroundings. This results in a rapid increase in temperature of the vapor. (5)

adiabatic expansion. A process in which a substance undergoes a large pressure and temperature drop without gaining or losing heat (Btu), such as passing out of a metering device. (50)

adjustable air band. A metal band on an oil burner that is used to regulate the amount of air the burner fan can draw in and blow through the air tube. (42)

adjustable wrench. A wrench with gripping jaws that can be moved to fit fasteners of different sizes. (7)

adsorption. A liquid or solid attracting and holding another substance on its outer surface. Often a gas or vapor is held in a condensed layer through physical attraction or capillary action onto a liquid or solid. For example, a drier adsorbs moisture from refrigerant. (20)

affinity. The tendency of a substance to absorb another substance. This characteristic is used in determining refrigerant and absorbant pairings in absorption refrigeration systems. (34)

Copyright Goodheart-Willcox Co., Inc. 2017

air. An invisible, odorless, and tasteless mixture of gases that fills earth's atmosphere. (27)

air-bound. A condition in which a section or component of a hydronic system has trapped enough air to completely block water flow. (39)

air change. When the volume of air within a building is replaced with an equal volume of air. (30)

air changes per hour (ACH). A measure of how many times the entire volume of air within a defined space is replaced in one hour. (35)

air coil. A component in a heat pump system that absorbs heat from or releases heat to the surrounding air by circulating refrigerant. (40)

air conditioning (a/c). According to ASHRAE, "the process of treating air so as to control simultaneously its temperature, humidity, cleanliness, and distribution to meet the requirements of the conditioned space." (27)

air conditioning and refrigeration (ACR) tubing. A type of copper tubing, usually sealed with gaseous nitrogen, manufactured specifically for circulating refrigerant in air conditioning and refrigeration systems. (8)

air-cooled condenser. A condenser that uses the air movement of either natural convection or forced drafts to desuperheat, condense, and subcool a system's high-pressure refrigerant. (21)

air-cooling evaporator. An evaporator that is designed to cool the air in a conditioned space. (21)

air curtain. A steady stream of air created by a fan and used for separating two spaces from each other (often one conditioned space and one unconditioned space). (29)

air defrosting. The process of allowing the heat from the air in a conditioned space to melt the frost from evaporator coils. (21)

air filter. A device made of fibrous materials used to remove solid particulates, such as dust, pollen, mold, and bacteria, from circulating air. (28)

airflow friction chart. A graph of duct diameters, airflow rates, pressure drops from friction, and air velocities. (29)

air handler flowmeter. An instrument that measures the total airflow through a central HVAC system's air handler. (30)

air-purifying respirator. A passive respirator that removes dust and certain chemicals from the air. (2)

air scoop. A component designed to remove air from a hydronic system that uses deflectors to create turbulence in the flow of water causing air bubbles to merge and rise to the top of the chamber where they are vented. (39)

air separator. A component designed to remove air from a hydronic system that uses a wire mesh element to create a swirling motion in the circulating water causing the formation of tiny bubbles that merge and rise to the top of the chamber where they are vented. (39)

air-side economizer. A subsystem of an HVAC system used to regulate the introduction of cool outdoor air into a building for "free cooling" when outdoor climate conditions are optimal. Because the compressor does not run during economizer operation, far less electrical power is used. (33)

air-source heat pump (ASHP). A heat pump that uses the outside air as a heat source or a heat sink for producing the desired temperature in a conditioned space. (40)

air-to-air heat pump. A type of air-source heat pump that transfers heat between outside air and air inside a conditioned space using forced air as the heat distribution method. (40)

air-to-water heat pump. A type of air-source heat pump that transfers heat between outside air and air inside a conditioned space using a hydronic system as the heat distribution method. (40)

air tube. The passage through which air from an oil burner fan is blown into the combustion chamber of an oil-fired appliance. Also called *blast tube*. (42)

air vent. A float-operated valve that allows air to escape from a hydronic system while preventing water from leaking out and outside air from coming in. (39)

alkylbenzene (AB) lubricant. A refrigeration lubricant made from propylene and benzene that is used with CFCs, HCFCs, and blends that include CFCs and HCFCs. (9)

alternating current (ac). Electric current in which the direction of electron flow reverses or switches at regular intervals. In 60 Hz current, electrons reverse direction 120 times per second. (12)

ambient temperature. The temperature of the air surrounding an object. (4)

American Wire Gage (AWG). A standardized system of designating wire size based on a wire's diameter. For sizes 18 AWG to 1 AWG, the wire diameter increases as the AWG number decreases. For larger aught (/0) sizes, wire size increases as the numbers increase. (13)

ammeter. An instrument that measures current in amperes in a conductor. See also two types of ammeters: *in-line ammeter* and *clamp-on ammeter*. (17)

ampere (A). A unit used to measure the flow of electric current. One ampere equals the flow of one coulomb per second. May be referred to as *amps*. (12)

anhydrous ammonia. Ammonia that is free of water. (34)

annealing. A process of cooling a metal slowly from a high temperature to make the metal soft. (8)

annual fuel utilization efficiency (AFUE) rating. A measurement of furnace efficiency that compares a furnace's yearly or seasonal energy output to the energy input for the same time period. The higher the AFUE rating, the more efficient and cost effective a furnace is. (41)

anode. In electronics, a positively charged segment of a semiconductor consisting of a P-type material, such as on a diode. (14)

anti–short cycle control. A type of solid-state relay that will stop a compressor from cycling on before a preset time has passed after shutdown. (53)

Copyright Goodheart-Willcox Co., Inc. 2017

apparent power. A circuit's calculated power value ($P = I \times E$), which does not take into account the effects of inductive reactance or capacitive reactance. The value is calculated in volt-amperes (VA). (13)

aquastat. A hydronic system control that measures the temperature of the boiler water and turns the burner or heating element on and off as needed to maintain the preset temperature. (39)

asbestos. A naturally occurring mineral that forms fiber bundles. It was once used in building construction for its strength and fire resistance but is no longer used because it is now known to be a cancer-causing agent. (28)

ash content. The amount of noncombustible contaminants in fuel oil. (42)

ASHRAE Standard 34. An ASHRAE standard that names refrigerants and assigns safety classifications according to their flammability and toxicity. (2)

aspect ratio. The ratio of a duct's wide side to its narrow side. (29)

atmosphere. The air surrounding the earth. This term also refers to atmospheric pressure at sea level, which is 14.7 psia (0 psig). (5)

atmospheric balancing. The process of bringing up to atmospheric pressure a part of an HVACR system that has been evacuated before opening it for service. This is commonly done by bypassing a small amount of vapor refrigerant through the gauge manifold until pressure reads 0 psig. Also called *pressure equalizing* or *balancing pressures*. (55)

atmospheric dust spot efficiency. A method used to measure the ability of an air filter to remove atmospheric dust by evaluating the flow rates on both sides of the filter and the quantity of the material it captures. (28)

atmospheric gas burner. A type of gas burner that uses the siphoning action of gas flow through its orifice to induce airflow through the burner without the need for a blower. (41)

atom. The smallest part of an element. (12)

atomization. The breaking up of a liquid into tiny droplets. In oil-fired appliances, fuel oil is atomized so that the fuel oil will vaporize rapidly and ignite in the combustion chamber. (42)

atomizing humidifier. A humidifier that sprays small water droplets into the air by mechanically flinging water against a diffuser or by forcing it through a nozzle. (35)

automatic defrost system. A defrost system in which a timer or control mechanism operates a defrosting process during a refrigeration system's Off cycle. (24)

automatic expansion valve (AXV). A refrigerant metering device operated by low-side pressure that throttles liquid refrigerant in the liquid line down to a constant pressure in the evaporator. Also called a *pressure-controlled expansion valve* or a *constant pressure valve*. (20)

auxiliary heat. A supplementary heat source in a heat pump system that is turned on when the heat pump cannot extract enough heat from the outside air, when the heat pump is in defrost mode, or as emergency heat when the compressor cannot operate. Auxiliary heat is often supplied by electric heating elements. (40)

available static pressure (ASP). The amount of friction or resistance used to design the longest duct run. (29)

Avogadro's law. A gas law stating that equal volumes of gases at equal pressures and temperatures contain equal numbers of molecules, regardless of the mass of the gases. (5)

axial flow fan. A propeller fan in which air leaves the fan along the direction the axle is pointing. (29)

azeotrope. A refrigerant blend with fixed boiling and condensing points. An azeotropic blend responds to pressure and temperature changes like a single refrigerant. Also called *azeotropic blends* and *azeotropic refrigerants*. (9)

back seated. A service valve position used for normal system operation. A back-seated service valve closes off the service port so pressure readings cannot be performed. (10)

backflow preventer. A hydronic system check valve installed in the makeup water line that prevents water from flowing back into the water main. (39)

BACnet. A common protocol or set of rules for software and hardware communication that allows controllers from one company to work with those from another company in the field of building control. BACnet is short for *building automation control network*. (45)

bacteria. Simple, single cell microorganisms responsible for the transfer of many diseases. (28)

baffles. Surfaces in and along air ducts that direct airflow through an evaporator and throughout a conditioned space cabinet. (21)

balance point. The point at which a heat pump's total heat output equals the heat loss of the conditioned space. If the ratio of heat pump output to heat loss is less than the balance point, auxiliary heat is required to maintain set point temperature. (40)

balanced pressure steam trap. A steam trap filled with a mixture of water and mineral spirits. The mixture vaporizes and condenses just below the temperature of steam to trigger the steam trap's valve. (39)

balancing. Sizing the ducts and adjusting the dampers to ensure that each room regulated by a forced-air HVAC system receives the correct amount of air. (30)

balancing valve. A hydronic system valve that adjusts the water flow to each terminal unit or zone in a system so that heat is evenly distributed throughout the system. Also called *globe valve*. (39)

bar. A unit of pressure equal to 14.5 psia, which is approximately equal to one atmosphere. (5)

barometric damper. A damper that opens and closes in reaction to static pressure. (36)

basin heater. An electric heater in the sump of a cooling tower used to prevent ice formation when a cooling tower must operate in very low temperature weather. (33)

Copyright Goodheart-Willcox Co., Inc. 2017

below-atmospheric-pressure element. A type of control device that opens an electrical circuit on temperature rise. Used to control heating temperature. (16)

belt-driven compressor. An open-drive compressor that is connected to its drive motor by a belt and pulley system. (18)

bending spring. A tool used to make manually bending tubing easier and to reduce the danger of flattening the tubing while bending it. These may be placed on the outside or inside of a tube for bending. (8)

bid. An estimate of the scope and cost of a project. (1)

biflow bypass TXV. A type of biflow thermostatic expansion valve that has a built-in bypass passage regulated by a check valve, so that refrigerant in one direction is metered into a refrigerant coil and refrigerant in the other direction is merely bypassed through the check valve. (40)

biflow metering TXV. A type of biflow thermostatic expansion valve that meters refrigerant flowing in either direction. These TXVs require special installation considerations and are generally used in packaged heat pumps or systems in which the two refrigerant coils are in close proximity to each other. (40)

biflow thermostatic expansion valve. A type of thermostatic expansion valve (TXV) that allows refrigerant to flow in both directions in a heat pump system. There are two different types of biflow TXVs. See *biflow bypass TXV* and *biflow metering TXV*. (40)

bimetal coil. A thermostatic control made of a coil of two different metals that expands and contracts with changes in temperature. These can be used to energize and de-energize switches by attaching a set of contracts or a mercury switch to the movable end of the coil. (16)

bimetal device. A device made of two different metals bonded together and formed into a particular shape. Temperature changes cause the metals to contract or expand, which makes the device bend in the desired direction. (16)

bimetal disc. A thermostatic control that consists of a concave disc composed of two different metals. The disc is dished in one direction when it is cooled and snaps into a dished position in the opposite direction as it warms. By adding electrical contacts to the dished portion, it can act as an electrical switch. (16)

bimetal steam trap. A steam trap that contains two dissimilar metal strips bonded together. Temperature changes cause the bimetal strip to bend in one direction or the other to trigger the steam trap's valve. (39)

bimetal strip. A thermostatic control made of two different metals bonded together and formed into a strip that reacts to different heat conditions. With electrical contacts attached to an end, it can operate as a temperature-responsive electrical switch. (16)

bioaerosols. Airborne microorganisms, such as viruses, bacteria, fungi, protozoa, mold, rust, dust mites, mildew, and yeasts. (28)

biocide tablet. A tablet used to prevent the formation of microorganisms in locations containing water. A common application of a biocide tablet is in the condensate pan of an indoor unit of a ductless split system. (31)

blank-off plate. A sheet metal plate that supports an evaporator coil and blocks off areas of the plenum so that all the air passing through the plenum is directed through the evaporator coil. (32)

blast chiller. A commercial refrigeration system that cools a large amount of cooked hot food rapidly and uniformly without freezing it. (47)

blast freezer. A commercial refrigeration system that cools and freezes a large amount of cooked hot food rapidly and uniformly. Also called *shock freezer*. (47)

bleed resistor. A high value resistor that slowly discharges a capacitor when power to the capacitor's circuit is turned off. When electrical voltage is applied during the On cycle, a bleed resistor acts as a virtual open switch (as if it was not even present in the circuit). (17)

blowback. The ignition of a large amount of vaporized fuel oil that blows soot backward out of the combustion chamber. (42)

blowdown. Cooling tower water that is intentionally drained for the purpose of reducing certain mineral concentrations in the water. (33)

blower. A motor-driven fan used to circulate air. (38)

blower door testing. A procedure used to determine the airtightness of a building's envelope and to find air leaks in the building. This process uses a fan to create a pressure difference between outdoors and a building's interior and the measurement of airflow. (30)

blown fuse. An electrical fuse in which the conductive element inside the fuse has melted to open the circuit and prevent excess current flow. (16)

boiler. A closed vessel that heats water for circulation through a hydronic system. (39)

bolt. A headed, threaded fastener designed to screw together with a nut. (7)

bonding. The creation of a continuous electrical connection of all the metal parts in an electrical system. (13)

bonnet. The sheet metal chamber in a furnace where heat collects before being distributed. The bonnet contains a furnace's heat exchanger. (41)

booster compressor. The name commonly given to the first compressor in a cascade system. (18)

booster pump. A pump used to move fuel oil from the main storage tank to a fuel oil accumulator or reservoir tank nearer to the oil burner. (42)

bore. Cylinder diameter, such as in a reciprocating compressor and referenced when determining its volume of vapor for calculating the heat-removing capacity of the compressor. (51)

bottom freezer. A refrigerator-freezer in which the frozen food compartment is located below the fresh food compartment. (23)

Copyright Goodheart-Willcox Co., Inc. 2017

Bourdon tube. A thin-walled tube of elastic metal that is bent into a circular shape and used in pressure gauges. As pressure inside the gauge increases, the tube straightens and moves the needle on the gauge. (10)

box end wrench. A wrench with an enclosed gripping head that fits over a nut or bolt head. Also called a *box wrench*. (7)

Boyle's law. A gas law describing the inverse relationship between pressure and volume, provided temperature remains constant. If temperature remains constant, a pressure increase corresponds to a decrease of volume, or a pressure decrease corresponds to an increase of volume. (5)

brazing. A process of joining metal objects with a filler metal that has a melting point above 840°F (450°C). (8)

breaker strips. Plastic strips that connect a refrigerator cabinet's outer shell to the liner. (26)

brine solution. A water solution to which substances have been added to raise its boiling temperature and lower its freezing temperature. (21)

British thermal unit (Btu). A US Customary unit of heat that is equivalent to the quantity of heat required to raise the temperature of 1 lb of water by 1°F. (4)

brushes. Devices composed of conductive materials used in an electrical generator to transfer the flow of electricity from the slip rings to an external circuit. Also used in some dc motors. (12)

bubble point. The temperature at which a liquid zeotrope first begins to boil. See *dew point* and *temperature glide*. (9)

bubble solution. A specialized leak-detection solution or a solution of soap and water that indicates a leak in tubing by bubbling as leaking vapor escapes the system. (10)

building control system. A master system that controls all of the individual energy management systems or subsystems in a building or campus. (45)

building inspector. Someone who reviews construction work to ensure that the construction adheres to the applicable building codes. (1)

building-integrated solar module. A solar module that is used as part of a building's material, not added as a separate feature. (44)

building-related illness (BRI). A diagnosable illness caused by exposure to airborne agents. (28)

built-up terminals. Electrical terminals that are bolted to a hermetic compressor dome. Built-up terminals make it easier for technicians to install replacement terminals if needed. (15)

burnout. A condition in which the insulation of an electric motor deteriorates due to overheating. This may be due to internal problems, such as shorted windings, a locked rotor, or bearing seizure. The burnout of a motor in a hermetic compressor can cause contamination problems throughout the refrigerant circuit. (26)

burnout filter-drier. A filter-drier designed for use after a hermetic compressor burnout. (55)

bushing. A cylindrical sleeve inside a motor bearing that is used to reduce the friction and wear on the motor shaft as it rotates. (17)

butterfly damper. A damper used to control airflow in round ducts. It consists of a disk that rotates on an axis along the duct's diameter. (29)

bypass damper. A damper in a bypass duct between supply and return plenums in forced-air zoned systems. (36)

bypass humidifier. A humidifier that humidifies air that is bypassed from the supply air plenum into the return air plenum. (35)

bypass plug. In an oil-fired heating system, a small plug that is threaded into the internal bypass between a fuel unit's inlet and return ports. The plug forces excess fuel oil to flow out of the fuel unit's return port, preventing it from flowing back to the fuel unit's inlet. (42)

cad cell. A light-sensitive semiconductor used to visually detect an oil burner's flame and communicate with a heating system's primary control unit. With no light applied to a cad cell, it has a high electrical resistance. When light is applied to a cad cell, its electrical resistance drops low. (42)

callback. A service call to repair a problem that had been improperly repaired. (3)

cap screw. A threaded fastener designed to hold parts together without using a nut. (7)

capacitance (C). The ability to store electrical energy in an electrostatic field, measured in farads (F). (12)

capacitive reactance. The opposition to alternating current as a result of capacitance, measured in ohms (Ω). Capacitive reactance causes voltage to lag behind current in a circuit. (13)

capacitor. A device designed to store an electrical charge. In HVACR, small capacitors are used in control circuitry, while larger capacitors are used to help start motors and increase motor efficiency. (12)

capacitor-start, capacitor-run (CSCR) motor. A single-phase induction motor that has a start capacitor and a run capacitor wired in series with the start winding. The start capacitor is only in the circuit during starting, and the run capacitor is kept in the motor circuit during full speed operation to improve the motor's efficiency. (15)

capacitor-start, induction-run (CSIR) motor. A single-phase induction motor that has a start capacitor wired in series with the start winding. The start capacitor helps to create high starting torque and drops out as the motor approaches full speed running mode. (15)

capacity check. For a commercial ice machine, a procedure that involves running through an ice production cycle, measuring temperatures, timing the length of the cycle, weighing the ice batch produced, and calculating the total daily production potential so these values may be compared with manufacturer specifications. (53)

capillary action. The movement of a liquid substance between two solid substances due to the molecular

Copyright Goodheart-Willcox Co., Inc. 2017

adhesive forces between the solids overcoming the liquid's cohesive forces. (8)

capillary tube. A refrigerant metering device consisting of a length of seamless tubing with a small and precisely formed inside diameter. This tube acts as a constant throttle on the refrigerant flow and a constant pressure drop. (20)

carbon dioxide (CO_2). A gaseous, nontoxic combination of carbon and oxygen that results from combustion and respiration. (28)

carbon monoxide (CO). A deadly, odorless, colorless gas produced by incomplete combustion of fuel. (28)

carburizing flame. A torch flame that has too much fuel gas (often acetylene) and not enough oxygen. It usually generates a lot of smoke. (8)

career clusters. A career education organizational model, consisting of sixteen broad categories of employment fields, that was developed by states in conjunction with educators, employers, and professional organizations. (1)

cascade refrigeration system. A multistage refrigeration system that consists of two or more separate refrigeration subsystems with separate, isolated refrigerant circuits that work together to multiply cooling effect. (49)

Category I furnace. A negative-pressure, noncondensing furnace with a flue gas temperature of at least 140°F (60°C). Many furnaces used in residential heating are Category I furnaces. (41)

Category II furnace. A negative-pressure, condensing furnace that requires special vent materials. Category II furnaces are rarely used in residential heating. (41)

Category III furnace. A positive-pressure, noncondensing furnace that is typically vented with stainless steel piping. Category III furnaces are rarely used in residential heating. (41)

Category IV furnace. A positive-pressure, condensing furnace with a flue gas temperature that is less than 140°F (60°C). Category IV furnaces are high-efficiency furnaces with secondary heat exchangers. (41)

cathode. In electronics, a negatively charged segment of a semiconductor, consisting of an N-type material, such as on a diode. (14)

cavitation. The formation and implosion of bubbles in a flowing liquid that can cause internal damage to a system. This problem can occur in hydronic systems, primarily in circulating pumps. (39)

Celsius scale. A temperature scale used in the SI system. At sea level (atmospheric pressure of 14.7 psi), the boiling point of water is 100°C, and the freezing point of water is 0°C. (4)

center punch. A type of punch used to mark the center of a hole to be drilled or alignment points before dismantling a unit. (7)

central air-conditioning system. A centrally located system that is capable of providing heating, cooling, humidity control, ventilation, and air cleaning to multiple spaces. (32)

central humidifier. A humidifier that is incorporated into a central HVAC system through bypass ductwork or by being installed directly into the return or supply ductwork. (35)

centralized computer control. A building system controller that consists of one or more centralized computers that make control decisions based on operating data, programmed information, and data already stored in computer memory. (45)

centrifugal compressor. A compressor consisting of a rotor-operated impeller with radial blades and a volute casing. As the rotor spins, it flings refrigerant vapor outward, where it compresses against the volute casing. (18)

centrifugal force. A force that acts outward from the center of rotation. (18)

centrifugal switch. A normally closed electrical switching device mounted on the end of a motor shaft that disconnects the start windings from the motor circuit. The switch is opened and closed by centrifugal force, which increases as motor speed increases. (15)

certification. An industry-recognized credential that show a commitment to continued professional development. (1)

cfm_{25}. The airflow needed to obtain –25 Pa in the conditioned space when pressure testing a central HVAC system's ductwork. See *duct testing*. (30)

cfm_{50}. The measured airflow through a blower door fan when indoor pressure is held at –50 Pa WRT outdoors. This measurement is used to calculate the number of air changes per hour (ACH). See ACH_{50}. (30)

charge compensator tank. A storage vessel used by some heat pumps during the heating mode to store extra liquid refrigerant. (40)

charging. Adding refrigerant to a refrigeration system. The proper amount of refrigerant is typically specified in terms of its weight. (11)

charging cylinder. A small refrigerant cylinder, usually holding 5 lb of refrigerant or less, that is used for adding precise amounts of refrigerant, typically to domestic appliances. (11)

Charles' law. A gas law that describes the direct relationship between volume and temperature, provided the pressure remains constant. If pressure is held constant, the volume of a gas will increase if gas temperature rises, and the volume will decrease if temperature drops. (5)

check valve. A valve that permits fluid flow in only one direction. (22)

chest freezer. A freezer unit that has its door on the top of the unit. (23)

chiller. A cooling system that uses a loop of chilled water instead of forced air to provide cooling to a conditioned area. Sometimes called a *chilled water system*. *Chiller* may also sometimes specifically refer to the evaporator that chills the water. (33)

chlorofluorocarbons (CFCs). A group of refrigerants that are composed of chlorine, fluorine, and carbon. CFCs have

Copyright Goodheart-Willcox Co., Inc. 2017

high ODP and GWP ratings and are a major cause of ozone depletion. (9)

circuit breaker. An electrical protection device that automatically opens a circuit when the current exceeds a predetermined level. The increased magnetic effect of the current surge causes a spring-loaded switch to trip and break the circuit. A circuit break can be reset for continued use, while a blown fuse must be replaced. (16)

circuit breaker. An overcurrent electrical protection device that automatically opens a circuit when the current exceeds a predetermined level. The increased magnetic effect of the high current causes a spring-loaded switch to trip and break the circuit. (13)

circulating pump. A motor-driven pump that circulates heated water through a hydronic system. (39)

clamp-on ammeter. An ammeter that senses and measures only alternating current based on the magnetic field produced by an alternating current as it flows through a conductor. Unlike in-line ammeters, clamp-on ammeters clamp around a single conductor using movable jaws and do not require breaking the circuit for measurements. (17)

Class 2 circuit. A circuit supplied by a power source that has an output no greater than 30 V and 1000 VA. (13)

Class A refrigerants. An ASHRAE toxicity grouping of refrigerants that are not known to be toxic at concentrations equal to or below 400 parts per million (ppm). (9)

Class B refrigerants. An ASHRAE toxicity grouping of refrigerants that are known to be toxic at concentrations equal to or below 400 ppm. (9)

Clean Air Act (CAA). A US federal law that seeks to limit ozone depletion and air pollution. Section 608 provides guidelines for recycling refrigerants and restrictions on releasing refrigerants into the atmosphere. (9)

clean room. A room in which the environment is highly maintained. The temperature, humidity, and air quality are tightly controlled to limit contamination from airborne particles. (30)

cleaning solvent. A chemical compound used to remove oil, grease, and sludge from a surface. (7)

cleaning tool. Any handheld tool that is used to clean surfaces in the ductwork of an HVAC system. These include brushes, scrapers, and agitation and vacuum devices. (30)

clearance space. The volume of space between the top of the piston head and the bottom of the valve plate when the piston is at top-dead-center (TDC) in a reciprocating compressor. (18)

client. A workstation from which a building control system is managed. It sends instructions to and receives information from the servers. (45)

climate. In reference to outdoor conditions, the long-term weather trends for a region. In reference to indoor environments, the conditions that are normally maintained in a conditioned space. (27)

climate zone. An area of land that has a common temperature range and yearly precipitation level. (46)

closed circuit. An electrical circuit that is complete, providing a continuous path for electrons to follow. (12)

closed-loop control system. A type of control system in which feedback from a measurement of the control point is fed to the controller for comparison with the set point in order to modify the system's reaction to offset. A sensor produces a signal based on the conditions in the controlled area and transmits it to the controller, which modifies the output accordingly. (16)

closed-loop cooling tower. A cooling tower arrangement in which there are two isolated streams of water. One water circuit flows through the condenser and half of a heat exchanger. Another water circuit flows through the cooling tower and the other half of a heat exchanger. The condenser water rejects its heat into the cooling tower water circuit through a shared heat exchanger. (33)

closed-loop ground-source heat pump system. A type of ground-source heat pump system that continuously circulates the same water or refrigerant. (40)

CO_2 test. A test that measures the amount of carbon dioxide in a furnace's flue gas to determine if complete combustion is taking place. (42)

coefficient of performance (COP) (of air-conditioning systems). The ratio of energy output to energy input. In air-conditioning systems, this represents efficiency using a numerical value with no units. Refer to *seasonal average COP*. (46)

coefficient of performance (COP) (of refrigerants). The ratio of refrigeration effect to heat of compression. Refrigerants with a high coefficient of performance produce their refrigerating effect more efficiently. (9)

cogeneration. The use of energy byproducts from one process as the primary energy source for another process. (34)

cold. The absence of heat, the result of the removal of heat. (4)

cold chisel. A metal tool with a beveled edge at one end used for cutting through or carving into a solid material. (7)

cold thermal energy storage (CTES). An energy storage system that cools the storage medium at night and uses the cooled medium at peak electrical demand times of the day. (44)

combination gas valve. A single gas valve that contains multiple components (such as a manual shutoff valve, multiple solenoid valves, and a pressure regulator) to control gas pressure and gas supply to the burners of a gas-fired heating system. (41)

combination (slip-joint) pliers. Pliers that have a pivot point allowing the span of the jaws to be adjusted. These are for general use but should not be used on nuts, bolts, or fittings. (7)

combination thermostat. A thermostat that can operate a cooling system and a heating system. Also called *heating-cooling thermostat*. (36)

combined gas law. A gas law that states that the ratio among a gas's pressure, volume, and temperature remains

Copyright Goodheart-Willcox Co., Inc. 2017

constant. It combines the concepts of Boyle's law, Charles' law, and Gay-Lussac's law to show the interrelationship of gas pressure, volume, and temperature. Essentially, if a gas's temperature increases, its pressure or volume must increase proportionally. Also, if a gas's temperature decreases, its pressure or volume must also decrease. (5)

combined heat and power (CHP) plant. A power plant that produces electricity and useful steam. (34)

combined-flow. An evaporative condenser design in which there is a parallel flow of air and sprayed water over a condenser coil and a crossflow of air and water through the fill surface. (21)

combustion. A chemical process of rapid oxidation in which fuel and oxygen combine to produce heat and light. (41)

combustion air. A term referring to primary air and secondary air in a fuel-burning furnace (41)

combustion blower. A motor-driven fan that brings fresh air into a heating system's combustion chamber and expels combustion gases out through the heat exchanger and flue. (38)

combustion efficiency. A measure of a furnace's combustion quality, which is essentially its ability to achieve complete combustion. The following variables are measured to determine combustion efficiency: carbon dioxide (CO_2) content, oxygen (O_2) content, carbon monoxide (CO) content, fuel gas pressure, and stack temperature. (41)

combustion head. A plate with slots and holes that is designed to promote combustion in an oil-fired furnace by directing airflow into the combustion chamber. It is located at the end of an oil burner's air tube. (42)

comfort cooling system. A high-temperature range air-conditioning system that reduces the temperature and humidity in living and work spaces to a level comfortable for the occupants. (31)

Comfort-Health Index. The sensation associated with each temperature and the effects that each temperature have on human physiology and health. (27)

common terminal. One of three motor terminals on a single-phase hermetic compressor. The common terminal connects to a single line that joins one end of the start winding to one end of the run winding. (15)

common wire. See *grounded conductor*. (25)

commutator. A slip ring that is split in half by an insulating material with each end of the rotor attached to one half of the ring. In a dc generator, a commutator forces the current to flow in one direction, creating direct current. (12)

complete combustion. A form of combustion in which fuel is burned in the presence of excess oxygen to produce only heat, water, and carbon dioxide. (41)

compound gauge. An instrument for measuring pressures both above and below atmospheric pressure. Also called a *low-side gauge*. (10)

compound refrigeration system. A multistage system that has two or more compressors connected in series. (49)

compression chiller economizer. A system component in a centrifugal compressor chiller that improves system efficiency by subcooling high-side refrigerant. This is accomplished by metering high-side refrigerant so that some refrigerant flashes off into vapor and carries heat with it to the space between the first and second stages of a centrifugal compressor. (33)

compression rings. Piston rings that are designed to prevent pressurized refrigerant vapor from blowing past the piston and into the crankcase. (18)

compressor. A vapor pump that draws low-pressure refrigerant vapor from the evaporator and squeezes or compresses it to a high-temperature and high-pressure vapor and into the high side of the system. (6)

concentrating collector. A solar collector that uses either mirror-type concentrators or lens-type concentrators to reflect or bend the light/heat into a collector. (44)

condensate pump. A pump designed to move condensate from a system and into a drain. (21)

condenser. A component in a refrigeration system that receives hot, high-pressure refrigerant vapor from the compressor and cools the gaseous refrigerant until it condenses back to its liquid state. (6)

condenser capacity. The amount of heat a condenser can reject. (54)

condenser condensate line. A refrigerant line running from the outlet of the condenser to the inlet of the liquid receiver. (51)

condenser pressure. In an HVACR system, another name for *high-side pressure*, *discharge pressure*, and *head pressure*. (6)

condenser pressure regulator. An open on rise of inlet pressure (ORI) valve that opens when condenser pressure rises to a proper level and closes to block the flow of refrigerant from the condenser to the liquid receiver when condenser pressure drops too low. Commonly used for head pressure control in low ambient conditions. Also called *condenser holdback valve*, *holdback pressure valve*, *head pressure control valve*, and *limiter valve*. (22)

condenser splitting. A method of head pressure control in low ambient conditions in which a condenser is divided into two separate spaces: one space that is used as a condenser year-round (see *summer/winter condenser*) and the other space (see *summer condenser*) that is isolated and evacuated during low ambient conditions. (22)

condensing boiler. A boiler designed to condense combustion gases, which allows the circulating water to absorb additional latent heat from the combustion gases. Condensing boilers are over 90% efficient. (39)

condensing furnace. A high-efficiency furnace with an annual fuel utilization efficiency (AFUE) rating above 90%. Condensing furnaces use primary and secondary heat exchangers to extract enough heat from the combustion gases that they condense. (38)

conditioned space. A specific space in which an HVACR system regulates conditions, such as temperature, pressure, and humidity. (16)

Copyright Goodheart-Willcox Co., Inc. 2017

conduction. The flow of heat between substances by molecular vibration. (4)

conductor. A material or substance that allows electrons to flow easily. Electrical conductors are typically made of metal. (12)

confined space. An area that is closed off from a larger space and is large enough for a person to enter and perform work therein. (2)

connecting rod. A reciprocating compressor component that connects the piston to the crankshaft. (18)

console air conditioner. An entire air-conditioning system mounted in a stand-up cabinet. Also called *vertical packaged terminal air conditioners*. (31)

contact point bounce. An unwanted effect that occurs when electrical contacts close through high amounts of pressure and then rebound from each other due to the force. Contact bounce is undesirable because it can create secondary arcs and reduce contact life. (36)

contactor. A heavy-duty type of electromagnetic relay that can handle high-current loads, such as motors. Contactors can have a variety of contact configurations, from a single set of contacts to five or six sets of contacts. (16)

contacts. The physical parts in switches and switched devices that touch to complete an electrical circuit. Also called *electrical contacts*. (14)

continuity. The condition that exists when there is an unbroken path between two points in an electrical circuit. (17)

continuous defrost timer. A defrost system in which a defrost timer continuously counts down to the next defrost cycle, regardless of whether the compressor is running or not. Such a system performs regular defrosting, but some of these cycles may be unnecessary. (24)

continuous duty. According to the NEC, operation at a substantially constant load for an indefinitely long time. (15)

continuous load. As defined by the NEC, an electrical load where the maximum current is expected to continue for 3 hours or more. (43)

continuous-cycle absorption system. An absorption system operated by the application of a limited amount of heat. The circulated refrigerant is evaporated by heat and subsequently reabsorbed, displacing the need for a compressor. (34)

contractual agreement. A legal agreement that specifies the terms of service, including initial repair work and follow-up maintenance. (3)

control circuit. A circuit that uses electrical or electronic devices to control current flow, causing loads in the power circuit to be either energized or de-energized. (14)

controlled device. A device that operates based on signals from a controller. Solenoids, contactors, relays, and other actuators are examples of controlled devices. (16)

controller. A circuit that responds to changes in the signals from sensors and issues signals to controlled devices. (16)

control point. The present condition as measured by a sensor in a conditioned area. (16)

control system. A collection of interacting components that work together to regulate the operation of a system. The basic components of a control system include sensors, controllers, and controlled devices. (16)

convection. The transfer of heat from one place to another by means of a liquid or gas. (4)

conventional boiler. A noncondensing boiler that operates at water temperatures above 140°F (60°C). (39)

cooling anticipator. In a thermostat, a high-value resistor wired in parallel with the bimetal coil temperature-sensing device that conducts current during the cooling system's Off cycle to produce heat that will trip the cooling system on several minutes before the conditioned area reaches the cut-in temperature. (36)

cooling degree days. A day in which the average temperature for a day is above 65°F (18°C). Cooling degree days and heating degree days are used to determine the heating or cooling needed for a given region. (27)

cooling tower. A structure that rejects heat from the cooling water of an HVACR system using the evaporation of water. (33)

corrosion. A chemical degradation of metal. In a hydronic system, corrosion occurs when the water is too acidic or when certain gases are dissolved in the water. (39)

coulomb. The quantity of electricity transferred by an electric current of one ampere in one second. A coulomb is equal to approximately 6.24×10^{18} electrons. (12)

counter electromotive force (cemf). The voltage induced in a running motor by the rotor's magnetic field that has a polarity opposite of the voltage applied to the stator. (15)

counterflow. A design in which two fluids flow in opposite direction of each other. This design is often used in cooling towers, evaporative condensers, and water-cooled condensers. (21)

counterflow cooling tower. A cooling tower in which air and water travel in opposite directions. (33)

CPVC (chlorinated polyvinyl chloride). A type of light beige or tan plastic pipe that may be used for hot and cold water lines, drains, and some furnace venting applications. (8)

cracked open. A service valve position where the valve stem has been turned just enough to lift the valve off the back seat. Cracking open a valve prevents a sudden pressure increase from damaging the gauge. Cracking open a service valve also allows refrigerant to flow through the system while providing system access through the service port. (10)

cracking. The slight opening of a valve, which causes the valve needle or plunger to leave its seat, allowing only a slow flow of fluid. (7)

crankcase. The portion of the compressor housing that supports the crankshaft. (18)

crankcase heater. An electric device on or in a compressor that supplies heat to the crankcase in order to evaporate any refrigerant that may be trapped in the oil or prevent

Copyright Goodheart-Willcox Co., Inc. 2017

refrigerant inside the compressor from condensing into liquid. (18)

crankcase pressure regulator (CPR). A valve with an adjustable pressure setting that prevents crankcase pressure from exceeding a preset safe value. A CPR protects the compressor from higher than normal pressure vapor from the suction line. Also called *crankcase pressure-regulating valve*, *suction regulator valve*, *compressor low-side pressure control valve*, and *reverse metering, evaporator control valve*. (19)

crankshaft. A device used to change rotary (circular) motion into reciprocating (back and forth) motion and vice versa, as used in reciprocating compressors and automobile engines. (18)

crawl space. A type of building foundation that leaves just enough space between the floor and the ground to allow access. (37)

critical pressure. The minimum pressure required for a vapor to liquefy when it is at its critical temperature. (5)

critical temperature. The highest temperature at which a substance may be liquefied. A vapor above its critical temperature cannot be liquefied regardless of the pressure applied to it. (5)

critically charged. A refrigeration system with a refrigerant charge that is very precise and must remain at this level for effective, trouble-free operation. (53)

crossflow cooling tower. A cooling tower design in which air flows across the wet deck from side to side, while cooling water drops downward from above. Water and airflow *cross* each other's paths. (33)

cryogenic food freezing. A process of fast-freezing using liquid nitrogen or carbon dioxide to turn perishable fresh food into long-lasting frozen food. (47)

crystalline solar cell. A solar cell made from a thin slice of silicon known as a wafer. (44)

cumulative run-time defrost system. An efficient type of timed defrost system that determines the defrost intervals based on the amount of time the compressor runs. (24)

current. The flow of electrons through a conductor. (12)

current electricity. The type of electricity in which electrons are flowing through a conductor. To contrast, see *static electricity*. (12)

current-limiting fuse. A fuse that opens a circuit when the current exceeds its limit and the fuse heats up. Current-limiting fuses use temperature-sensitive resistors that close when they cool back down. (16)

current relay. A relay that is activated by a single-phase motor's high starting current running directly through the current relay's coil winding. Current relays are used to close and open a motor's start winding circuit to provide a motor with more starting torque. Also called *amperage relays*. (16)

customer relations. The interaction of a business with customers. Customer relations determine a customer's evaluation of a technician by the technician's job performance, appearance, and attitude. (3)

cut-in. The condition value at which a device begins operation. (16)

cut-out. The condition value at which a device ceases operation. (16)

C-value. See *thermal conductance*. (37)

cylinder head. A metal plate positioned on top of the valve plate and bolted to the cylinder block. The cylinder head holds the valve plate in position and seals the cylinder. (18)

cylinder unloading. The disabling or reducing of a reciprocating compressor's cylinder pumping ability. Cylinder unloading can be used to reduce the load during startup or to decrease system capacity in order to reduce refrigeration effect and lower power consumption. There are several different methods of cylinder unloading. (33)

Dalton's law. A law stating that the pressure of a mixture of gases is equal to the sum of the pressures of each gas. (5)

deaeration. The release of gases dissolved in a liquid. In a hydronic system, deaeration can reduce corrosion caused by gases dissolved in the water. (39)

deep vacuum. An evacuation method that uses a vacuum pump to pull a vacuum of 250 microns or less on a refrigeration system in order to dehydrate the system. (11)

defrost timer. An electric control device that starts and stops an HVACR system's defrost cycle. (21)

degree days. A measure used to determine the heating or cooling needed for a given region. (27)

dehumidifier. A device that decreases relative humidity by condensing moisture out of the air. It uses a cooling coil over which air is blown to condense moisture out of the air as it comes in contact with the cold surface. (35)

dehydration. The drying of food. (23)

demand defrost. A defrost control system that uses sensors to measure heat pump system variables (such as the temperatures of the discharge line, liquid line, indoor coil, and outdoor coil) in order to keep defrost cycle times to a minimum. (40)

demand defrost controller. A type of domestic refrigeration defrost control device that activates a defrost cycle based on the number of times the cabinet door is opened. (24)

demineralized water. Water that has been treated to remove minerals. (35)

density. A substance's mass per unit of volume, usually measured in lb/ft^3 or kg/m^3. (4)

desiccant. A substance that collects and holds moisture. In a dehumidification system, a hygroscopic substance that is used to adsorb moisture from the air. (35)

device pressure losses (DPL). Pressure losses in a duct system caused by devices other than ducts. (29)

dew point. The temperature below which water vapor in the air will start to condense, or at which the air has 100% relative humidity. (27)

dew point (of refrigerants). The temperature at which a vapor zeotrope first begins to condense. See *bubble point* and *temperature glide*. (9)

Copyright Goodheart-Willcox Co., Inc. 2017

diac. A solid-state device that allows current to flow in both directions. For current to flow through a diac, the applied voltage must reach or exceed the diac's breakover voltage. (14)

diagonal pliers. A type of pliers with angled jaws designed to make nearly flush cuts. Commonly used in electrical work. (7)

dielectric. An insulating material, such as paper, mica, or ceramic, used in a capacitor to separate conducting surfaces. (12)

dielectric strength. A measure of the amount of electrical current that a refrigeration lubricant can withstand without breaking down. Lubricants should have a minimum value of 25,000 volts. (9)

differential. The number of units (the difference) between a control system's cut-out value and cut-in value. (16)

differential adjustment. An adjustment built into a temperature or pressure control that increases or decreases the difference between the cut-in and cut-out values. This adjustment may change just the cut-in value, just the cut-out value, or both values equal amounts in opposite directions. (16)

diffuser. A nonadjustable fixture designed to evenly distribute the flow of air. (29)

digital charging scale. An electronic scale on which a refrigerant cylinder is placed to measure the amount of refrigerant entering or leaving the cylinder by tracking the cylinder's weight. (10)

diode. A solid-state device composed of a P-type material and an N-type material. Electrons will flow through a diode in only one direction, from the cathode to the anode. A diode functions as a check valve for electrons. (14)

DIP switches. *Dual in-line package* switches. Small switches grouped together in a single package. These are often used on circuit boards to manage system settings on a thermostat subbase or air handler control board. (36)

direct-acting reversing valve. A type of reversing valve that uses the direct action of the solenoid plunger to move the piston and sliding section of tubing inside the valve. (40)

direct current (dc). Electric current in which electrons flow in only one direction. Direct current is the type of current produced by batteries. (12)

direct digital control (DDC). A control system that utilizes multiple digital and analog inputs and outputs in the form of low-voltage or low-current signals connected to a microprocessor to operate an HVACR or automated building system. (16)

direct-drive compressor. An open-drive compressor that is driven by a motor connected directly to the compressor by a coupling between their shafts. (18)

direct-exchange (DX) heat pump. A type of ground-source heat pump that circulates refrigerant through tubing buried underground. (40)

direct expansion evaporator. An evaporator into which refrigerant is fed at the same rate that it evaporates. (33)

direct-fired. A term describing commercial absorption systems that are directly heated by a burner or other heating element. To contrast, see *indirect-fired*. (34)

direct radiant heat. An electric heating system in which the heating elements are mounted in a fixture that focuses the heat energy emitted by the elements on the objects to be warmed. (43)

direct return hydronic system. A type of two-pipe hydronic system with terminal units along branches of varying lengths. The terminal unit that is closest to the boiler has the shortest length of supply and return piping, and the terminal unit that is farthest away from the boiler has the longest length of supply and return piping. (39)

direct-spark ignition (DSI) system. A type of gas furnace ignition system that uses an electric spark to ignite the gas burners. (41)

direct-venting system. A two-pipe venting system for a furnace. One pipe is dedicated to venting flue gases, and the other pipe is dedicated to bringing in fresh air for combustion. (41)

dirty sock syndrome. A foul odor emanating from room registers that is caused by the growth of mold and bacteria on the indoor coil of a heat pump system. (40)

discharge line pressure switch. A control device used to sense discharge line pressure and opens on a rise in pressure to turn off the system and protect the compressor from dangerously high head pressure. (19)

discharge line thermostat. A control device used to sense discharge line temperature and opens on a rise in temperature to turn off the system and protect the compressor from dangerously high temperature. (19)

discharge pressure. In an HVACR system, another name for *high-side pressure*, *condenser pressure*, and *head pressure*. (6)

discharge service valve (DSV). A high-side service valve connected directly to a compressor at its outlet, considered a compressor service valve. During normal operation, hot, high-pressure refrigerant vapor flows through a DSV. (10)

dispensing freezer. A commercial refrigeration system that cools or fast-freezes and dispenses liquid mixes into soft serve or batch ice cream, shakes, or frozen beverages. (47)

dissolved air. Air trapped between molecules of circulating water in a hydronic system. Air scoops or air separators can be installed to reduce the amount of dissolved air in a system. (39)

distillation quality. The ability of a fuel to vaporize. Used to describe fuel oil in oil-fired heating systems. (42)

distributed system. In commercial refrigeration, a unit containing control devices and multiple compressors that circulate refrigerant through remote condensers and the evaporators in nearby conditioned spaces. (47)

distributor. A device that splits the flow of refrigerant into several paths. Often installed between a refrigerant metering device and evaporator and used to reduce pressure drop across a large evaporator. (20)

Copyright Goodheart-Willcox Co., Inc. 2017

DOP HEPAP Method. An efficiency test used mainly with high-efficiency air filters. (28)

doping. The addition of impurities to a pure semiconductor to change its conduction traits to make into a P-type or N-type material. (14)

double-cut file. A type of file that has teeth cut in two directions, used to remove metal quickly. (7)

double-effect absorption system. An absorption system with two generators: one primary and one secondary. The secondary, smaller, low-temperature generator can recover some of the waste heat from the primary generator or it can absorb solar heat or waste heat from an industrial process. (34)

double flare. A flare made with a double thickness of tubing metal, recommended only for larger size tubing with a diameter greater than 5/16". (8)

downflow furnace. A furnace design in which return air is taken in from the top and forced downward around the heat exchanger. It is commonly used in houses where the ductwork runs below the level of the furnace. Also called *counterflow furnace*. (38)

draft. In a combustion heating system, the movement of flue gas. Draft affects combustion as it allows for the supply of oxygen for burning. It also affects system efficiency regarding heat transfer in a heat exchanger. Faster draft reduces heat transfer, and slower draft increases heat transfer. (42)

draft gauge. A gauge used to measure the air pressure of the flue in a combustion heating system. (42)

draft regulator. A device installed in a flue pipe outlet that regulates the intake of indoor air into the flue to moderate or stabilize the flow of flue gas. Draft regulators are only used in certain types of flues (Class A and B) and can operate different ways: thermostatically, electrically, or barometrically. (41)

draft test. A test used to determine the rate of flue gas flow in a combustion heating system. Draft is typically low pressure, so it is measured in inches of water column (in. WC). A draft test can be measured in the flue or in the combustion chamber. See *flue draft test* and *overfire draft test*. (42)

drainback system. In an active liquid-based solar heating system, a system design that uses gravity to drain liquid from the solar collectors whenever the pump is off. (44)

drift. The loss of a cooling tower's water when it is broken into droplets small enough to be caught in a draft and carried away between the louvers. (33)

drift punch. A type of punch used to align holes in mating surfaces so that a fastener can be inserted. (7)

drip leg. A piping arrangement designed to trap and collect possible moisture or sediment that may flow with fuel gas. (41)

dry-base boiler. A boiler in which the area under the combustion chamber is dry and the water is contained in an area above the burner. (39)

dry-bulb temperature. The air temperature that does not take into account the effect of humidity in the air. (27)

dry ice. Carbon dioxide (CO_2) frozen solid. (48)

dry underfloor radiant heating system. A hydronic radiant heating system that consists of tubing attached to a wood floor or subfloor. (39)

dual-pressure regulator. A control valve with two pilot pressure regulators. (20)

dual-voltage motor. A motor that has its stator windings arranged in pairs so that it can be used with two different voltages. Three-phase motors are typically dual-voltage motors. Wire the stator windings in series for high voltage or in parallel for low voltage. (15)

duct. A channel or tube for conveying air in a heating and cooling system. (29)

duct blaster. An instrument used for duct testing that pressurizes the ductwork of a central HVAC system using a variable-speed fan and measures precise leakage with gauges. (30)

duct booster. A fan placed in series with a run of ductwork that operates to increase airflow when a duct is too small or too long or has too many elbows. (30)

ductboard. A compressed fiberglass panel that can be easily cut with a knife and formed into a square or rectangular shape for making ductwork or plenum. (29)

duct heater. An array of electric heating elements contained in a single unit that can be installed in a run of ductwork. (43)

ductless split system. A split air-conditioning system that does not use forced-air ductwork as a means of distributing cooled air. Like a traditional split system, a ductless split system has a condensing unit (compressor and condenser) outside a building that is connected by tubing to a cooling coil (evaporator) inside the building. Arrangements and number of indoor units vary by installation. (31)

duct sweeper. A cleaning tool used to release dust, mold, and mildew from the sides of ducts by rotating through ductwork. (30)

duct testing. Pressurizing a central HVAC system's ductwork and taking measurements to determine the amount of leakage and to locate duct leaks. (30)

dust. Small particles (1–200 microns) that become temporarily airborne from wind, a sudden earth disturbance, or mechanical work on a solid substance. (28)

eccentric. A shaft section that is larger and has a different center than the rest of the shaft. (18)

eccentric reducer fitting. A fitting used to join tubing of different sizes in a hot-water hydronic system. The fitting offsets the centerlines of the differently sized tubes to reduce the danger of air pockets forming. (39)

eddy currents. Small circular fluid patterns. In a conditioned space cabinet, these could be airflow patterns that disturb proper airflow. (21)

Copyright Goodheart-Willcox Co., Inc. 2017

effective latent heat. The amount of heat absorbed from a conditioned space cabinet and evaporator. (50)

effective length. The length of a duct run determined by adding the physical length of the ductwork to effective length values for each fitting in a duct run. (29)

effective temperature. The combined effect of dry-bulb temperature, wet-bulb temperature, and air movement that provides an equal sensation of warmth or cold (27)

ejector. A domestic ice maker component that pushes ice out of its mold and into a storage bin. (24)

elbow. A part of the duct system with a bend, often 90°. (29)

electrical circuit. A path for electrons to flow from a power source, through conductors, across a load, and back to the power source. (12)

electrical load. Any device that consumes electricity to perform work, such as a motor. (12)

electric baseboard heating unit. A convection heating unit that consists of an electric heating element in a casing that is mounted close to the floor on a wall, usually under a window. (43)

electric evaporator pressure regulator (EEPR). An EPR that uses a stepper motor to proportionally modulate its valve position in reaction to evaporator temperature. (22)

electric furnace. A furnace that consists of a central air handler with electric heating elements that are used to warm circulating air for a conditioned space. (43)

electric heat defrost. A method of defrost in which electric heating coils installed in an evaporator (or air-source heat pump's outdoor coil), around it, or within the refrigerant passages can be energized to melt ice and frost buildup. (21)

electric heating element. A conductor through which electric current is passed in order to produce heat. There are three basic types of electric heating elements: open wire, open ribbon, and tubular cased wire. (43)

electric interlock. A safety device that prevents operation of certain devices unless certain conditions are met. In a gas furnace, these are safety devices that prevent the ignition control module from opening the gas valve or turning on the indoor blower until all proper operating conditions are met. (41)

electricity. The flow of electrons from one atom to another. (12)

electric radiant heat. A system that uses electric heating elements to radiate heat that primarily warms objects instead of air. Electric radiant heat is generally classified as direct or indirect. (43)

electric resistance heating. The process of producing heat by conducting electricity across electric heating elements. (43)

electrode gap. In an oil burner, the distance between the ends of the electrode tips. (42)

electrodeposition. A process in which metallic particles are applied to another metal surface (conduction plate) using an electric current. This process bonds the surface material to the metal conduction plate. (44)

electromagnet. A magnet created by the application of electric current to a conductor coiled around a piece of soft iron. (12)

electromagnetic interference (EMI). Electrical noise that can disrupt electronics, such as the ignition control module on a furnace. (41)

electromagnetism. The magnetic effect caused by current flowing through a coil of wire. (12)

electromotive force (emf). The electrical force or electrical pressure created by a potential difference in atomic charges between two points. Also called *voltage*. (12)

electron. A negatively charged subatomic particle that orbits around the nucleus of an atom. (12)

electronic air cleaner. An air cleaning device that puts a static electrical charge on all particles in the air that pass through it. These particles are then attracted to collector plates with an opposite electrical charge. (28)

electronically commutated motor (ECM). A programmable, brushless dc motor with an electronic control module that controls voltage to the stator windings. ECMs use permanent magnets for their rotors. (15)

electronic expansion valve (EEV). An expansion valve metering device that uses an electric operator instead of the diaphragm power assembly of the TXV or the spring assembly of the AXV. (20)

electronic leak detection. A leak detection method that uses an electronic sensor capable of detecting very small leaks of halogenated refrigerant. (10)

embrittlement. A weakening of metal caused by long-term corrosion, which can lead to structural failure along seams, under rivets, and at tube ends. (39)

emissivity. The relative ability of a surface to allow light rays to pass through. (37)

end bell. The caps or plates at either end of a motor frame that house the bearings and support the rotor. (15)

endplay. The axial movement of a motor shaft as it rotates. (17)

end switch. An electrical switch often used as a limit switch that is connected to the end of a motor's shaft. In furnaces, an end switch may be used to detect combustion blower operation in a furnace. It is attached to the end of a damper motor shaft and closes when the damper has turned open a certain amount or angle. (41)

energy. The ability to effect a change in matter. (4)

energy audit. The process of evaluating a building's energy consumption and identifying methods of reducing energy cost and usage. (45)

energy auditor. Someone who inspects and tests a building and then prepares a report summarizing the current energy usage of the building and recommends ways to reduce energy usage. (1)

Copyright Goodheart-Willcox Co., Inc. 2017

energy conservation. Reducing the amount of energy used for a particular process. In HVACR, this includes replacing older systems with more efficient systems, correctly installing equipment, using proper service techniques, performing preventive maintenance, and upgrading existing systems and buildings to improve their efficiency. (46)

energy efficiency ratio (EER). A performance ratio that expresses an air conditioner's cooling capacity in Btu/hr for each watt of power consumed. (46)

energy recovery ventilator (ERV). A mechanical ventilation system that passes incoming fresh air and outgoing stale air through a series of parallel passages. As each air stream passes through the ERV, heat and humidity are exchanged, so the incoming air is closer to the temperature and humidity level of the outgoing air. (28)

Energy Star. A label given to buildings and appliances built according to a set of US Department of Energy (DOE) guidelines that promote increased energy efficiency. (46)

energy use intensity (EUI). The annual energy use per square foot of a commercial building in a certain climate zone. The EUI is calculated by dividing energy consumption in Btu by the square footage of conditioned space. (45)

enthalpy. The total amount of heat in a substance, calculated from an accepted reference temperature. For water calculations, the reference temperature is 32°F (0°C). For refrigerant calculations, the accepted reference temperature is –40°F (–40°C). On psychrometric charts, enthalpy is the total heat content in the air sample. (4)

enthalpy control. A control feature for air-side economizers that prevents or stops economizer operation if outdoor relative humidity is too high. Since indoor comfort relies not only on temperature but also on humidity, air's moisture content is taken into account for economizer operation. In this case, the word *enthalpy* refers to heat content. A certain number of Btus must be removed from air to condense moisture from the air. (33)

entrained air. Air in a hydronic system consisting of small air bubbles that travel along with the circulating water. Entrained air can be removed with air scoops and air separators. (39)

Environmental Impact Assessment (EIA). In the HVAC industry, this is a government review process that is often used to determine how a water-source heat pump may affect the quality of lake, stream, or pond fish life and habitat. (40)

Environmental Protection Agency (EPA). A US governmental agency that enforces the rules for working with refrigerants. All HVACR technicians must be certified by the EPA. (9)

enzymes. Specific types of proteins in food that trigger organic change. (23)

epoxy repair kit. A repair kit containing all the materials (sandpaper, surface cleaner, resin, and hardener) needed to patch a small hole in an aluminum evaporator. (26)

epoxy resin. A polymer substance used to repair small leaks in a refrigeration system. One-part epoxies require the use of heat to harden, while two-part epoxies come with a hardener that is mixed with the epoxy at room temperature. (11)

equalizer. A small external tube connecting the suction line at the evaporator outlet to a chamber inside the expansion valve, just below the diaphragm. This tube is used to balance pressure and compensate for any pressure drop across an evaporator in order to have the correct refrigerant flow through the valve. (20)

equivalent temperature. Temperature that represents how warm the combination of humidity and temperature feels to the occupant of a space. (27)

estimator. Someone who produces a project bid by calculating the cost of a project's equipment and material, time and labor needed, and cost of permits and inspections. (1)

eutectic plate. A thin, rectangular tank containing an evaporator surrounded by a solution that freezes at a desired temperature. Primarily used in truck or trailer refrigeration. (48)

eutectic salts. A combination of inorganic salts, water, and various elements formulated to freeze at a desired temperature. (44)

evacuated tube collector. An efficient type of solar collector that uses tubes containing fluid contained within slightly larger glass tubes. The glass tube is sealed and the air between the tubes is removed, creating a vacuum. (44)

evacuation. The removal of all vapors, gases, and fluids from a refrigeration system. The two main methods of evacuation are deep vacuum and triple evacuation. The process of *pulling a vacuum* (11)

evaporative condenser. A condenser that uses drafts from fans to aid in evaporating a water mist on and around the refrigerant-carrying tubes of the condenser to condense and subcool high-side refrigerant. (21)

evaporative cooling. The natural cooling effect of evaporation, used to cool a space or objects. (34)

evaporative humidifier. A humidifier that adds moisture to the air through evaporation. (35)

evaporator. A component in a refrigeration system where low-pressure refrigerant liquid vaporizes and absorbs heat. (6)

evaporator pressure regulator (EPR). A pressure-regulating valve that restricts the flow of refrigerant coming out of the evaporator to maintain a set minimum pressure in the evaporator while the refrigeration system is operating. It maintains a higher pressure than in the suction line, so its evaporator can operate at a higher temperature than other evaporators on a shared suction line. Also called *holdback valve*, *two-temperature valve*, and *constant pressure valve*. (22)

Copyright Goodheart-Willcox Co., Inc. 2017

evaporator pressure. In an HVACR system, another name for *low-side pressure* and *suction pressure*. (6)

excelsior. Fine curled wood shavings. An HVAC application of excelsior is as fibers formed into a tight lattice wall used in a greenhouse as part of an evaporative cooling system. (34)

excess air. Any secondary air that exceeds the amount of air necessary for complete combustion in a furnace. (41)

exfiltration. The natural leakage of inside air out of a building through doors, windows, and other construction joints. (28)

exosphere. The outermost layer of earth's atmosphere that extends outward from the edge of the thermosphere to a distance of 6,200 miles, as it gradually blends with space. (27)

expansion steam trap. A steam trap that has an internal material that expands and contracts with temperature change to trigger the steam trap's valve. (39)

expansion tank. In a hydronic system, a tank that helps maintain a stable system pressure by storing water as it expands and contracts due to temperature changes. Also called a *compression tank*. In a secondary loop refrigeration system of a commercial refrigeration system, a cylinder containing a pressure responsive bladder that is used to account for changes in secondary loop pressure. (39)

expendable refrigerant. A refrigerant that typically has a very low boiling temperature and is used only once in a system for purposes such as freezing food. (9)

expendable refrigeration system. A refrigeration system in which the refrigerant is discarded or released into the atmosphere after it has evaporated. Also called an *open-cycle refrigeration system* or *chemical refrigeration system*. (9)

external static pressure (ESP). The pressure difference between a blower's inlet and outlet. (29)

Fahrenheit scale. A temperature scale used in the US Customary system. At sea level (atmospheric pressure of 14.7 psi), the boiling point of water is 212°F and the freezing point of water is 32°F. (4)

fan convector. A type of terminal unit in a hydronic system that uses a fan to blow air across the surface of the heat exchanger tubing, which increases the rate of heat transfer and improves convection. (39)

fan heater. A type of convection heater that uses electric heating elements to produce warm air, which is distributed to a conditioned space by a fan. (43)

farad (F). A unit used to measure a capacitor's capacitance. A farad is equal to an electrical charge of one coulomb with the potential to discharge one volt of electrical pressure. Most capacitors used in HVACR systems are rated in microfarads. (12)

fast-acting fuse. A fuse that blows immediately after the maximum rating of the fuse is exceeded. (16)

feedback. The information detected by a sensor in a conditioned area that is sent to the controller to determine what action needs to be taken. (16)

field pole. An electromagnet in an ac motor's stator whose polarity changes as the flow of current alternates in the field windings. (15)

field winding. In an electric motor, the wires wrapped around the field poles of the stator that create a magnetic field when current flows through them. (15)

field-erected air-conditioning system. A system in which all components are purchased individually and assembled at the spot where the system is to be used. (32)

file. A hand tool with cutting ridges, or teeth, used to clean and shape metal surfaces. (7)

fill. In a cooling tower's wet decks, specially designed sheets or structures with different ridges, corrugations, or designs used to increase air-water contact with the lowest possible air pressure drop. (33)

filter-drier. A device used to remove moisture, dirt, metal, and other debris from circulating refrigerant. (6)

fin-and-tube evaporator. An evaporator that features metal fins of various styles and types connected to the evaporator tubing. (21)

fin comb. A tool used to straighten the bent fins of evaporators, condensers, and other heat exchangers with fins. Also called a *fin straightener*. (55)

fixed filter humidifier. A humidifier with a pad that consists of numerous layers of a tight metallic mesh wetted by water metered through a solenoid valve. (35)

flame failure response time (FFRT). The amount of time for an oil furnace's primary control unit to sense that there is no flame when the thermostat is calling for heat. (42)

flame rectification. The process of using a pilot flame or gas burner flame to change a small electric current from alternating current to direct current. Ignition control modules rely on flame rectification to verify the presence of a flame in a furnace. (41)

flame retention oil burner. An oil burner with a combustion head that directs combustion air in a manner that retains its flame, making it more compact and more efficient. (42)

flame rollout. A phenomenon in which the flame in a furnace spills backward out of the burner. (41)

flammability. A substance's capacity to ignite. Refrigerants have a flammability rating of 1, 2, 2L, or 3 under ASHRAE Standard 34. (9)

flammability limits. The range of fuel concentrations in a mixture of fuel and air within which the fuel will burn when an ignition source is present. (41)

flare. An enlargement at the end of a piece of tubing, usually made at about a 45° angle, by which the tubing is connected to a threaded fitting. (8)

flare nut wrench. A wrench with a small opening in the gripping head, similar to an open end wrench, but capable of providing maximum surface area contact with flare nuts. (7)

flashback arrestor. A type of check valve with a built-in flame arrestor that is installed in the supply hose of a

Copyright Goodheart-Willcox Co., Inc. 2017

torch to prevent the flame from traveling inside the hose to the supply tank. (8)

flash gas. The instantaneous evaporation of liquid refrigerant. In an evaporator, flash gas occurs from the pressure drop between the high side and low side of the system. This pressure drop allows flash gas to absorb heat, which helps to cool the rest of the liquid refrigerant. In a liquid line, the unintended evaporation of high-pressure liquid refrigerant, which reduces system efficiency and can damage an expansion valve. (6)

flash point. The temperature at which the vapors of a refrigeration lubricant ignite. A high flash point means that a lubricant is thermally stable. (9)

flat-plate collector. A solar energy collector that uses a series of flat-plates with an insulated surface to collect solar energy. (44)

floc point. The highest temperature at which wax separation occurs in a refrigeration lubricant. A low floc point reduces problems associated with wax separation. (9)

flooded system. An HVACR system that uses a low-side float (LSF) or high-side float (HSF) to maintain a certain level of liquid refrigerant in the evaporator. (20)

flow check piston. A metering device used in heat pump systems that meters refrigerant passing through it in one direction and moves its piston to allow refrigerant to pass freely in the other direction. (40)

flow-control valve. A hydronic system valve used to ensure that water flows in the proper direction through the system. (39)

flow hood. An instrument used to direct and calculate all of the airflow through a duct at a given supply or return. (30)

flow switch. An electrical switch that is opened or closed based on flow of a fluid. In a hydronic system, a flow switch may be used to shut down the system or bypass parts of it when there is inadequate water flow. (39)

flue draft test. A draft test used to measure only the draft in the flue pipe of a combustion heating system. See also *overfire draft test*. (42)

fluorescent dye leak detection. A leak detection method that uses a fluorescent dye, which is circulated through the system. An ultraviolet light is required to identify the location of a leak. (10)

flux. A substance applied to surfaces to be joined by brazing or soldering to keep oxides from forming and to aid in the flow of filler metal. (8)

foot-pound (ft-lb). A unit of work. A foot-pound is the amount of work done in lifting 1 lb a distance of 1′. (4)

force (F). Energy applied to matter that, unless counteracted by opposing forces, causes a change in the matter's velocity. (4)

forced-air condenser. A condenser that uses a fan to blow air over condenser tubes to remove heat from refrigerant. (6)

forced-air heating system. A heating system that uses a blower to circulate heated air through ducts to a conditioned space. The blower also draws cool air from the conditioned space and into the air handler. (38)

forced draft. The exhaust from a fan. (29)

forced-draft cooling tower. A cooling tower that uses a fan placed at the air inlet to draw air in through itself and blow it through and out of the tower. (33)

forced-draft evaporator. An evaporator that uses a motor-driven fan to circulate air across the evaporator tubing. (6)

forward bias. A diode setup that allows current to flow through the diode. The negative terminal of a dc power supply is connected to the cathode, and the positive terminal is connected to the anode. (14)

fractional efficiency test. An advanced technique used to measure air filter performance in which extremely accurate equipment is used to count the number of particles trapped by the air filter. (28)

fractionation. Separation of a zeotropic blend into its individual refrigerants during phase change. (9)

free air. Bubbles of air that collect at the high points in a hydronic system. Free air is released through air vents. (39)

free air displacement. Speed at which vapor is pumped through a vacuum pump, measured in cfm (cubic feet per minute). Also called *volume capacity*. (10)

free cooling. The use of an air-side economizer to draw in cool outdoor air to reduce indoor air temperature. (36)

freezant. A type of refrigerant, such as liquid nitrogen, used to rapidly freeze foods. (9)

freezer burn. The dehydration of frozen food, which results in a change in color, flavor, and texture of the food. (23)

freezestat. A safety control device used in forced-air zoned systems that functions as a open-on-drop thermostat set to open if air temperature right above the evaporator coil drops to around 33°F. This stops the compressor to prevent the formation of ice on an evaporator, which can occur when airflow is reduced (such as when a zone damper closes and a bypass damper does not compensate adequately). (36)

friction loss. The air pressure drop resulting from air contacting the inside surface of a duct. (29)

friction rate. The friction loss along the total effective length of ductwork that results in a pressure drop equal to available static pressure. (29)

front gap. In an oil burner, the horizontal distance between the center of the front tip of the nozzle and the tips of the electrodes. (42)

front seated. A service valve position used to block the flow of refrigerant through the valve. A front-seated valve allows a technician to use the service port and to redistribute or isolate refrigerant in the system. (10)

frost back. The accumulation of condensation on a suction line due to the difference in the line temperature and ambient temperature. (20)

Copyright Goodheart-Willcox Co., Inc. 2017

fuel line filter. A filter used to remove impurities from fuel oil before the fuel oil reaches the oil burner for combustion. (42)

fuel oil. A refined form of petroleum used to produce heat in an oil-fired heating system. The most commonly used fuel oil in residential and light commercial heating is No. 2 fuel oil. (42)

fuel unit. An oil burner subsystem consisting of a motor-driven pump that performs three tasks. It moves fuel oil from the storage tank to the oil burner, acts as a secondary filter after the fuel line filter, and regulates the pressure of the fuel oil pumped to the oil burner. (42)

full-load amperage (FLA). The electrical current level at which a motor's full-load torque and horsepower are reached. (15)

fully halogenated. A term describing refrigerant that contains halogens, such as chlorine and fluorine, in the place of hydrogen. CFCs are fully halogenated compounds. (9)

fumes. Small, solid, airborne particulates formed by the condensation and solidification of gaseous materials. (28)

fuse. An overcurrent electrical protection device containing a metal conductor in series with an electrical circuit that is designed to conduct a certain amount of current before it melts to open the circuit. (13)

fusible link. A heat-sensitive device that opens an electric circuit when the ambient temperature rises too high. A fusible link must be replaced once it has been opened. (43)

fusible plug. A relief valve that consists of a threaded plug with a metal core that melts at a much lower temperature than the outer shell. These are commonly used on refrigerant cylinders to prevent bursting due to excessive heat. (10)

gable fan. A fan installed at a louvered gable opening of a vented attic and used for attic ventilation. (29)

galvanic action. The corrosion of metal that occurs when two different metals are in contact in moist air. (52)

gas. Any physical substance with no definite shape or volume, which expands to fill its container. (4)

gas burner. A device that mixes primary air and fuel gas from a manifold to burn a flame aimed into a furnace's heat exchanger. (41)

gasket. A thin seal installed between the mating surfaces of a case or housing to prevent leaks at the joint, such as between a compressor and its service valves. In refrigeration cabinet construction, a flexible rubber material pressed into a channel on the door to form an airtight seal between the door and cabinet when the door is closed. (7)

gas manifold. A pipe with multiple sockets that hold spuds that direct fuel gas into burners in a gas-fire appliance. (41)

gateway. In BACnet, a device similar to a router that is connected between native and nonnative devices that "opens" a message, translates it, packages it, and sends it on. (45)

gauge manifold. An instrument consisting of a compound gauge, a high-pressure gauge, and multiple ports and hand valves. Used to check pressures and perform service operations, such as system evacuation, refrigerant recovery, and refrigerant charging. (10)

Gay-Lussac's law. A gas law that states that at constant volume, the absolute pressure of a given quantity of a gas varies directly with its absolute temperature. In other words, when a gas is held at a constant volume, its pressure and temperature will rise together or will fall together. (5)

global warming potential (GWP). A numeric value assigned to refrigerants to express the risk each refrigerant poses to warming the environment compared to carbon dioxide, which has a GWP of 1. (9)

Globally Harmonized System (GHS). A system for standardizing and harmonizing the classification and labeling of all chemicals. (2)

glow coil. In gas-fired heating systems, a high-resistance heating element used in a hot-surface ignition (HSI) system that illuminates when conducting electric current and ignites the burner flame. Also called a *hot-surface igniter*. A glow coil is just one of several different types of ignition methods of gas-fired appliances. (41)

gravitational circulation. A natural phenomenon of air movement that occurs because cold air is denser than warm air and sinks below warmer, less dense air. (21)

gravity flow basin. A water-filled container on top of a cooling tower that has precision holes through which accumulated water flows onto wet decks. (33)

gravity heating system. A heating system that relies on natural convection to distribute heated air. Heated air rises and cool air falls. (38)

grille. A nonadjustable fixture used to cover return duct inlets. (29)

ground. The earth to which an electrical system connects. (13)

ground coil. An underground length of tubing through which refrigerant is circulated in a direct-exchange ground-source heat pump system. (40)

ground fault. A condition in which a device or ungrounded metal part becomes electrically hot or live. This is a dangerous condition in which a short circuit to ground that is waiting to happen. This may also be called a *short to ground*. (13)

ground fault circuit interrupter (GFCI). An electrical protection device that detects imbalances between ungrounded and grounded conductors of a circuit. A GFCI opens the electrical circuit when equipment connected to it is defective, misused, or improperly grounded. (13)

grounded conductor. The neutral wires connected to a grounded transformer to create a return path in an electrical circuit. (13)

grounding. The act of connecting something to the earth or the equipment that connects something to the earth. (13)

Copyright Goodheart-Willcox Co., Inc. 2017

ground loop. A length of underground tubing that circulates water or a water-based solution running to and from the water coil (a heat pump's water-to-refrigerant heat exchanger). The ground loop absorbs or expels heat at two locations: in the water coil and in its tubing underground. (40)

ground-source heat pump (GSHP). A heat pump that uses the earth as a heat source or a heat sink for producing the desired temperature in a conditioned space. A ground-source heat pump circulates water or refrigerant through tubing placed underground or underwater. (40)

gun burner. An oil burner that uses a motor to operate a fan and a pump in order to deliver a pressurized mixture of air and fuel oil to the flame in the combustion chamber. (42)

hacksaw. A type of hand saw used for cutting metals and tubing. (7)

halide torch leak detection. A leak detection method that uses a hose to siphon air through a torch burning near a copper plate. Any leaking refrigerant sucked up by the hose turns the torch flame green. (10)

hammer. A hand tool used for pounding or striking that consists of a hard head attached to a handle. (7)

hard lockout. A system shutdown after a furnace fails to light during its trial for ignition (TFI) period. A hard lockout requires a service call to reset or interrupt power to the ignition control module. (41)

hard start kit. A kit sized to a specific voltage that is used to start a stuck single-phase compressor motor. The kit consists of a capacitor, a PTC or potential relay, and wires. (17)

hazard. A potential for harm. According to OSHA, hazard is "associated with a condition or activity that, if left uncontrolled, can result in an injury or illness." (2)

Hazard Communication Standard (HCS). An OSHA standard that requires chemical manufacturers, distributors, or importers to provide safety data sheets (SDS) to communicate the hazards of hazardous chemical products. (2)

hazard pictogram. A symbol used to convey health, physical, and environmental hazard information. (2)

hazard statement. A standard phrase assigned to a hazard class and category that describes the nature of the hazard (2)

head pressure. In an HVACR system, another name for *high-side pressure*, *condenser pressure*, and *discharge pressure*. (6)

head pressure control. Methods of controlling head pressure under varying conditions, primarily low ambient conditions. See *condenser pressure regulator*, *receiver pressure regulator*, *low-ambient control*, and other head pressure control topics. (21)

heat. A form of energy that, when applied to a substance, results in the increased motion of atoms. (4)

heat anticipator. A small resistance coil used by a thermostat to produce enough heat to keep the thermostat warmer than the ambient temperature so the thermostat will cycle off the heat before reaching the cut-out temperature and avoid system overshoot. (36)

heat exchanger. Any device in which heat is exchanged between two mediums. A wide variety of heat exchangers are used in HVACR systems. Common examples include evaporators, condensers, and suction-line, liquid-line heat exchangers. Heating systems have much different heat exchangers that are based on their method of heat production. (20)

heat exchanger (in a capillary tube system). The area where the capillary tube and the suction line are in contact. The capillary tube transfers some of its heat to the cooler suction line through conduction, which provides superheating in the suction line and subcooling in the liquid line and improves system efficiency. (20)

heat exchanger (in heating systems). A sealed chamber where the heat of combustion is transferred to the air or water used to heat a conditioned space. The heat exchanger also carries combustion gases to a flue or vent where they are released outdoors. (38)

heat gain. The increase of heat within a given space as a result of direct heating by solar radiation and of heat radiated by other sources, such as lights, equipment, or people. (37)

heat gain HTM. A value used in determining a building's heat gain. This value is calculated by subtracting the indoor design temperature (IDT) from the outdoor design temperature (ODT) and adjusting for sun exposure, heat storage, and other factors. See *heat transfer multiplier (HTM)*. (37)

heating degree days. A day in which the average temperature for a day is below 65°F (18°C). Cooling degree days and heating degree days are used to determine the heating or cooling needed for a given region (27)

heating seasonal performance factor (HSPF). A measurement of how efficiently a heat pump works throughout the heating season. (46)

heating-cooling thermostat. A thermostat that can operate a cooling system and a heating system. Also called a *combination thermostat*. (36)

heat insulator. A substance that conducts heat poorly. (4)

heat lag. The amount of time it takes for heat to travel through a substance that is heated on one side. (37)

heat leakage. The heat that is conducted through the walls, ceilings, and floors when there is a temperature difference between spaces. (37)

heat leakage load. When determining the total heat load, the amount of heat from the surrounding air that is transferred through the materials of the cabinet into the conditioned space. (50)

heat load. The amount of heat that must be added or removed from a space in order to maintain the desired temperature in that space. (37)

heat loss. The transfer of heat from inside to outside by means of conduction, convection, and radiation through all surfaces of a house. (37)

Copyright Goodheart-Willcox Co., Inc. 2017

heat loss HTM. A value used in determining a building's heat loss. This value is calculated by subtracting the outdoor design temperature (ODT) from the indoor design temperature (IDT). See *heat transfer multiplier (HTM)*. (37)

heat of compression. Heat energy added to a vapor when it is compressed. (5)

heat pump. A compression refrigeration system that can reverse the circulating flow of refrigerant in order to add or remove heat from a conditioned space. Basic air-to-air heat pumps are similar to comfort cooling split air-conditioning systems, but they can reverse the flow of refrigerant in order to provide heating. See also *air-source heat pump (ASHP)*, *air-to-air heat pump*, *air-to-water heat pump*, *ground-source heat pump (GSHP)*, and *water-source heat pump (WSHP)*. (40)

heat recovery system. A collection of devices used to reclaim waste heat for a building's reuse as climate control heating or water heating. Also called *heat reclaim system* or *heat reclamation system*. (21)

heat recovery ventilator (HRV). A heat exchanger that passes incoming fresh air and outgoing stale air through a series of parallel passages. As each air stream passes through the HRV, heat is exchanged, so the incoming air is closer to the temperature of the outgoing air. (28)

heat sink. A surface that absorbs radiant heat that strikes the surface. (27)

heat transfer multiplier (HTM). A value used in determining a building's heat loss or heat gain that is calculated by multiplying a building component's U-value by a temperature difference. These values are often available on charts. (37)

heat transfer rate. The amount of heat conducted through a structure for a given unit of time. (37)

hermetic compressor. A compressor that includes an integrated drive motor in a sealed unit. (18)

hex key wrench. Hexagonal bar or shaft designed to fit the hexagonal indents in the heads of screws. Also called an *Allen wrench*. (7)

highboy furnace. A furnace that is taller than it is wide or long. (38)

high-efficiency gas furnace. A furnace that has a secondary heat exchanger capable of extracting enough heat from flue gases to cause them to condense. This type of furnace has an AFUE rating between 90% and 97%. Also called a *condensing furnace*. (41)

high head pressure. Excessive pressure at the compressor's outlet, which is frequently caused by a dirty condenser, though can also result from various other causes. (26)

high-limit control. A control device in a boiler's combustion chamber or warm-water outlet that automatically shuts off the fuel supply if the water temperature or pressure gets too high. (39)

high-limit switch. A safety device placed in the bonnet of a furnace, near the heat exchanger, that opens its electrical switch in response to high temperature in order to protect the heat exchanger from overheating by opening the gas valve circuit and stopping the flow of fuel gas to the burners. One example of a high-limit switch is a bimetallic snap disc. A high-limit switch may sometimes be called a *safety stat*. (41)

high-pressure chiller. A compression chiller that operates under high pressures and is used primarily for commercial and industrial process cooling. (33)

high-pressure gauge. An instrument capable of measuring high pressure on a single continuous scale. Also called a *high-side gauge*. (10)

high-pressure motor control. A safety control device used to turn off the compressor before dangerously high pressure is reached. (16)

high side. The parts of a refrigeration system subject to high pressure, such as the compressor, condenser, liquid receiver, and liquid line. (6)

high-side charging. A method of injecting liquid refrigerant into the high side of a refrigeration system through a high-side service valve, often the liquid receiver service valve (LRSV). (52)

high-side float (HSF). A float-type metering device that regulates refrigerant flow into the evaporator based on the volume of liquid refrigerant in the high-side receiver. (20)

high-side pressure. The pressure value on the high side of an HVACR system. High-side pressure can also be called *discharge pressure*, *condenser pressure*, *head pressure*, and several other names, depending on circumstances. (6)

high-stage compressor. In a compound refrigeration system, a compressor that draws in refrigerant from the low-stage compressor, pumps refrigerant to a higher temperature and higher pressure, and discharges into the condenser. (49)

hole flow. The principle that explains how electrons flow through a semiconductor giving the appearance of holes moving in the opposite direction. (14)

horizontal furnace. A furnace that is designed to be placed on its side. Return air flows in a horizontal path through one end of the furnace, across the heat exchanger, and out through the opposite end of the furnace. (38)

horsepower (hp). A US Customary unit of mechanical power equal to 550 ft-lb of work per second. (4)

hot and cold merchandiser. A commercial unit that holds hot food in a heated section and cold food in a refrigerated section. (47)

hot-gas bypass valve. A valve that regulates certain amounts of hot refrigerant vapor from the discharge line to enter the low-side of the system for the sake of capacity control. (22)

hot-gas defrost. A defrost system in which the evaporator is defrosted by hot-gas refrigerant vapor pumped directly from the compressor discharge line into the evaporator tubing. (21)

hot-gas defrost valve. A valve regulating a refrigerant line between the compressor discharge line and the

Copyright Goodheart-Willcox Co., Inc. 2017

evaporator that opens to allow hot gas to circulate through the evaporator to defrost it. (22)

hot pull down. The process of a refrigeration system that is starting or restarting with its conditioned space temperature being pulled down to normal operating temperature from a much higher starting temperature (often ambient temperature). (19)

hot-surface igniter. In gas-fired heating systems, a high-resistance heating element used in a hot-surface ignition (HSI) system that illuminates when conducting electric current and ignites the burner flame. Also called a *glow coil*. A hot-surface igniter is just one of several different types of ignition methods of gas-fired appliances. (41)

hot-surface ignition (HSI) system. A type of gas furnace ignition system in which a silicon carbide igniter, also called a glow coil, is used to light the gas burners, eliminating the need for a standing or intermittent pilot light. (41)

hot water reclaim tank. A cylinder filled with water that absorbs heat from the hot-gas refrigerant flowing through a refrigeration system's discharge line. (21)

hot wire. See *ungrounded conductor*. (25)

hot-wire anemometer. An anemometer that is placed directly in the path of airflow with a velocity-sensing device consisting of a temperature-sensitive wire element. (27)

humidifier. A piece of equipment that adds water vapor to the air. See *atomizing humidifier*, *bypass humidifier*, *central humidifier*, *evaporative humidifier*, *fixed filter humidifier*, *impeller humidifier*, *nozzle-type humidifier*, *piezoelectric (ultrasonic) humidifier*, *plate humidifier*, *portable humidifier*, *rotating disk humidifier*, *rotating drum-type humidifier*, *under-duct humidifier*, and *vaporizing humidifier*. (35)

humidistat. A control device that responds to changes in humidity and activates and deactivates parts of the humidity control systems, such as humidifiers, dehumidifiers, or air mixers as needed. (35)

humidity. The presence of moisture or water vapor in the air. (27)

hunting. A responsive mechanism going too far in one direction and then overcorrecting and going too far in the other direction. This is also referred to as *surging*. (20)

HVAC Excellence. An organization that develops standards for HVACR curriculum and provides accreditation to a school's HVACR program and certification to students, technicians, and instructors. (1)

HVACR designer. Someone who prepares designs for smaller or more common air-conditioning systems but is generally not licensed and does not have the same level of knowledge as an HVACR engineer. HVACR designer plans may still need approval by an engineer. (1)

HVACR drafter. Someone who works with engineers and designers to prepare construction drawings for HVACR systems. (1)

HVACR engineer. Someone with a four-year mechanical engineering degree that analyzes a building or refrigerated space to determine the requirements of the system. Engineers often have a state license for this work. (1)

hybrid solar energy system. A solar energy system that is a combination of both a passive and an active system. (44)

hydrocarbons (HCs). Organic substances that contain carbon and hydrogen. These are components of petroleum and natural gas. Known for their use as fuel and in the production of plastics, solvents, and industrial chemicals, HCs can also be used as refrigerants with low ODP and GWP ratings. (9)

hydrochlorofluorocarbons (HCFCs). A group of refrigerants composed of hydrogen, chlorine, fluorine, and carbon. HCFCs are less harmful to the ozone layer than CFCs but may have high GWP ratings. (9)

hydrofluorocarbons (HFCs). A group of refrigerants that contain hydrogen, carbon, and fluorine, but not chlorine. HFCs have no ozone depletion potential. (9)

hydrofluoro-olefins (HFOs). A newer group of refrigerants with low ODP and GWP ratings. They are composed of hydrogen, fluorine, and carbon, but they have at least one double bond between the carbon atoms. (9)

hydronic system. A system that distributes conditioned water or steam to spaces in order to heat or cool those spaces. (39)

hygrometer. An instrument used to measure moisture in the air (usually displayed as relative humidity). (27)

hygroscopic element. The sensing element of a traditional electromechanical humidistat. It stretches as the moisture content of the air increases and shrinks as humidity decreases. (35)

ice bank. In a refrigeration system, a solid block of ice that is intentionally formed around an evaporator during periods of low demand and melts during periods of high demand. (47)

ice machine. A commercial refrigeration system that automatically freezes and forms water into ice and dispenses it for consumer use. (47)

ice thickness sensor. A device that monitors the thickness of the ice forming in the molds of a vertical evaporator cube ice machine. (53)

ignition carryover. The length of time (in seconds) that an oil furnace igniter will continue to spark after the primary control unit senses a flame. Ignition carryover only applies to furnaces with interrupted ignition, as intermittent ignition continues sparking throughout a furnace's heating cycle. (42)

ignition point. The minimum temperature at which a flame will ignite and continue to burn fuel oil vapor as the vapor rises from a pool of liquid fuel oil. (42)

ignition system. A furnace subsystem designed to light the burners safely and monitor them for continued safe operation. In a gas-fired heating system, the ignition system is controlled by an ignition control module. In an oil-fired heating system, ignition is controlled by a primary control unit. (41)

Copyright Goodheart-Willcox Co., Inc. 2017

ignition temperature. The heat required to initiate combustion. This temperature level varies for different fuels. (41)

ignition transformer. A step-up transformer that generates the high voltage necessary to ignite the flame in an oil-fired furnace. The high voltage arcs across a gap between two electrodes where it ignites fuel oil exiting the air tube of the oil burner. (42)

immersed evaporator. A liquid-cooling evaporator consisting of a plain coil that is submerged and mounted inside a container filled with a liquid. (21)

impedance. The opposition to the flow of alternating current in an ac circuit. (16)

impeller (compressor). In a centrifugal compressor, the compressor's rotor that operates similar to a circulating pump. (18)

impeller (hydronics). In a hydronic system, the part of a circulating pump that spins and forces water through the system. (39)

impeller humidifier. A humidifier in which a spinning disk flings water against a diffuser to atomize the water on impact. The water droplets then enter the airstream. (35)

incomplete combustion. A form of combustion in which a flame does not receive enough oxygen to finish the combustion process, resulting in unburned carbon. (41)

indirect radiant heat. An electric heating system in which the heating elements produce heat that warms a large surface, such as a floor or a panel on a ceiling or wall, which then radiates its heat to the solid objects in a conditioned space. Also called *surface radiant heat*. (43)

indirect-fired. A term describing commercial absorption systems in which the heat source is produced somewhere outside the system and then delivered to the absorption system's generator as piped-in steam, hot water, or hot gas. To contrast, see *direct-fired*. (34)

indoor air quality (IAQ). The quality of the air within buildings and structures, especially as it relates to the health and comfort of building occupants. (28)

indoor blower. A motor-driven fan in a forced-air system that creates airflow through the ductwork to deliver conditioned air to the conditioned space and to draw air from the conditioned space into the air handler to be heated or cooled. (38)

indoor coil. One of two refrigerant-circulating heat exchanger coils in a heat pump system. The indoor coil is located inside and warms or cools air for the conditioned space. (40)

indoor design temperature (IDT). In calculating heat loads, the ideal indoor temperature that the heating or cooling system works to maintain. (37)

indoor reset control. A hydronic system control that adjusts the boiler temperature to match the heating load by monitoring the cycle time required to satisfy a call for heat. (39)

induced draft. The air flowing into a fan. (29)

induced-draft cooling tower. A cooling tower that uses a fan placed at the air exhaust to draw air into the tower through louvers on an opposing side, across the wet deck, and out of the tower through the fan. (33)

induced magnetism. The ability of a magnetic field to produce magnetism in a metal. (12)

inductance. An electrical property that opposes a current change in an ac circuit. This opposition to current change creates a noticeable power loss in a circuit. (13)

induction. The process of transferring electricity using a magnetic field. For example, transformers use induction to transfer alternating current from one coil of wire to another. (12)

induction motor. An ac motor that operates by using the magnetic field generated in the stator to induce current in the rotor. (15)

inductive reactance. The opposition to alternating current as a result of inductance. Inductive reactance causes current to lag behind voltage in a circuit. (13)

inefficient compressor. A compressor with reduced pumping ability after sustaining wear and tear on its working parts. Operational measurements reveal higher than normal suction pressure and lower than normal discharge pressure. (53)

infiltration. The natural and unintentional or accidental leakage of outside air into a building through doors, cracks around windows, and other construction joints. (28)

initialization. An overdriving routine in which a controller, when first powered, will send an electronic expansion valve (EEV) more steps than the valve can use. (20)

in-line ammeter. An ammeter that is connected to a circuit with leads to measure a circuit's current. In-line ammeters must break the circuit to be connected in series to take measurements. (17)

inshot burner. A single-port gas burner that feeds the mixture of fuel gas and air through a large orifice to produce a large flame that is directed toward the heat exchanger. (41)

inspection mirror. A small adjustable mirror mounted on a long extension that is used for inspection. (25)

inspection tool. A tool that allows the technician to see inside ductwork in order to identify debris and contamination, monitor the cleaning process, and evaluate the success of the cleaning procedure. (30)

installation. Work that involves the initial setup of equipment and systems. (1)

insulator. A material or substance that resists the flow of electrons. Examples of insulators include mica, glass, rubber, plastic, and paper. (12)

integrated ignition control module. A gas furnace control that uses advanced electronics to provide greater functionality than a nonintegrated control module, such as the ability to perform self-diagnostics. (41)

Copyright Goodheart-Willcox Co., Inc. 2017

intercooler. A heat exchanger in a compound refrigeration system that removes superheat from the low-stage discharge vapor before it enters the high-stage compressor. (49)

intermittent absorption system. An absorption system that operates intermittently. It uses one limited charge of fuel that should operate the system for one day. (34)

intermittent defrost timer. A device that controls a cumulative run-time defrost system by counting down to the next defrost cycle only when the compressor is running. (24)

intermittent duty. According to the NEC, operation for alternate intervals of (1) load and no load; or (2) load and rest; or (3) load, no load, and rest. Motors that are intermittent duty are rated by how long they can safely run with a full load within 9°F (5°C) of their rated ambient temperature. These ratings are 5, 15, 30, or 60 minutes. (15)

intermittent ignition. An oil furnace ignition system that applies a high voltage to the electrodes throughout oil burner operation. (42)

intermittent-pilot ignition system. A type of gas furnace ignition system that burns and monitors its pilot light only while the thermostat is calling for heat. When the furnace is off, the pilot is not lit. (41)

inter-purge. A function of a gas furnace ignition control module. During a soft lockout, the control module cycles on the combustion blower to vent any combustion gases remaining in the heat exchanger after a failed ignition attempt. (41)

interrupted ignition. An oil furnace ignition system that applies a high voltage to the electrodes for only a brief period of time at the beginning of oil burner operation. (42)

inverter. An electronic device that converts direct current to alternating current. (14)

joule (J). An SI unit of work equal to the force of one newton through a distance of one meter. (4)

jumpered. A situation in which a jumper wire is connected in parallel with an electrical device. (55)

keel cooler. In marine HVACR, a condenser located on the outer hull of a boat near the keel to take advantage of water's ability to absorb heat. (48)

Kelvin scale. An absolute temperature scale that uses the same increments as the Celsius scale. 0°K is equal to –273°C. (4)

kickspace fan convector. A fan convector designed to fit into very tight spaces, such as in the small space under kitchen and bathroom cabinets. (39)

kinetic energy. Energy of motion. (4)

king valve. Another name for a liquid receiver service valve that is installed between the outlet of a liquid receiver and the liquid line. During normal operation, warm, high-pressure refrigerant liquid flows through it. (10)

K-value. See *thermal conductivity*. (37)

ladder diagram. An electrical line diagram that shows the devices and connections in a circuit arranged in the order that they activate during circuit operation. The vertical lines in the diagram identify the power supply, and the horizontal lines contain the various devices and controls located in the circuit. (16)

latent heat. Heat that brings about a substance's change of state with no change in its temperature. (4)

latent heat of fusion. The amount of heat added to or removed from a substance to change it from a solid to a liquid or a liquid to a solid. Also referred to as the *latent heat of melting* or the *latent heat of freezing*. (4)

latent heat of vaporization. The amount of heat added to or removed from a substance to change it from a liquid to a gas or a gas to a liquid. Also referred to as *latent heat of condensation*. In heat loads and system thermodynamics, the rate at which heat is absorbed by the refrigerant as it vaporizes. (4)

law of conservation of energy. A law stating that energy cannot be created or destroyed, only changed from one form to another. (4)

lean. An air and fuel mixture in which there is too little fuel. If too lean, combustion cannot occur at all. (41)

learning thermostat. A thermostat that can remember an occupant's desired set point and adapt the HVAC system operation to automatically program on and off cycles and temperature set points. (36)

Legionnaires' disease. A building-related illness caused by the Legionella bacteria, which can live in cooling towers, evaporative condensers, and domestic water systems. (28)

level (orientation). A term describing a perfectly horizontal line. Used in installation work. (7)

level (tool). A tool used in installation work to set a line at level (perfectly horizontal), plumb (perfectly vertical), or perfect 45° angle. (7)

lifelong learning. Updating and increasing one's knowledge of one's career field over the course of a lifetime. (1)

lineman's pliers. A type of pliers equipped with both a gripping surface and a cutting edge, mainly used in electrical work. (7)

line voltage. The voltage of a building's electrical wiring, which is usually 120 Vac or 240 Vac. (36)

line-voltage thermostat. A thermostat that typically operates using either 120 Vac or 240 Vac. (36)

liquid. Any physical substance that has no definite shape but has a definite volume. A liquid takes the shape of its container. (4)

liquid-cooling evaporator. An evaporator designed to cool a liquid rather than air. (21)

liquid injection valve. A refrigerant control valve installed in parallel with a hot-gas bypass valve that directs liquid refrigerant from the liquid line to combine with bypassed hot gas to provide a cooler (desuperheated) bypassed refrigerant mixture into the low side of the system for capacity control. Also called *desuperheating valve*, *desuperheating expansion valve*, or *desuperheating TXV*. (22)

Copyright Goodheart-Willcox Co., Inc. 2017

liquid line. Tubing that carries liquid refrigerant from the condenser or liquid receiver to the metering device. (6)

liquid line manifold. A refrigerant-carrying body that distributes high-pressure liquid refrigerant from the liquid line to separate metering devices and their corresponding evaporators. (22)

liquid line service valve. A high-side service valve connected to the liquid line of a system, usually located closer to the condenser than the metering device. During normal system operation, warm, high-pressure refrigerant liquid flows through it. (10)

liquid receiver. A tank on the high side that is connected between the outlet of a condenser and a liquid line that is used for refrigerant storage. (6)

liquid receiver service valve (LRSV). A high-side service valve located between the liquid receiver's outlet and the liquid line's inlet. Also called a *king valve*. During normal operation, warm, high-pressure refrigerant liquid flows through it. (10)

liquid recovery method. An active recovery procedure that uses a recovery machine to recover liquid refrigerant from the high side of a system. (11)

liquid slugging. A condition in which too much refrigerant in the evaporator results in liquid refrigerant being drawn into the compressor. (20)

listing. Leaning to one side, usually caused by an uneven floor. This can cause unusual noises from vibration of the condensing unit in domestic appliances. (25)

lithium bromide. A nontoxic, nonflammable, nonexplosive, and chemically stable salt used in some absorption systems. Represented by the chemical formula LiBr. (34)

lithium bromide absorption chiller. An absorption system that uses water as the refrigerant and lithium bromide (LiBr) as the absorbant. (34)

localized controller. A building system controller used to provide independent control for a specific system or piece of equipment. (45)

local sensing. When a high-voltage electrode and flame rod are packaged together in a direct-spark ignition system for a gas-heating system. A single device is responsible for both providing the spark and detecting the flame. (41)

locked rotor amperage (LRA). The current that a motor draws as power is first applied to start turning the rotor. This value may be two to six times higher than full-load amperage (FLA). See also *full-load amperage (FLA)*. (15)

locker plant. A plant smaller than a processing plant that prepares, fast-freezes, and stores various food products. (47)

lockout (LO). The practice of locking a mechanism or an electrical switch in the open position so that maintenance or service work can be performed safely. (2)

lockout relay. A special high-impedance relay that keeps a circuit from restarting when any of the safety controls in the circuit have opened. Power to the lockout relay coil must be interrupted to reset the lockout relay contacts and return the system to normal operation. (16)

lockout/tagout (LOTO). The combination of locking out and tagging out, in which a mechanism or an electrical switch is locked open and a tag is placed on it to inform others that service work is in process and that this mechanism or switch's position should not be changed. (2)

LonTalk. A proprietary communications protocol developed by Echelon that permits integration of components from different manufacturers in a building control system. (45)

low-ambient control (LAC). A control valve that combines a condenser pressure regulator and a receiver pressure regulator in a single valve body. Commonly used for head pressure control in low ambient conditions. Also called a *combination condenser-receiver pressure regulator*, *combination ORI/ORD valve*, *combination head pressure control*, or *low-ambient control (LAC) valve*. (22)

lowboy furnace. A furnace designed to be shorter and longer or wider than a highboy furnace of comparable capacity. It is installed in spaces where there is limited vertical clearance. (38)

low-pressure chiller. A compression chiller operating under low pressures that is capable of producing very low evaporator temperatures. It is typically a centrifugal chiller charged with R-123. (33)

low-pressure motor control. A control device that reacts to the low-side pressure it senses by closing an electric switch on a rise to a preset pressure (cut-in setting) and opening that switch on a drop to a preset pressure (cut-out setting). (16)

low-pressure safety control. A pressure-sensitive element, such as a diaphragm or bellows, that is set to shut down the compressor in the event of refrigerant loss or an evaporator freeze-up. (16)

low side. The parts of a refrigeration system subject to low pressure, such as the evaporator, accumulator, and suction line. (6)

low-side charging. A method of injecting refrigerant vapor into the low side of a refrigeration system through a low-side service valve, often the suction service valve (SSV). (52)

low-side float (LSF). A refrigerant control that uses a float-operated valve to maintain a constant level of liquid refrigerant in the evaporator. (20)

low-side pressure. The pressure value on the low side of an HVACR system. Low-side pressure can also be called *suction pressure*, *evaporator pressure*, and several other names, depending on circumstances. (6)

low-stage compressor. In a compound refrigeration system, a compressor connected to the suction line that pumps the lower temperature and lower pressure refrigerant into the high-stage compressor. (49)

low-voltage thermostat. A thermostat that operates at 24 Vac supplied by a step-down transformer. It often uses relays to switch line voltage circuits on and off. (36)

low-water cutoff (LWCO). A control that ensures that a hydronic system operates only when it contains the

Copyright Goodheart-Willcox Co., Inc. 2017

proper amount of water. A low-water cutoff may operate a makeup water valve or shut down the system if the water level drops too low. (39)

LP gas. Liquefied petroleum, which consists primarily of liquefied propane (C_3H_8) and also some liquefied butane (C_4H_{10}). (41)

machine screw. A threaded fastener that can be screwed into place or held with a tightened nut. (7)

magnetic field. A space in which lines of magnetic force exist. (12)

magnetic flux. The lines of force of a magnet. (12)

maintenance. Service performed regularly to reduce the likelihood of a future breakdown and to minimize any reduction of system performance. (3)

maintenance service contract. An agreement for providing periodic maintenance and service of a system for a fixed rate. (3)

makeup air unit. A device that controls and regulates the necessary intake of fresh air into a building. (38)

makeup water. Water added to a cooling tower's sump through a float switch-operated valve to replace water lost through evaporation, drift, and blowdown. (33)

mallet. A type of small hammer, usually with a rubber or plastic striking surface, used for safely hitting parts without damaging their surfaces. (7)

manifold valve. A shutoff valve installed near a suction line manifold or a liquid line manifold. (22)

manometer. An instrument for measuring low pressure levels of gases and vapors, such as air velocity in ductwork. Gas pressure is balanced against a column of liquid, such as water, often in a U-shaped tube. (7)

Manual D. A manual developed by ACCA to be used to design both the supply and return ducts of a building. (29)

Manual J. A manual developed by ACCA to be used in calculating the heating and cooling loads of residential buildings. (37)

mass. The quantity of matter an object contains. (4)

master thermostat. In a zoned system, this is the thermostat that governs system operation and receives temperature input and calls for operation from slave thermostats. See *slave thermostat*. (36)

master-slave thermostat design. An older form of controlling a zoned system consisting of a master thermostat that operates based on the inputs from several slave thermostats. (36)

matter. Anything that occupies space and has mass. (4)

medium hard water. Well water that is untreated and contains a mineral content of 5 to 15 grains per gallon of water. (35)

megohmmeter. An electrical insulation tester that is used to detect current leaks or possible areas of insulation failure along conductors. A megohmmeter measures resistance by applying a known voltage supplied by the meter. (17)

mercury contactor. A switching device that immerses its electrodes into a small pool of mercury for electrical contact. A mercury contactor can be used to silently open and close a circuit feeding electric heating elements, such as in duct heaters. (43)

mercury switch. An electrical switch consisting of a sealed tube containing a small puddle of mercury and two to four contacts made at the ends of wires that run outside the tube. Contact is made when a mercury switch is tilted, which causes the mercury puddle to slide down the tube and complete the circuit. (36)

MERV (Minimum Efficiency Reporting Value). A measurement scale developed by ASHRAE to rate the effectiveness of air filters. (28)

mesosphere. The layer of the atmosphere that extends from 170,000′ (32 mi) to 280,000′ (53 mi). (27)

metering device. A device used to regulate the flow of liquid refrigerant into the evaporator, such as a capillary tube, an expansion valve, or a float valve. (6)

metering evaporator pressure regulator. An EPR that opens its valve in proportion to evaporator pressure. The higher the evaporator pressure, the more the valve opens. (22)

metering orifice. A fixed-orifice metering device that consists of a fitting with a small hole, called an orifice, between the fitting's inlet and outlet. The orifice acts as a constant throttle on the refrigerant flow and a constant pressure drop. (20)

microchannel. A type of heat exchanger construction in which fluid passages are less than 1 mm in diameter. These small refrigerant passages are surrounded by tightly packed fins that further increase surface area for efficient heat transfer. Microchannel heat exchangers can serve as evaporators, condensers, and other heat transfer applications. (21)

micron. A unit used to measure extremely low pressures. For example, 1000 microns are equivalent to 1 mm Hg. Microns are used when measuring vacuum for system evacuation. (10)

microprocessor. An electronic component that functions as the control center of a system. It is capable of accepting information, storing it, and reacting in some preset way. (14)

mid-efficiency gas furnace. A furnace that has no secondary heat exchanger, which means some heat energy is lost in the venting of hot flue gases. This type of furnace has an AFUE range of 79%–83%. Also called *noncondensing furnace*. (41)

mid-position. A service valve position midway between front seated and back seated. When a valve is in mid-position, refrigerant flows through the valve, and service port access is still available. (10)

milk cooler. A commercial refrigeration system that cools fresh milk to the legally required temperatures in a large tank. (47)

millivolt thermostat. A heating thermostat that operates a small solenoid valve powered by a very small voltage

Copyright Goodheart-Willcox Co., Inc. 2017

produced by a thermocouple device sensing a standing pilot light. These may only be used in systems having a standing pilot. (36)

mineral oil (MO). A type of refrigeration lubricant made from refined crude oil and generally used only with CFCs and HCFCs. (9)

miscellaneous heat loads. Concerning heat loads and system thermodynamics, all sources of heat not covered by heat leakage, product cooling, and respiration heat loads, which may include lights, electric motors, people, and defrosting heat sources. (50)

mixing valve. A hydronic system valve that blends hot water from one inlet with cooler water from another inlet so that water leaving the valve is at the desired temperature. (39)

Modbus. A communication protocol used in building control and automation that was originally developed for use with programmable logic controllers (PLCs). (45)

modulate. A control term meaning to increase or decrease the intensity of operations. Examples include variable refrigerant flow or some thermostats controlling multistage heating. (36)

modulating furnace. A furnace controlled by solid-state integrated controls that can vary its heat output from 40% to 100% of its total capacity. (38)

modulating refrigeration system. A refrigeration system that is able to adjust its capacity to more closely match a variable heat load. (49)

moisture indicator. A sight glass with a color-changing element that is used to indicate a system's moisture content. (22)

mold. A growth of minute fungi that forms on vegetable and animal matter. Air conditioning applications may provide a favorable environment for their growth and development. The spores from certain molds can cause illness. (28)

Montreal Protocol. A document that banned the production of CFCs in all large, developed countries by January 1, 1996. (9)

MOP thermostatic expansion valve. A TXV that closes tightly during the Off cycle and remains closed during pull-down. The valve remains closed until pressure drops below the maximum operating pressure (MOP). This delay in valve opening permits rapid pull-down and prevents floodback and overloading of the compressor motor. (20)

motorized mixing valve. A type of mixing valve that uses an electronic sensor to monitor water temperature and a built-in electric motor to adjust the valve as needed based on the sensor feedback. (39)

motor nameplate. A plate mounted on the outside of a motor's frame that displays essential motor information. (15)

motor starter. A heavy-duty type of electromagnetic relay similar to a contactor that can handle high current loads, such as those for operating motors. Unlike a contactor, a motor starter has built-in overload protection. (16, 45)

motor terminal box. A box mounted on the outside of a motor's frame in which electrical connections are made to control and power the motor. (15)

motor water valve. An electric water valve that uses a motor to open, close, and position the valve to control water flow. (33)

muffler. A cylinder with internal baffles that mute the noise caused by refrigerant vapor pulsation, thereby reducing sound and vibration. (18)

mullion heater. A low-wattage electric heater around the door opening of a refrigerator-freezer that keeps the exterior surfaces of the cabinet warm enough to prevent humidity in the air from condensing on the cabinet. (24)

multimeter. A single electrical meter that can measure multiple electrical variables, such as voltage, current, and resistance. Also called *volt-ohm-milliammeter (VOM)*. (17)

multiple-blade damper. A device used in square or rectangular ducts to restrict or completely shut off airflow to a room or zone. (29)

multiple chemical sensitivity (MCS). An unexplained condition that manifests itself in reported sensitivities and adverse reactions to low levels of chemicals, bioaerosols, and other irritants. (28)

multiple-compressor system. A modulating refrigeration system in which two or more compressors operate in parallel for variable system capacity. (49)

multiple-evaporator system. A refrigeration system with two or more evaporators connected to only one condensing unit. (49)

multipoise furnace. A furnace that can be configured manually to make it an upflow, downflow, or horizontal furnace. (38)

multipurpose fuse. A fuse that will not blow during small overloads lasting only short periods of time, but will blow immediately if an extremely high overload occurs. (16)

multistage system. A refrigeration system with more than one stage of compression. The two general types are cascade systems and compound systems. (49)

multistage thermostat. A thermostat that can control a system's heating and cooling capacity through various means, such as modulating compressor and fan operation or varying fuel combustion or electrical power. (36)

multizone ductless split system. A comfort cooling system consisting of one or more outdoor units, multiple independent indoor units, and individual temperature controls for each indoor unit. Zoned cooling is used, but no ductwork is used. (31)

NATE. North American Technical Excellence, an independent professional certification organization, offering multiple certifications divided into installation and service and also senior level categories. (1)

Copyright Goodheart-Willcox Co., Inc. 2017

natural-convection condenser. A condenser without a fan that relies on differences in temperature for air movement. Also called *static condenser* or *natural-draft condenser*. (6)

natural-draft cooling tower. A cooling tower that relies on wind and natural convection to blow through the cooling tower to aid evaporation. (33)

natural-draft evaporator. An evaporator without a fan that relies on natural convection, gravity, and differences in pressure and temperature for air circulation. Also called *static evaporator*. (6)

near-azeotropes. Refrigerant blends that are technically zeotropic blends, but have a smaller range of boiling (bubble) and condensing (dew) points. Also called *near-azeotropic blends* and *near-azeotropic refrigerants*. (9)

negative temperature coefficient (NTC). A device's inverse relation response of decreasing a certain characteristic as temperature increases and vice versa. For example, an NTC thermistor decreases in resistance as temperature increases and vice versa. (14)

net metering. A process in which homeowners can sell excess electrical energy they generate back to the utility company. (44)

networking. The process of connecting with other individuals within a group or industry. (1)

neutral flame. A torch flame with the correct mixture of fuel gas and oxygen that is most efficient in brazing. It has a bluish-white inner cone and an outer flame with a bit of reddish-purple. (8)

neutron. A subatomic particle with no charge that is located in the nucleus of an atom. (12)

newton. A unit of force used in the SI system, equal to the force required to accelerate an object that has a mass of 1 kilogram to 1 m/sec^2. (4)

nitrogen oxide (NO_X). A combination of nitrogen and oxygen atoms that is formed at high temperatures, such as those developed during combustion in an automobile engine. Nitrogen oxide is one of the substances that contributes to smog production. (28)

noise absorber. Any type of material that mutes noise. In forced-air systems, felt-lined or soft-insulation-lined ducts are used to absorb noise. (30)

noise amplifier. Anything that can pick up a small vibration and reflect it at a frequency and direction that effectively increases the noise. This is usually a hard, smooth surface like a wall, ceiling, floor, or other furnishing. (30)

noise carrier. A rigid structure that carries vibrations to places where the sound may be annoying. Floors, ceilings, ducts, doors, and pipes can all act as noise carriers. (30)

noise source. An audible vibration that is loud enough to be heard. This vibration may originate in the heating system, cooling system, or fan mechanism. (30)

non-100% shutoff. A function of a gas furnace ignition control module. When the flame rod does not detect a flame, the control module will close the gas valve but not close the pilot valve. (41)

noncondensables. Foreign substances that can enter the refrigerant circuit of an HVACR system but do not phase change along with refrigerant. These tend to become trapped in the system's condenser and raise head pressure until removed. A common noncondensable is air. (53)

noncondensing furnace. A low-efficiency furnace with an annual fuel utilization efficiency (AFUE) rating between 80% and 90%. Noncondensing furnaces have a single heat exchanger to transfer heat from the combustion gases to the air circulated to the conditioned space. (38)

nonfreezing solution defrost. A defrost system that circulates a heated, nonfreezing solution in tubing near and around the evaporator during the Off cycle to melt ice and frost. (21)

nonintegrated ignition control module. An older type of gas furnace control that can open and close a gas valve, control a spark or hot-surface igniter, and monitor electric interlocks. (41)

normally closed (NC). A term describing the state of electrical contacts being usually closed. NC contacts are open only when their switch or switching device is actuated. (14)

normally closed damper. A damper that is in the closed position when power is not applied to its motor. (36)

normally open (NO). A term describing the state of electrical contacts being usually open. NO contacts are closed only when their switch or switching device is actuated. (14)

normally open damper. A damper that is in the open position when power is not applied to its motor. (36)

nozzle-type humidifier. A humidifier in which water is forced through a restrictive nozzle to create a very fine mist. The fine mist is injected directly into the supply airflow. (35)

N-type material. A negatively charged semiconductor material that has a surplus of electrons. (14)

nucleus. The central part of an atom that consists of protons and neutrons. (12)

Occupational Safety and Health Act (OSHA). A US national code that covers workplace safety for workers and equipment. (2)

off-cycle defrost. A method of defrost in which air from the conditioned space is circulated over the evaporator during the Off cycle. (21)

offset. The difference between the set point and the control point in a closed-loop control system. Offset is sometimes called *error*. (16)

ohm. A unit used to measure electrical resistance, represented by the capitalized Greek letter omega (Ω). One ohm of resistance allows one volt to push a current of one ampere through a circuit. (12)

ohm out. An electrical term meaning to measure the resistance of an electrical load. Only do this with electrical power disconnected and after checking with a voltmeter that no voltage is applied (0 V measurement). (36)

Ohm's law. A mathematical relationship among voltage, current, and resistance in an electrical circuit ($E = I \times R$). (12)

Copyright Goodheart-Willcox Co., Inc. 2017

ohmmeter. A meter used for measuring electrical resistance in an electrical circuit. It may also be used to check for short circuits, circuit continuity, and ground faults. (14)

oil binding. A condition in which the oil picked up by vapor refrigerant does not return to the compressor. The oil forms a layer on the surface of the liquid refrigerant in the evaporator and prevents the refrigerant from evaporating at a rapid rate or at the temperature corresponding to the pressure. (20)

oil burner. A device that controls the burning of fuel oil in an oil-fired heating system. There are two types of oil burners: pot burners and gun burners. (42)

oil burner fan. A fan that provides combustion air for the flame in the combustion chamber of an oil-fired heating system. Also called *blower wheel*. (42)

oil burner motor. A motor that provides power for the fan and fuel unit (oil pump) in an oil burner assembly. Oil burner motors are either split-phase motors or permanent split capacitor (PSC) motors. (42)

oil burner nozzle. A metal piece with a specially sized orifice that controls the amount of fuel oil passing from the air tube into the combustion chamber. An oil burner nozzle is responsible for atomizing, metering, and patterning fuel oil entering the combustion chamber. (42)

oil canning. The sound of expanding and contracting ducts when a blower starts and stops. This can usually be prevented by cross-breaking large ductwork panels. (29)

oil deaerator. In an oil-fired heating system, a device installed in a fuel line that removes air and other gases from fuel oil. (42)

oilless bushing. A method of bearing lubrication in which a motor shaft passes through a sintered bronze bushing that is saturated with oil. (17)

oil level regulator. In a refrigeration system, an oil control device that regulates the level of refrigerant oil within a compressor using a float mechanism. (19)

oil reservoir. A storage vessel that holds a refrigerant oil supply for a compressor or a group of compressors in a refrigeration system. (19)

oil ring. In a reciprocating compressor, a piston ring that lubricates the cylinder wall and prevents excess oil from entering the cylinder. (18)

oil safety control. In a refrigeration system, a form of control that will shut off electrical power to the compressor if the net oil pressure or oil level drops below normal for a certain amount of time. (19)

oil separator. An HVACR system component that removes refrigerant oil from high-pressure refrigerant vapor as both refrigerant and oil leave the compressor. (6)

oil slugging. Excess amounts of oil being pumped out of the compressor due to oil foaming. (18)

one-pipe fuel delivery system. A fuel oil delivery system that uses a single fuel line between the fuel oil tank and the oil burner. (42)

one-pipe hydronic system. A hydronic system in which a single pipe supplies hot water from the boiler and carries return water back to the boiler. The terminal units in a one-pipe system are on branch circuits called secondary loops. (39)

open circuit. An electrical circuit that is interrupted or broken at some point, preventing the flow of current. (12)

open-drive compressor. A compressor that is driven by an external source of mechanical power (usually an electric motor). Also called an *external-drive compressor*. (18)

open end wrench. A wrench with an opening in the gripping head. Used where socket wrenches and box end wrenches cannot be used. (7)

open-loop control system. A type of control system in which the controller sends commands to a controlled device with no detected information from the conditioned space being returned to the controller. (16)

open-loop cooling tower. A cooling tower in which the same water that flows through the water-cooled condenser also flows directly over the cooling tower's wet decks and fill. (33)

open-loop ground-source heat pump system. A type of ground-source heat pump system that uses a well, pond, or lake as its water source, heat sink, and heat source. The body of water also serves as the discharge location for water. (40)

open on rise of differential pressure (ORD) valve. A refrigerant control valve that opens when a certain pressure difference occurs between its inlet and outlet. ORD valves are often used as receiver pressure regulators. (22)

open on rise of inlet pressure (ORI) valve. A refrigerant control valve that opens when inlet pressure rises to a certain preset level and closes when inlet pressure drops below a preset level. ORI valves are often used as condenser pressure regulators and evaporator pressure regulators. (22)

open ribbon. An uninsulated electric heating element that is composed of flat strips to provide more surface area for air contact than a straight, uncoiled open wire. (43)

open wire. An uninsulated electric heating element that is often formed into coils, allowing more wire to be used in a smaller space. (43)

operating cycle. The number of hours that a compressor operates per day. (51)

orifice. A small opening through which only a small amount of fluid can flow. An orifice may be used as a metering device to control refrigerant or other fluid flow or regulate pressure. (20)

O-ring. A flexible ring (usually made of elastomers) installed at the joints between mating parts to prevent leaks. (18)

outdoor coil. One of two refrigerant-circulating heat exchanger coils in a heat pump system. The outdoor coil absorbs or expels heat for the indoor coil. (40)

outdoor design temperature (ODT). In calculating heat loads, ODT represents extremely cold conditions for

Copyright Goodheart-Willcox Co., Inc. 2017

the geographical region where the heating system is installed. (37)

outdoor reset control. An auxiliary control that modifies the operating temperature range of a hydronic system based on the difference between outdoor and indoor temperatures. (39)

outside length. The distance around the outside of a V-belt. A V-belt's size is measured by its outside length. (17)

overdefrosting. A condition in which a defrost cycle continues long enough to raise the temperature of the conditioned space too high. (21)

overfire draft test. A draft test used to measure only the draft in the combustion chamber of a combustion heating system. See also *flue draft test*. (42)

overfiring. A condition in which a combustion heating system creates too much heat, causing a high flue gas temperature and reducing system efficiency. (42)

overflow switch. An electrical switch used to sense liquid level and prevent an overflow condition. A common application of an overflow switch is in an indoor unit of a ductless split system. It turns off the system if condensate is sensed at a certain level to prevent overflow by the continued formation of condensate. (31)

overload. A condition in which too much current flows through an electrical circuit. An overload can lead to excessive heat generation and result in fire or deterioration of electrical insulation. An overload's current is not as high as in a short circuit. (13)

oxidizing flame. A torch flame with more oxygen than a neutral flame, recognized by its small, sharply pointed inner cone and the hissing sound it creates. (8)

oxyacetylene. A torch configuration that mixes pure oxygen and acetylene for an extremely hot flame used for brazing, welding, and cutting. (8)

ozone (O_3). A form of oxygen that has 3 atoms per molecule, instead of two atoms (oxygen, O_2). It can be photochemically produced in nature. It is a disinfectant and is sometimes used in small quantities to purify water or maintain a sterile atmosphere. Large concentrations may be harmful to health. (28)

ozone depletion potential (ODP). A numerical value assigned to refrigerants to compare the destructive potential each refrigerant poses to the ozone layer compared to R-11, which has an ODP of 1. (9)

packaged outdoor air-conditioning unit. A packaged air-conditioning system installed on a concrete pad or supporting structure adjacent to a building with return and supply air ducts between the unit and building. (33)

packaged system. A refrigeration unit designed, built, and shipped by the manufacturer and includes all of the major refrigeration components, piping, and electrical wiring. (49)

packaged terminal air conditioner (PTAC). A type of self-contained ductless air-conditioning system commonly used in hotels and apartment buildings. These are installed in an outside wall cavity and are usually designed to provide cooling and heating. (31)

packaged terminal heat pump (PTHP). A type of self-contained ductless heat pump that can reverse its refrigeration cycle for comfort heating or cooling. (31)

PAHRA. The Partnership for Air Conditioning, Heating, Refrigeration Accreditation, which is an organization that provides accreditation for schools and other training providers with HVACR programs. (1)

parallel circuit. An electrical circuit in which current can flow to and from the power source along more than one path. (12)

parallel compressor rack. An arrangement of compressors piped in parallel with a common suction line, a common liquid line, and a common liquid receiver. These are commonly used in multiple-compressor systems and provide a variable cooling capacity based on demand. (47)

partial vacuum. Any pressure below atmospheric pressure (14.7 psia). (5)

pascal. A unit of pressure used in the SI system equal to 1 newton per square meter. (5)

Pascal's law. A law stating that pressure applied to a confined fluid is transmitted equally and undiminished in all directions. (5)

passively chilled beverage dispenser. A commercial refrigerated dispenser that transports syrup and water through stainless steel tubing that is surrounded by the same ice that is dispensed for use in individual drinks. (47)

passive recovery. A refrigerant recovery method that uses the pressure inside a system or the system's compressor to force refrigerant into an unpressurized container. Passive recovery is only used on smaller HVACR systems. (11)

passive solar energy system. A solar energy system that depends on solar radiation striking directly on the area to be heated. A greenhouse is a good example. (44)

patterning. In an oil-fired heating system, the directing of atomized fuel oil droplets into the combustion chamber in the correct pattern and at the correct angle. (42)

Peltier effect. A phenomenon that occurs when current is passed through the junction of two dissimilar metals, causing heat to be absorbed in one part of the junction and moved to another part of the junction. It is the basis of modern thermoelectric refrigeration. (48)

perfect vacuum. A condition in which pressure cannot be further reduced, equal to 0 psia. (5)

permanent split capacitor (PSC) motor. A single-phase induction motor that uses a single run capacitor in series with the start winding throughout the motor's entire operation. It does not use a centrifugal switch or relay to switch off any capacitors or windings. (15)

personal protective equipment (PPE). Safety equipment worn by a technician to minimize exposure to health and physical hazards. Example include gloves, hard hats, goggles, and respirators. (2)

Copyright Goodheart-Willcox Co., Inc. 2017

phase change material (PCM). A storage medium used in latent thermal energy storage systems that is able to change phase states from solid to liquid or from liquid to solid within the range of operating temperatures and pressures. (44)

phase loss monitor. An overload protection device that monitors the voltage of each phase of a three-phase motor's power supply. A phase loss monitor opens the motor circuit if one of the phases blows a fuse or opens a circuit breaker. (17)

phase splitting. A motor condition where the current flowing through the start winding is out of phase with the current flowing through the run winding. Phase splitting is the means by which single-phase motors create a rotating magnetic field in the stator with enough torque to cause the rotor to start turning. (15)

photoelectric device. A semiconductor device that changes its ability to conduct electricity or produces an electrical signal in response to visible, infrared, or ultraviolet light. (14)

photovoltaic cell. A solar cell that converts light energy into electrical energy through the process of photovoltaics. (44)

pickup voltage. The voltage required in a motor's start winding to energize a potential relay coil, which drops the start capacitor out of the circuit. Pickup voltage is typically generated when a motor reaches around three-fourths of its normal operating speed. (16)

pictorial diagram. An electrical wiring diagram that is used primarily in service or installation manuals to illustrate how electrical devices are connected in a unit. Pictorial diagrams also show the approximate physical location of devices in a unit. (16)

piercing valve. A device that is used to access HVACR systems that have no service ports or access ports. The valve is secured to tubing by being bolted or brazed on. (10)

piezoelectric crystal. An electronic device that vibrates when electric current is run through it. It is commonly used in piezoelectric humidifiers. (35)

piezoelectric (ultrasonic) humidifier. A humidifier that uses a vibrating element to atomize water. (35)

pilot light. A small flame located near a furnace's gas burners that provides the initial heat to ignite a gas furnace. Also called a *pilot flame* or just *pilot*. A pilot light is just one of several different types of ignition methods of gas-fired appliances. (41)

pilot-operated reversing valve. A type of reversing valve that uses a solenoid pilot valve to move the piston and sliding section of tubing in the reversing valve. The solenoid pilot valve has capillary tubes that provide passageways for high-pressure discharge vapor from the compressor to push against the piston in the reversing valve to move it, which changes the inner connection of the tubing stubs and the direction of refrigerant flow. (40)

pinch-off tool. A tool used to isolate parts or sections of tubing by applying pressure to deform and seal the tubing. To permanently seal a pinched tube, apply brazing filler using a torch. (25)

pin punch. A type of punch used to drive retainer pins in or out. (7)

pipe schedule. A term that is paired with a number to indicate a pipe's wall thickness. (8)

pipe wrench. A wrench used to grip pipes and other cylindrical objects. (7)

piston. A reciprocating compressor component that moves up and down in the cylinder to draw in and compress the refrigerant vapor. (18)

piston pin. A small metal cylinder that connects a reciprocating compressor's piston to its connecting rod. (18)

piston ring. In reciprocating compressors, a split metal ring installed in a groove on the piston. Piston rings push outward to form a seal between the side of the piston and the cylinder wall. (18)

pitot tube. An instrument consisting of a tube pointed directly into the airflow that measures total air pressure and static air pressure. When used with a manometer, it can be used to determine air velocity. (27)

plate evaporator. An evaporator fabricated from two metal sheets, welded together, that form a series of passages through which refrigerant flows. (21)

plate heat exchanger. A heat exchange device composed of a set of thin metal sheets that form two separate passageways that share a significant amount of common surface area. (21)

plate humidifier. An evaporative humidifier that consists of a series of porous plates and a water pan. (35)

plenum-mounted humidifier. A central humidifier that is designed to be installed through the side of a return or supply ductwork plenum. (35)

pliers. Multipurpose hand tool used for bending, gripping, and cutting. (7)

plumb. A term describing a perfectly vertical line. Used in installation work. (7)

pneumatic motor. A device consisting of a piston in a cylinder or pressing against a diaphragm that may be used to operate dampers, valves, and switches in a pneumatic control system. (33)

pneumatics. The use of pressurized air to perform certain mechanical actions. (33)

pole. The movable part of an electrical switch. (14)

pollen. The small particles released by plants as part of their reproductive cycle. Since these airborne particles create irritating symptoms and ailments for many people, pollen removal is an important function of air conditioning. (28)

pollen count. A measurement of the amount of pollen in a given space. (28)

pollutant. A substance that is in some way a detriment to comfort, health, and a desirable environment. Three common indoor air pollutants are asbestos, bioaerosols, and radon. (28)

Copyright Goodheart-Willcox Co., Inc. 2017

polyalkylene glycol (PAG) lubricant. A type of refrigeration lubricant designed for use with HFCs. (9)

polyol ester (POE) lubricant. A group of synthetic refrigeration lubricants that are compatible with CFCs, HCFCs, and HFCs. (9)

ponded roof. A flat roof that maintains 2″ to 3″ (5 cm to 8 cm) of standing water, which absorbs heat from the sun and dissipates that heat through evaporation. (46)

portable air conditioner. A self-contained air-conditioning system packaged in one case that is often equipped with wheels so the unit can be rolled where needed to spot cool an area. (31)

portable humidifier. A standalone humidifier placed where a specific humidity level needs to be maintained. (35)

positive pressure. A pressure greater than atmospheric pressure, which is 14.7 psia. (11)

positive temperature coefficient (PTC). A device's direct relation response of increasing a certain characteristic as temperature increases and vice versa. For example, a PTC thermistor increases in resistance as temperature increases and vice versa. (14)

positive temperature coefficient (PTC) relay. An electronic relay that uses a PTC thermistor to control a motor circuit by increasing its resistance as it senses high ambient temperature. (16)

post-condenser loop. A type of condensation control that uses the heat of the liquid line to prevent condensation from forming on a cabinet's surfaces. Also called a *Yoder loop*. (24)

post-purge. A function of a gas furnace ignition control module. After the gas burner has stopped operating, the control module keeps the combustion blower on for a preset time to vent any combustion gases remaining in the heat exchanger. (41)

pot burner. An oil burner that maintains a flame using a carburetor to feed the flame with vaporized fuel oil rising from a small pool of liquid fuel oil. (42)

potential energy. Stored energy. Energy related to an object's position, such as water behind a dam, a suspended weight that could drop, or electrical voltage across a battery's terminals. (4)

potential relay. An electromagnetic relay that operates when a single-phase motor's counter electromotive force (cemf) is sufficient to energize the relay's electromagnetic coil. Potential relays are used to disengage a motor's start capacitor from the circuit. Also called *voltage relays*. (16)

pour point. The lowest temperature at which a refrigeration lubricant will flow. Lubricants with low viscosities have low pour points. (9)

power. The rate at which work is performed. The SI unit of work is the watt, and the US Customary unit of work is the horsepower. (4)

power burner. In gas-fired appliances, a type of gas burner that uses a blower to force both primary and secondary air into the burner tube. (41)

power factor. The ratio of true power to apparent power, given as a percentage. (13)

power factor meter. An instrument used to provide a direct reading of the power factor in an electrical circuit. (17)

power-open/power-closed damper. A damper that requires electrical power to open and electrical power to close. (36)

power-stealing thermostat. An electronic thermostat that draws a small amount of electrical power from the low-voltage side of an HVAC system's control circuit to operate the thermostat's electronics. (36)

preignition. A primary control unit function that occurs when the thermostat calls for heat in an oil-fired heating system. During preignition, the primary control unit energizes the igniter to establish an electric arc before the oil burner motor provides the mixture of fuel oil and air for combustion. (42)

pre-purge. A function of a gas furnace ignition control module. Before ignition is attempted, the control module cycles on the combustion blower to empty the heat exchanger of any combustion gases and to fill it with fresh air, which helps to prevent incomplete combustion and misfires. (41)

pressure. Force per unit of area. The SI unit of pressure is the pascal or kilopascal, and the US Customary unit of pressure is pounds per square inch (psi). (5)

pressure dew point. The temperature at which moisture condenses in pressurized air (air that is not at atmospheric pressure). (47)

pressured water system. A collection of components used in a cooling tower that pumps water through pipes and out of spray heads along the top of wet decks. (33)

pressure-enthalpy diagram. A graph that plots a refrigerant's thermodynamic properties against pressure and heat conditions. Also called a *pressure-heat diagram*. (9)

pressure-enthalpy table. A numerical chart that shows the thermodynamic properties of a refrigerant under saturated conditions. (9)

pressure gauge. An instrument that measures and displays the pressure of a contained fluid. Different types of pressure gauges include high-pressure gauges, compound gauges, and vacuum gauges. (10)

pressure limiter. A device within a TXV that prevents evaporator pressure from exceeding a safe operating limit. (20)

pressure lubrication system. A compressor lubrication system that uses a pump to pressurize oil, which is then distributed to all bearing and other high-wear surfaces through dedicated oil passages. (18)

pressure motor control. A motor control device used to regulate a compressor's motor based on low-side pressure, high-side pressure, or oil pressure. (16)

pressure-reducing valve (PRV). A hydronic system valve installed in the makeup water line that reduces the pressure of the water supplied by the water main to the operating pressure needed by the hydronic system. Also called *feed valve*, *boiler feed valve*, *boiler fill valve*, and other names. (39)

Copyright Goodheart-Willcox Co., Inc. 2017

pressure-regulating valve. A valve that modulates refrigerant flow to maintain a desired pressure. (22)

pressure-temperature (P/T) chart. A table listing boiling temperatures for corresponding pressures. These often list numbers for more than one refrigerant. (9)

pressure-temperature curve. A visual graph of the direct relationship between the pressure and temperature of a saturated refrigerant. (9)

pressure switch. An electrical switch that actuates based on pressure sensed. In heating systems, a device that confirms combustion blower operation through the use of a diaphragm that is sensitive to differences in pressure on each side of the combustion blower. (41)

pressure water valve. A water valve that regulates water flow to a water-cooled condenser based on the valve's bellows' reaction to high-side refrigerant pressure. (33)

prick punch. A type of punch with a sharp point used only in layout work. Also called a *scratch awl*. (7)

primary air (in a combustion heating system). The air mixed with fuel prior to furnace ignition. (41)

primary air (in a forced-air distribution system). The air delivered to a room from the supply duct. (29)

primary coil. The coil of wire in an electrical transformer that is connected to the ac electrical source. As alternating current passes through the primary coil, it creates a magnetic field that induces alternating current in the secondary coil of the transformer. (12)

primary control unit. A type of control device that starts and stops an oil furnace while monitoring variables for safe operation. A primary control unit is equivalent to a gas furnace's ignition control module. (42)

primary heat exchanger. In a combustion heating system, a heat exchanger connected directly to the combustion chamber that transfers sensible heat from the combustion gases to the air circulated to the conditioned space. (38)

primary refrigerant. A refrigerant that absorbs heat from another fluid and rejects it from the system. In a chiller system, primary refrigerant absorbs heat from the secondary refrigerant and rejects the heat from the system. In a cascade refrigeration system, refrigerant in the high-stage subsystem cools the secondary refrigerant and rejects the heat from the system. (33)

printed circuit board (PCB). An insulated board with thin layers of conductive metal placed in strips on the board. The strips act as electrical pathways to connect electronic devices. (14)

processing plant. A plant that freezes food rapidly by exposing as much of it as possible to the lowest possible temperature using a fast-freezing system. (47)

process tube. A small length of tubing installed by the manufacturer, through a compressor's housing so the appliance's refrigeration system can be evacuated, tested, and charged during the assembly process. These are left for technicians to use to access the system if necessary. (25)

product heat load. The heat contained in products that are placed in a refrigerated space. (50)

programmable thermostat. A thermostat that contains a microprocessor that functions as a clock and allows the user to select different conditions for different blocks of time. (36)

proton. A positively charged subatomic particle that is located in the nucleus of an atom. (12)

psychrometric chart. A graph of the various properties of air, such as dry-bulb and wet-bulb temperatures, relative humidity, specific volume, and specific humidity. (27)

psychrometry. The science studying the thermodynamic properties of air and water vapor. (27)

P-type material. A positively charged semiconductor material with holes, or positively charged spaces, that are ready to receive electrons. (14)

pulley. A grooved wheel with two flanges that is used to change rotational direction, increase or decrease rotational speed, or provide mechanical advantage. (17)

pump-down. The relocation of a system's entire refrigerant charge into the liquid receiver, which allows a technician to repair leaks and replace components without having to recover a system's refrigerant charge. (11)

pump-down defrost. A method of defrost in which a liquid line solenoid valve closes before the compressor cycles off in order to remove refrigerant from the evaporator to expedite the defrosting process. (21)

pump-down solenoid. A liquid line solenoid that is closed by the defrost system while the compressor continues to run and pumps down the evaporator's refrigerant into the liquid receiver or high-side refrigerant circuit. (21)

punch. A cylindrical metal tool used for a variety of purposes, such as marking metal, punching holes, and driving out pins. See *center punch*, *drift punch*, *pin punch*, and *prick punch*. (7)

punctuality. Being on time for work and for appointments and also returning from lunch or breaks at the proper time. (1)

purge unit. In low-pressure compression chillers, an auxiliary component designed to remove noncondensables from the refrigerant circuit in order to preserve system efficiency and prevent damage. (33)

purging. The process of removing unwanted air, vapors, dirt, and moisture from a system by flushing them into the atmosphere with a compressed gas (typically nitrogen or carbon dioxide). (8)

push-pull liquid recovery method. A refrigerant recovery process that uses pressure differences to remove liquid refrigerant from an HVACR system. Vapor refrigerant is pulled from the recovery cylinder and pumped into the HVACR system, which pushes the liquid refrigerant out of the system and into the cylinder. (11)

PVC (polyvinyl chloride). A type of white plastic pipe used for cold water supply, drain lines, fresh air inlet, and some furnace exhaust applications. (8)

Copyright Goodheart-Willcox Co., Inc. 2017

PWM solenoid EEV. A refrigerant metering device that uses a pulse width modulation (PWM) signal to control the operation of a solenoid valve for variable refrigerant flow. (20)

queen valve. A service valve that is installed between the condenser and the inlet of the liquid receiver. During normal operation, warm, high-pressure refrigerant liquid flows through it. (10)

quench valve. A thermostatic expansion valve (TXV) that operates based on discharge line temperature and acts as a liquid injection valve from the liquid line to the suction line in truck and trailer refrigeration systems. (48)

quick chiller. A type of commercial refrigeration system that cools hot food rapidly and uniformly without freezing the product. (47)

quick-connect coupling. A coupling that can be connected to the evaporator coil or condensing unit without losing refrigerant or getting air into the system. (32)

radial flow fan. A centrifugal fan in which air leaves the fan at a right angle from the direction the axle is pointing. (29)

radiant hydronic system. A system in which heated water is circulated through plastic or composite tubing that is enclosed in walls or floors and causes the warmed floors or walls to radiate heat into the conditioned space. (39)

radiation. The transfer of heat by heat rays. (4)

radiator. A type of terminal unit in a hydronic system that absorbs heat from water or steam and transfers it to the conditioned space through natural convection. (39)

radon (Rn). An odorless, tasteless, radioactive, inert gas that occurs naturally in soil and rocks and has been shown to cause lung cancer. (28)

range. The set of numbers between and including the cut-in and cut-out values of a control system. (16)

range adjustment. An adjustment that regulates the minimum and maximum temperature or pressure in a control system. (16)

Rankine scale. An absolute temperature scale that uses the same increments as the Fahrenheit scale. 0°R is equal to –460°F. (4)

rated full-load speed. A motor's speed (RPM) under a full load when both the rated voltage and frequency are supplied. (15)

rated voltage. The voltage level where a motor will perform at its best. Also sometimes called *nameplate voltage*. (15)

receiver pressure regulator. An open on rise of differential pressure (ORD) valve that allows hot-gas refrigerant from the compressor discharge line to bypass the condenser and directly enter the liquid receiver when a certain pressure difference occurs between the discharge line and the liquid receiver. Commonly used for head pressure control in low ambient conditions. Also called *discharge vapor bypass valve*, *condenser bypass valve*, *ORD head pressure regulator*, and *hot-gas condenser bypass valve*. (22)

reciprocating. Up-and-down or back-and-forth movement in a straight line. (6)

reciprocating compressor. A compressor that functions by changing the rotational movement of the crankshaft into the reciprocating motion of the pistons. (18)

reclaiming. Processing a recovered refrigerant so that it is chemically pure. This is performed only at a specialized facility. EPA regulations require chemical analysis and testing to ensure purity. (10)

recovering. Removing refrigerant from a system and storing it in an external container, called a recovery cylinder. Refrigerant recovery is performed before accessing a refrigerant circuit for repair or service to prevent the venting of refrigerants into the atmosphere. (10)

recovery cylinder. A refrigerant cylinder designed specifically to store refrigerant recovered from a system. Recovery cylinders are always yellow on top and gray on the bottom. (10)

recovery/recycling machine. A machine that recovers and cleans refrigerant. These machines can be used on site or at a local service shop. (10)

rectifier. An electronic circuit made from an arrangement of diodes that converts alternating current to direct current. (14)

recycle limit. The number of times an oil furnace will try to ignite for a single call for heat before the primary control unit locks out the system. Also called *limited recycle*. (42)

recycle time. The amount of time, in seconds, before an oil furnace's igniter can attempt ignition again after a failed ignition attempt. (42)

recycling. Cleaning a refrigerant for reuse by using filter-driers to separate out contaminants. Unlike reclamation, recycling can usually be performed on the jobsite. (10)

reed switch. An electrical switch that has a pair of electrical contacts mounted on magnetic reeds sealed in a glass tube that are opened and closed by an outside magnet. (36)

refractory material. The fire-resistant material that lines a furnace's combustion chamber. (42)

refrigerant. A substance used in a refrigeration system to absorb heat from a conditioned space and release heat outside the conditioned space. Refrigerants typically have very low boiling points at atmospheric pressure. (6)

refrigerant blend. A mixture of two or more established refrigerants. These are classified as azeotropic, zeotropic, or near-azeotropic. (9)

refrigerant dye leak detection. A leak detection method that involves charging a dye into a refrigeration system. If the system has a leak, the color of the dye can be seen at the point of the leak. (10)

refrigerant jet system. A cooling system that uses waste heat to help pressurize refrigerant and drive it from the evaporator to the condenser. (48)

refrigerant line valve. A valve that controls the flow of refrigerant through system piping. (22)

refrigerant migration. The movement of refrigerant through an HVACR system during the Off cycle. (22)

Copyright Goodheart-Willcox Co., Inc. 2017

refrigerant quality. A description of how much of the mass of a refrigerant is in the liquid state and how much is in the vapor state. The percentage represents the amount of refrigerant in the vapor state. (50)

refrigeration lubricant. A lubricant charged into a refrigeration system to lubricate moving parts. The four main types of lubricants are polyol ester (POE), alkylbenzene (AB), polyalkylene glycol (PAG), and mineral oil (MO). (9)

refrigeration service valve wrench. A wrench used to operate a refrigeration service valve. These may have heads to fit milled square stem ends or may have an adapter to fit into a special socket. (7)

refrigeration system analyzer. An instrument that is the combination of a gauge manifold, temperature sensors, and other sensing elements into one package that includes digital connectivity and often some troubleshooting capabilities. (10)

register. A grille-like device through which heated or cooled air is released into a room. (29)

relative density. The ratio of the mass of a certain volume of gas compared to the mass of an equal volume of hydrogen. Hydrogen is the lightest gas and has a relative density of 1. The heavier the gas, the higher its relative density. (4)

relative humidity (rh). A ratio of the moisture content in the air compared to the maximum amount of moisture (saturation) that the air can hold at its current temperature. (27, 35)

relay. An electrical switch that operates under the control of an outside electrical signal. Relays are commonly used to start or stop other system components, such as a motors. (14)

relief valve. A safety valve that prevents equipment damage or personal injury by venting refrigerant when the system pressure exceeds the maximum safe limit. (22)

remote controller. A building system controller that can control the operation of one or more energy-consuming devices from a remote location. (45)

remote sensing. When the high-voltage electrode used to spark a flame in a furnace and the flame rod used to detect the flame are separate components. (41)

remote temperature-sensing element. A device that reacts to temperature change and sends a signal to a control device. Two common types include above-atmospheric-pressure elements and below-atmospheric-pressure elements. (16)

repair. Service required to fix a system that is not operating correctly (3).

reset limit. The number of times an oil furnace's primary control unit can be reset from a lockout. Also called *limited reset*, *restricted lockout*, or *lockout*. (42)

resistance. An electrical property that measures a material's opposition to the flow of electrons through it. (12)

resistor. An electrical or electronic component used to offer a specific level of resistance in a circuit. (12)

respiration heat. The heat produced by fruits and vegetables in cold storage as their biological processes continue and they absorb oxygen and release carbon dioxide, ethylene gas, and heat. (50)

retarder. An extra spring built into pressure gauges to measure readings at higher pressures. Pressure gauges with retarders will have a change in graduation markings at the high-pressure end of the scale. (10)

retrofitting. Updating an existing refrigeration system to new standards, usually by replacing an outdated refrigerant and certain component parts of the system. (11)

return air duct. A duct carrying air from a conditioned space to the mixing air duct or plenum. (29)

reverse bias. A diode setup that does not allow current to flow through the diode. The negative terminal of a dc power supply is connected to the anode, and the positive terminal is connected to the cathode. (14)

reverse cycle defrost. An air-source heat pump defrost method in which refrigerant flow through the heat pump is reversed, which means the heat pump essentially operates in cooling mode to melt any ice buildup on the outdoor coil but with the outdoor fan off. (40)

reverse cycle hot-gas defrost. A variation of the standard hot-gas defrost in which the flow of refrigerant through the evaporator is reversed. (21)

reverse return hydronic system. A type of two-pipe hydronic system in which all branches are approximately the same length. The terminal unit closest to the boiler has the shortest length of supply piping but the longest length of return piping, and the terminal unit farthest from the boiler has the longest length of supply piping but the shortest length of return piping. (39)

reversing valve. A four-way manifold controlled by a solenoid valve that allows a heat pump to switch between cooling mode and heating mode by causing the refrigerant to flow in either direction. (40)

ribbon burner. A type of gas burner that feeds a fuel gas and primary air mixture along the length of a burner producing a solid flame on top. (41)

rich. An air and fuel mixture in which there is too much fuel and not enough oxygen. (41)

riser (construction). A vertical component. There are a variety of risers associated with different aspects of construction. A common HVAC example is a riser used to install an air-source heat pump's outdoor unit above ground level to avoid accumulated snow from blocking side airways during the cold season. (40)

riser (tubing/piping practice). A length of vertical refrigerant line. (22)

riser valve. A shutoff valve that controls refrigerant flow through a liquid riser or suction riser. (22)

rollout switch. A furnace safety device in the form of a heat-sensing electrical switch located near the burners that is designed to cut off the gas supply if a flame rollout occurs. (41)

Copyright Goodheart-Willcox Co., Inc. 2017

roof mist cooling system. An evaporative cooling system in which small amounts of water are misted on top of the roof. When the water evaporates, it absorbs a relatively large amount of heat from the roof's surface and prevents the heat from entering the structure. (34)

roof pond cooling. A method of evaporative cooling by maintaining a certain level of water covering the surface of a building's roof. The water blocks heat from sun rays and absorbs heat from indoors. Evaporation cools the standing water and system controls maintain the water level. (34)

rooftop unit (RTU). A packaged air-conditioning system designed specifically to be installed on the roof of a building. (33)

room air conditioner. An inexpensive and simple self-contained air-conditioning system that provides cooling to a portion of a building or residence. These are available as window units or through-the-wall units. (31)

root mean square (rms). The value used to equate the heat produced by an alternating current to a direct current value that would produce the same amount of heat. (13)

rotary compressor. A compressor in which vapor compression takes place in spaces between the cylinder wall and sides of an off-center rotor that spins inside the cylinder. (18)

rotating disk humidifier. A humidifier that uses a series of plastic disks covered with shallow grooves. The disks are partially submerged in a water pan. As air passes around the rotating disks, the residual water in the grooves evaporates into the air. (35)

rotating drum–type humidifier. A humidifier that uses a water pan and a rotating drum covered in an absorbent filter sleeve. The bottom portion of the drum is submerged in the water pan. As the drum rotates, it soaks up water from the pan. The water evaporates from the sleeve when the moistened section is rotated into the airstream. (35)

rotor. In an electric motor, an axle-mounted unit that rotates as the polarities of the stator's field poles change. In some cases, a rotor can also be called the *armature*. (15)

router. In BACnet, a device that passes a message from one device to another in a network without changing the form or content of the message. (45)

RSES. The Refrigeration Service Engineers Society, which is an organization that provides educational and certification programs to HVACR professionals of varying experience levels. (1)

run capacitor. A device that uses a stored electrical charge to boost motor torque while the motor is running. Run capacitors also dissipate heat generated by the motor. (15)

running terminal. The motor terminal on a single-phase hermetic compressor that connects to one end of the run winding. The opposite end of the run winding is connected to the common terminal. (15)

run winding. Stator windings that are energized during the entire operation of a single-phase induction motor. Run windings are made of larger diameter wire than start windings, which gives them a lower resistance. (15)

rupture disc. A valve body containing a thin metal disc that bursts before the pressure in a system reaches dangerous levels. Used as a one-time pressure relief valve. (22)

R-value. See *thermal resistance*. (37)

safety data sheet (SDS). A document in a uniform format that includes section numbers, headings, and associated information to communicate the hazards of hazardous chemical products, as required by OSHA's Hazard Communication Standard (HCS). (2)

sail switch. An electrical switch that is actuated by flow pushing against a sail to mechanically change the position of the switch. In a furnace, a sail switch acts as a safety device that confirms combustion blower operation by using a large paddle to catch the blower's draft to open or close electrical contacts. Also called *vane switch* or *airflow switch*. (41)

saturated liquid. In an HVACR system, a refrigerant in liquid form under conditions that would cause some of the liquid to vaporize if any amount of heat were added or if pressure was decreased. (50)

saturated vapor. In an HVACR system, a refrigerant in vapor form under conditions that would cause some of the vapor to condense if any amount of heat were removed from it or if pressure was increased. Saturated vapor is most commonly found in an HVACR system's evaporator and condenser during system operation. (5)

Schrader valve. A type of valve that consists of a hollow tube with a spring-loaded pin that blocks access through the tube. The valve is opened when the pin is pushed down and automatically closes to minimize refrigerant loss. (10)

Scotch yoke. A variation of the reciprocating compressor that has a long piston with an elliptical slot at the bottom of its skirt. The piston is connected directly to the crankshaft pin, which slides from side-to-side in the slot as the crankshaft rotates. Scotch yoke compressors have no connecting rods. (18)

screw compressor. A compressor in which vapor is compressed by a pair of meshing helical rotors. (18)

screwdriver. A hand tool consisting of a handle, a shaft, and a head with a sized and shaped tip, used for turning screws. (7)

scroll compressor. A compressor in which vapor compression takes place between a fixed scroll and an orbiting scroll. (18)

seasonal average COP. The average efficiency of a system throughout a heating or cooling season. (46)

seasonal energy efficiency ratio (SEER). A rating similar to EER that estimates the average efficiency of an air conditioner throughout the entire cooling season. (46)

secondary air. The air added to a furnace's flame after ignition to support combustion. (41)

secondary coil. The coil of wire in a transformer in which voltage is induced by the changing magnetic field

Copyright Goodheart-Willcox Co., Inc. 2017

created by alternating current passing through the primary coil. (12)

secondary heat exchanger. In a combustion heating system, a heat exchanger attached at the outlet of the primary heat exchanger. It transfers both sensible and latent heat from the combustion gases to the circulating air. The transfer of latent heat allows some of the combustion gas to condense to liquid. (38)

secondary loop refrigeration system. A commercial refrigeration system in which a secondary loop circulates a nonphase-changing fluid for absorbing heat from a conditioned space and transfers that heat through a heat exchanger to a phase-changing refrigerant in a direct expansion refrigeration circuit. (49)

secondary refrigerant. In a compression chiller system, a fluid that is circulated to absorb heat from a conditioned space. In a cascade refrigeration system, refrigerant in the low-stage subsystem that provides cooling to the conditioned space. (33)

Seebeck effect. The concept underlying the production of thermoelectricity. When heat is applied to the junction of two dissimilar metals (a thermocouple's hot junction), the temperature difference between the two metals produces a voltage. (14)

selective surface. A special absorber surface used to increase the temperature of a collector. (44)

self-contained air-conditioning system. A comfort cooling system with all parts and controls in a single cabinet. An example is a room air conditioner unit. (31)

self-contained water cooler. A standalone water cooler that has its own water supply from a tank and does not have a drain. (47)

semiconductor. A material or substance that is ordinarily an insulator, but can be made to conduct electricity. A semiconductor's conductivity may be controlled by light, pressure, temperature, and other devices. (12)

semi-hermetic compressor. A compressor that contains a motor and compressor inside a multipart shell that is bolted together. Sometimes called *serviceable hermetic compressor*. (18)

sensible heat. Heat that causes a temperature change in a substance. (4)

sensible heat ratio (SHR). The amount of heat that affects the air temperature compared to the total heat added to or released from the air. (27)

sensing bulb. A sealed fluid-filled sensing device that reacts to heat by changing its internal pressure. A sensing bulb is connected by a capillary tube to a diaphragm or bellows, such as on a TXV or temperature motor control. (16)

sensor. A device that detects and responds to a stimulus, such as a change in temperature or pressure. Most sensors are electronic devices and used in control circuits. (14)

sequencer. A device that closes and opens its electrical contacts on a time delay for energizing a series of electrical loads in sequence. It is used to control when each heating element is energized in an electric furnace or duct heater. (43)

series circuit. An electrical circuit in which current has only a single path to follow. (12)

series loop hydronic system. A system designed so that all of the circulating water passes through each component in the system before returning to the boiler. (39)

series-parallel circuit. An electrical circuit that includes a combination of series and parallel circuits. (12)

server. A controller or device in a building control system that uses BACnet. (45)

service. Work that involves performing scheduled maintenance or troubleshooting and repairing existing systems. (1)

service heat load. The sum of the various heat loads that result from operation of a refrigeration system for a given period of time, usually 24 hours. Includes heat loads resulting from products stored in the cabinet, cabinet air changes, and operation of fans, lights, and other electrical devices inside the cabinet. Also called *usage heat load*. (50)

service valve. A refrigerant valve that enables technicians to seal off parts of a refrigeration system and provide a connection to the system for taking pressure readings and adding or removing refrigerant or oil. When installed at certain points of the system, the service valve is given a specific name. See *discharge service valve (DSV)*, *king valve*, *liquid line service valve*, *liquid receiver service valve (LRSV)*, *queen valve*, *suction line service valve*, and *suction service valve (SSV)*. (10)

servicing. Performing the work needed to correct a problem. (3)

set point. The desired condition in a closed-loop control system. (16)

shaded-pole motor. A single-phase motor that uses shaded field poles instead of a start winding to produce starting torque. One-third of each stator pole is split from the rest of the pole and wrapped with a copper band or copper wire. (15)

shaft seal. On open-drive compressors, a sealing device that is installed between a shaft and the case where it emerges. (18)

shell-and-coil condenser. A water-cooled condenser consisting of a coil of copper water tubing winding around the inside of a metal refrigerant shell. (21)

shell-and-tube condenser. A water-cooled condenser composed of a long refrigerant cylinder filled with straight copper tubes that circulate cooling water. (21)

short circuit. An electrical problem that results when a conductor routes current around a component or an electrical load instead of through it. With no electrical load, a short circuit's current value is very high. (13)

short cycling. When an HVACR system starts and stops too frequently, running for a shorter time than it should. (17)

Copyright Goodheart-Willcox Co., Inc. 2017

shutoff valve. A two-way valve used to block flow through a refrigerant line. An example is a manual valve that blocks or permits refrigerant flow through an evaporator in a multiple-evaporator system. (22)

sick building syndrome (SBS). An indoor air quality condition that can be confirmed when approximately 20% or more of a building's occupants complain of drowsiness, fatigue, eye and skin irritations, or respiratory problems. (28)

side-by-side. A refrigerator-freezer in which the frozen food is on one side of the cabinet and the fresh food compartment is on the other. (23)

sight glass. A small viewport installed in a refrigerant liquid line used to observe fluid flow and may contain a moisture indicator element. (22)

signal word. A specific word used to emphasize hazards and indicate the relative level of severity of the hazard assigned to a GHS hazard class and category. (2)

silicon-controlled rectifier (SCR). A three-terminal semiconductor switching device that conducts current in only one direction. The device's breakover voltage must be exceeded or current must be applied to its gate circuit in order to trigger conduction. (14)

single flare. A flare made with a single thickness of tubing. (8)

single phasing. A condition in which a three-phase motor loses one or more of its three phases. (17)

single-cut file. A type of file that has teeth cut in one direction, used for finishing surfaces. (7)

single-effect absorption system. An absorption system in which all of the heat released in the condensation of the refrigerant is transferred to the cooling water and then dissipated to the atmosphere in the cooling tower. A single-effect absorption system has one generator, while a double-effect absorption system has two generators. (34)

single-phase. A type of electrical power that has a single alternating voltage signal. Most residential power circuits operate on 120 V single-phase power. (13)

single-phase motor. An ac induction motor that runs on a single phase of alternating current. (15)

slave thermostat. In a zoned system, a room thermostat that measures temperature and issues calls for system operation to a master thermostat. See *master thermostat* and *master-slave thermostat design*. (36)

slip. The difference between a motor's synchronous speed and rated full-load speed due to magnetic slippage. (15)

slip ring. A cylindrical piece of conductive material used in an ac electrical generator to transfer the electricity from the wire loop (rotor) to the brushes. (12)

slip ring lubricating system. A motor bearing lubrication system in which a brass ring rests on the motor shaft and dips into the oil well below as the shaft turns to lubricate the bearing. (17)

slotted burner. A type of gas burner that feeds a mixture of fuel gas and primary air through a series of narrow slots. (41)

smoke. A composition of solid particles carried into the atmosphere by gaseous products of incomplete combustion. (28)

smoke test. A test in which a sample of flue gas is passed through filter paper that becomes stained by the smoke. The stained paper is compared with premade samples to gauge whether incomplete combustion is occurring. (42)

SNAP (Significant New Alternatives Policy). The EPA program that evaluates and regulates substitutes for high ODP refrigerants. Its goal is to progress the phase out of older refrigerants and meet the ozone protection provisions of the Clean Air Act (CAA). (9)

snap-action evaporator pressure regulator. An EPR with a definite cut-in pressure and temperature, causing the valve to be only fully open or fully closed. (22)

socket wrench. A type of wrench that consists of a bar or handle with a socket head on one end. (7)

soft lockout. A system shutdown after a furnace fails to light during its trial for ignition (TFI) period. An ignition control module with soft lockout quits trying to ignite the furnace for a specified period of time before attempting ignition again. (41)

soft water. Natural, untreated water with a low mineral content (less than 5 grains per gallon) and no chlorides. The natural source is rainwater. (35)

softened water. Water in which minerals have been removed by the ion exchange process (as with a water softener). Unwanted mineral ions are replaced with water-soluble sodium salts. (35)

solar array. An electrical device consisting of a large array of connected solar cells or solar modules. (44)

solar cell. A cell that converts light energy into electrical energy through the process of photovoltaics. (44)

solar domestic hot water (DHW) system. A system that harnesses solar energy to heat domestic water for tasks such as dishwashing, showering, and laundry. (44)

solar energy. Electromagnetic energy transmitted by the sun. (44)

solar module. An individual solar panel consisting of multiple solar cells, wiring, a frame, and glass. (44)

soldering. A process of joining metal objects with a filler metal that has a melting temperature below 840°F (450°C). (8)

solenoid. An electromagnetic device composed of a coil of wire wrapped around a case with a movable iron core that is called a plunger. These are commonly fitted to a valve body and used to control the opening and closing of valves. (14)

solenoid valve. An automatically controlled valve operated using an electromagnet to open and close a fluid passage with a movable core (plunger). (22)

solenoid water valve. An electric water valve that opens and closes by the operation of a solenoid. (33)

Copyright Goodheart-Willcox Co., Inc. 2017

solid. Any physical substance that keeps its shape and volume even when not contained. (4)

solid desiccant. A drying agent, in solid form, used in a filter-drier to adsorb moisture in the system. (26)

solid-state device. A semiconductor device. An electronic device with no moving parts. (14)

solid-state igniter. A device that uses solid-state circuitry to generate a high voltage necessary to ignite a flame in an oil furnace. (42)

solid-state relay (SSR). A relay that uses electronic components (such as transistors, silicon-controlled rectifiers, or triacs) rather than mechanical components to switch circuits on and off. SSRs are used to start single-phase motors and are often referred to as *electronic relays*. (16)

solvent welding. The process of joining two components of the same plastic material using a solvent that temporarily dissolves the surface polymers, allowing the polymer chains to become entangled. (8)

spark igniter. A device that creates an electric spark across a gap between two electrodes when the ignition control module applies a high voltage to the electrodes. A spark igniter is just one of several different types of ignition methods of gas-fired appliances. (41)

specialty certification. A certification that focuses on a specific topic that is either outside the scope of work for a typical HVACR technician or more specific than topics included in standard professional certification. (1)

specific enthalpy. Enthalpy per unit of mass, measured in Btu per pound or joules per kilogram. (4)

specific gravity. The ratio of the mass of a certain volume of a liquid or a solid compared to the mass of an equal volume of water. (4)

specific heat capacity. The amount of heat added to or released from 1 lb of a substance when it changes 1°F. (4)

specific volume. The volume of a specific amount of gas under standard conditions. In US Customary units, specific volume is the volume of 1 lb of gas at 68°F and 29.92 in. Hg of pressure. In air measurement, the volume of space an amount of air will occupy at a given pressure and temperature. (4)

splash system. A compressor lubrication system that relies on the moving internal parts of the compressor to distribute oil by splashing. (18)

split air-conditioning system. A comfort cooling system that divides up its components into two or more separate locations. A split system's condensing unit may be placed outdoors and its evaporating unit may be placed indoors. (31)

split condenser valve. In a split condenser arrangement, a three-way solenoid valve in the discharge line that responds to ambient conditions or high-side pressure by directing refrigerant into only one of the condenser spaces (summer/winter condenser) during low ambient conditions or directing refrigerant into both condenser spaces (summer condenser and summer/winter condenser) when head pressure is high enough. (22)

split damper. A damper used where an air path branches off into two directions. When it closes one branch of the duct, it opens the other. (29)

split system. A site engineered refrigeration system whose condensing unit, evaporators, piping, and wiring were purchased separately and assembled at the jobsite. These are often custom designed for specific applications. (49)

split-phase motor. A single-phase induction motor that uses the different inductance values of its start winding and run winding to produce phase splitting and achieve initial rotation. (15)

spot cool. Using an air conditioner to cool a specific, limited area. (31)

spring-loaded relief valve. A valve that opens to vent refrigerant under excessive pressure and then closes when enough refrigerant has been released from the system to lower the pressure. (22)

spud. A gas burner attachment with a specially sized orifice designed to direct an exact amount of fuel gas into a burner. (41)

squirrel cage rotor. An electric motor's rotor that is made of metal bars mounted on an iron core. (15)

stack relay. A heat-sensing device that uses a bimetal element to detect an oil burner flame. A stack relay is mounted in the flue of an oil furnace so that it can sense the heat produced by fuel oil combustion. Also called *stack switch*. (42)

stack temperature. The temperature of the flue gas in the flue minus the temperature of the combustion air. Combustion air temperature varies by its source. If it is drawn in from the furnace room, combustion air will be at room temperature. If it is drawn in from outdoors, it will be outdoor air temperature. Stack temperature is indicative of a fuel-burning appliance's combustion efficiency. The lower it is, the more efficient it is. Stack temperature may also be called *net stack temperature*. (41)

standard oil burner. An oil burner with a combustion head that directs combustion air to produce a somewhat lazy and unrestrained flame. (42)

standby. The time when an oil furnace is not burning fuel oil for heat. (42)

standby power. When a refrigerated trailer's refrigeration system is plugged into the electrical grid while the trailer is idle. (48)

standing-pilot ignition system. A type of gas furnace ignition system that uses a continuously burning pilot to ignite the burners when there is a call for heat. (41)

start capacitor. A capacitor used to provide starting torque during the start-up of some single-phase motors. A start capacitor is dropped out of the motor circuit after the motor reaches full speed. (15)

starting collar. A coupling used to join round ducts to a square duct or plenum. Starting collars have a tabbed

Copyright Goodheart-Willcox Co., Inc. 2017

end that is inserted into the plenum and a crimped end over which is inserted the plain end of a round duct. (29)

starting terminal. The motor terminal on a single-phase hermetic compressor that connects to one end of the start winding. The opposite end of the start winding is connected to the common terminal. (15)

start winding. Stator windings that are used for motor starting and additional torque in single-phase induction motors. Start windings are made of smaller diameter wire than run windings, which gives them a higher resistance. (15)

starved evaporator. A condition in which not enough refrigerant flows into the evaporator, resulting in superheat that is too high and a severely reduced cooling effect. (22)

starving. A condition in which liquid refrigerant is present in only part of the evaporator. (20)

static electricity. The accumulation of an electric charge that results when an object picks up negative charges, such as when rubbing against another object. In maintaining air quality, static electricity is used by electronic air cleaners, which build up an electric charge on particles in the air. (12)

static loss. The pressure drop that occurs from the bottom of a riser to its top due to the weight of liquid refrigerant in the line. (51)

static pressure disk. A component mounted inside an oil burner's air tube that is designed to disturb airflow from the burner fan to create turbulence for mixing air and fuel oil. Also called *static disk*. (42)

stationary refrigerant detector. A refrigerant detector in a fixed location that will note an increase of refrigerant vapors or gases in advance of dangerous levels. These may be installed in a mechanical room or use multiple sensors throughout a facility that communicate with a central unit. (2)

stator (centrifugal compressor). The volute casing that holds the rotating impeller of a centrifugal compressor. (18)

stator (electric motor). The stationary part of an electric motor that is attached to the inside of the motor housing. The stator can also be called the *frame*. (15)

steam heating system. A type of hydronic system in which water is heated into steam and piped to radiators throughout the conditioned space. The steam releases heat as it condenses back into a liquid inside the radiator and returns to the boiler for reheating. (39)

steam jet system. A system that provides cooling using high-pressure steam to induce low pressure in an evaporator. (48)

Stirling cycle. A closed thermodynamic cycle that can convert thermal energy into mechanical energy and vice versa. (48)

stoichiometric combustion. A form of combustion in which the burning of fuel occurs with the exact amount of oxygen needed to change the carbon and hydrogen molecules into water and carbon dioxide. Also called *perfect combustion*. (41)

storage cylinder. A large 100- to 150-lb refrigerant cylinder that is used to charge smaller service cylinders. A storage cylinder is often positioned upside-down with the valve at the bottom. (10)

stratification. A gradual difference in air temperature from floor to ceiling because cold air sinks to the floor and warmer air rises to the ceiling. (27)

stratosphere. The layer of the atmosphere that extends from 56,000′ (10.6 mi) up to 170,000′ (32 mi). The stratosphere contains the ozone layer. (27)

street fitting. An angled fitting that is male on one end and female on the other. Street fittings may be threaded steel pipe fittings, brazed/soldered fittings for copper tubing, or plastic fittings, too. The purpose of street fittings is to reduce the number of fittings used for offsets and other configurations (8)

stroke. The distance traveled by a piston, such as in a reciprocating compressor. (51)

strong solution. In an absorption refrigeration system, a solution in which the absorbant is saturated with refrigerant. To contrast, see *weak solution*. (34)

structural insulated panel (SIP). A prefabricated building material made of a foam core between two layers of oriented strand board or plywood. These can be used to build walls and roofing. (46)

subcooler. A type of heat exchanger through which flows liquid line refrigerant of a low-temperature system and the low-side refrigerant of a high-temperature system. A subcooler acts as the high-temperature system's evaporator and absorbs heat to subcool the liquid line refrigerant of the low-temperature system for increased system efficiency. (21)

subcooling. The amount of heat removed from a refrigerant after it has condensed, measured in degrees. Technicians calculate subcooling to determine if systems with thermostatic expansion valves have the correct refrigerant charge. (11)

sublimation. The process of a solid changing directly into a vapor. (48)

suction line. The tubing used to carry refrigerant vapor from evaporator to compressor. (6)

suction line-liquid line heat exchanger. A component that brings the liquid line into contact with the suction line so that heat of the warmer liquid line transfers to the cooler suction line. This protects certain components and increases overall system efficiency. (21)

suction line pressure drop. The pressure difference between the pressures measured at an evaporator outlet and a compressor inlet. (54)

suction line service valve. A low-side service valve connected to the suction line of a system. During normal operation, cool, low-pressure refrigerant vapor flows through it. (10)

Copyright Goodheart-Willcox Co., Inc. 2017

suction pressure. In an HVACR system, another name for *low-side pressure* and *evaporator pressure*. (6)

suction service valve (SSV). A low-side service valve connected directly to a compressor at its inlet, considered a compressor service valve. During normal operation, cool, low-pressure refrigerant vapor flows through it. (10)

sulfur dioxide (SO_2). A common gaseous pollutant produced by burning coal, gas, or oil. (28)

summer condenser. A section of a condenser used in a split condenser arrangement that is used as a condenser in warm and moderate weather and evacuated and isolated during low ambient conditions. This is used as one method of head pressure control for low-ambient conditions. (22)

summer/winter condenser. A section of a condenser used in a split condenser arrangement that is used as a condenser year-round. In low-ambient conditions, the summer condenser is evacuated and isolated, and the summer/winter condenser functions as the only condenser. This is used as one method of head pressure control for low-ambient conditions. (22)

superheat. The amount of heat added to a refrigerant after it has evaporated on the low side (measured in degrees). With capillary tubes system, technicians calculate superheat to determine the correct refrigerant charge. When used with thermostatic expansion valves, superheat refers to the difference in temperature between the evaporator inlet and the sensing bulb. (11)

superheated. A condition in which a vapor's temperature has increased above its boiling point. A superheated refrigerant will need to reduce in temperature (reduce sensible heat) before it can condense into a liquid (reduce latent heat). (6)

supplied-air respirator. A respirator that provides supplemental oxygen. (2)

sustainable design. The use of materials and processes that lower energy costs, reduce operating and maintenance costs, increase productivity, and decrease the amount of pollution that is generated. (37)

swaging. The mechanical enlarging of one piece of tubing to allow another piece of tubing of the same diameter to be inserted into the enlarged tubing. The joint is then soldered or brazed. (8)

sweet water. Tap water used in immersed evaporators. (21)

sweet water bath. A setup with an evaporator immersed in sweet water. (21)

swinging-vane anemometer. An air velocity-measuring instrument that operates on the principle that incoming air will push on a small vane, causing it to deflect at different angles as the air velocity changes. (27)

switch. An electrical device used to open or close any part of an electrical circuit by disconnecting and connecting contacts. (14)

synchronous speed. The speed (RPM) of the rotating magnetic field in an electric motor's stator. A motor runs at synchronous speed if the speed of the rotor equals the speed of the stator's rotating magnetic field. (15)

synthetic dust weight arrestance. A measure of an air filter's ability to remove synthetic dust from the air. It is calculated by comparing the weight of the synthetic dust that gets caught in an air filter being tested and the weight of the amount of dust fed into the air filter. (28)

system lag. A temperature drop occurring between the time the heating system turns on and the time heat is delivered to the conditioned area. (36)

system overshoot. Concerning control systems, when the temperature of a conditioned space exceeds the thermostat's set point. It is a heat lag that occurs when a furnace shuts down and the amount of residual heat that has built up is sent by the blower through the ductwork and into the conditioned space, raising the temperature above the thermostat set point. (36)

tagout (TO). The practice of placing a tag on a mechanism or an electrical switch to inform others that service work is in process and that this mechanism or switch's position should not be changed. (2)

taking initiative. Seeing what needs to be done and doing it without being told. (1)

tap water cooler. A water cooler that has a plumbed water supply and drain connections. (47)

tare weight. The weight of a refrigerant cylinder when it is empty, typically stamped on the outside of the cylinder. (11)

temperature. The measure of the heat intensity or heat level of a substance. (4)

temperature glide. The temperature difference between the bubble point and dew point (vapor and liquid states) of a zeotropic blend. Zeotropic blends are unique because most substances evaporate and condense at a single temperature for any given pressure. See *bubble point* and *dew point*. (9)

temperature limit switch. In a heating system, a safety control that ensures that a measured temperature does not exceed a certain level. (36)

temperature motor control. A device that reacts to the heat it senses by closing or opening an electric switch to start or stop the operation of a motor. (16)

temperature survey. Taking and recording temperature measurements at different locations (such as along a liquid line) and comparing them. (54)

temperature swing. The total difference of the high and low temperature in a room. (36)

terminal unit. A hydronic system heat exchanger that transfers heat from circulating water or steam in a hydronic system to the air in a conditioned space. Also called *heat emitter*. (39)

therm. A quantity of heat equal to 100,000 Btu. (4)

thermal conductance (C-value). The measure of the amount of heat that will pass through one square foot of the

Copyright Goodheart-Willcox Co., Inc. 2017

component in one hour when there is a temperature difference of 1°F between one side of the component and the other. (37)

thermal conductivity (K-value). The measure of the amount of heat that will pass through one square foot of the material one inch thick, in one hour, when there is a 1°F temperature difference between the two sides of the material. (37)

thermal detection system. In a standing pilot appliance, a system of confirming that a pilot light is still burning, usually sensing it with a thermocouple or bimetallic element. (41)

thermal energy storage (TES). The temporary storage of heat energy for later use. (44)

thermal mass. A physical characteristic in which a substance readily absorbs and stores heat. Equivalent to thermal capacitance or heat capacity. (44)

thermal overload. A type of compressor protection device mounted to the compressor shell near the compressor motor terminals and wired in series with the common wire. Its bimetal element controls a normally closed (NC) switch and reacts to compressor and ambient air temperature by opening on a rise in temperature to shut off the compressor. Sometimes called a *bimetal overload*. (19)

thermal precipitation. The collection of dirt around warm-air grilles and windows resulting from a tendency of dirt suspended in the warm air to collect on cooler surfaces. (30)

thermal resistance (R-value). A measure of a material's or building component's resistance to heat transfer. (37)

thermal stability. A lubricant's ability to remain stable in high heat areas. (9)

thermal transmittance (U-value). The rate of heat transfer through one square foot of a structure in one hour when there is a temperature difference of 1°F between one side of the structure and the other. Unlike thermal conductance, it includes an adjustment for air movement and boundary air films. (37)

thermistor. A solid-state device that changes its resistance as its temperature changes. See *negative temperature coefficient (NTC)* and *positive temperature coefficient (PTC)*. (14)

thermocouple. A device made of two dissimilar metals that generates electricity when it is heated. (14)

thermoelectric couple. A junction formed by one N-type material and one P-type material that uses the Peltier effect to produce thermoelectric refrigeration. (48)

thermoelectric module. Several thermoelectric couples connected in series to produce a greater thermoelectric refrigeration effect. (48)

thermoelectric refrigeration. The process of transferring heat energy from one place to another using the movement of electrons, based on the Peltier effect. (48)

thermometer. An instrument used for measuring temperatures. (7)

thermosiphon effect. The natural movement of water resulting from water rising as it heats and falling as it cools. (44)

thermosphere. The layer of the atmosphere that extends from 280,000′ (53 mi) to 2,100,000′ (400 mi). This layer contains the ionosphere and is marked by temperatures that increase with altitude, reaching 2730°F (1500°C). (27)

thermostat. In basic terms, a sensing device that reacts to temperature change. More broadly, a temperature control that starts and stops an HVAC system when preset temperature conditions are reached. (36)

thermostatic expansion valve (TXV). A type of expansion valve metering device that adjusts refrigerant flow rate based on maintaining a superheat value that is being measured by a sensing bulb at the evaporator outlet. By modulating the refrigerant flow rate, the valve can compensate for varying loads. (20)

thermostatic mixing valve (TMV). In a hydronic heating system, a type of mixing valve with a built-in thermostatic element that reacts physically to changes in water temperature at the valve outlet in order to adjust the mixture ratio as needed to maintain the desired temperature. (39)

thermostatic water valve. A water valve that regulates water flow to a water-cooled condenser based on the temperature of condenser exhaust water. (33)

thin film solar cell. A solar cell that is constructed by depositing layers of photovoltaic material on a ceramic, stainless steel, or glass substratum. (44)

three-phase. A type of electrical power that has three alternating voltage signals in a single circuit. The three separate voltage signals alternate in three separate phases, which creates the effect of providing constant power. (13)

three-phase motor. An induction motor that has three sets of stator windings that are energized by three-phase power. Each set of windings is connected to one phase of the three-phase power source. (15)

throw (in air distribution work). In reference to room air movement, the distance air travels from a duct outlet before it slows to 50 fpm. (29)

throw (in electrical work). The movement of an electrical switch's pole. (14)

time-delay fuse. A fuse that will not blow unless an overload condition exists for a certain period of time, typically ten seconds. Also called a *dual-element fuse*. (16)

time-initiated, pressure-terminated defrost timer. A defrost timer that turns on defrost operations at a preset time and turns off defrost operations when a preset pressure is reached. (21)

time-initiated, temperature-terminated defrost timer. A defrost timer that turns on defrost operations at a preset time and turns off defrost operations when the evaporator reaches a preset cut-out temperature. (21)

time-initiated, time-terminated defrost timer. A defrost timer that turns on defrost operations at a preset time and turns off defrost operations at a preset time. (21)

Copyright Goodheart-Willcox Co., Inc. 2017

ton of refrigeration. The refrigerating effect (cooling capacity) equal to the melting of 1 ton of ice in 24 hours, equivalent to 288,000 Btu/day or 12,000 Btu/hr or 200 Btu/minute. (4)

top freezer. A refrigerator-freezer design in which the frozen food compartment is located above the fresh food compartment. (23)

torque. The work performed by a twisting or turning action, such as a rotating motor shaft. (15)

torque wrench. A type of wrench, similar to a socket wrench, that consists of a socket head on one end and a handle with a gauge for measuring torque. (7)

torr. A unit of pressure equal to 1/760 of an atmosphere (1 mm Hg), normally used for measuring vacuum pressure. (5)

total cooling load. A combination of sensible and latent heat gain required to be removed from a building for hot weather cooling. (37)

total effective length (TEL). The greatest effective length for a supply duct run in a system added to the greatest effective length for a return duct run. (29)

total energy management (TEM). A conservation concept in which a building is viewed in terms of its total energy usage, rather than by analyzing the requirements of separate systems. (45)

total energy system. An electricity generating system designed to capture and use waste heat in a building. Also called a *cogeneration system* or *combined heat and power (CHP) system*. (46)

total equivalent length. A calculated value determined by adding of the length of a refrigerant line and the equivalent length for each fitting and valve used along the line. This value is used to calculate pressure drop. (51)

total heat load. The sum of the heat loads resulting from heat leakage, air changes, stored products, and miscellaneous heat sources. (50)

total heat loss. The amount of heat required to be added to a building in Btu/hr for cold weather heating. (37)

total heat of rejection (THR). The total heat load for a refrigeration system and the energy added to the refrigerant by the compressor. A value referenced when selecting a system's condenser. (51)

total pressure drop. In reference to blower sizing, the difference between the supply air duct static pressure and the return air duct static pressure. (29)

toxicity. A measure of the harm that exposure to a substance can cause a person. ASHRAE Standard 34 classifies refrigerants as either Class A (nontoxic) or Class B (toxic). (9)

transducer. A device that converts an input signal from one form of energy to an output signal of another form of energy. (14)

transformer. Electromagnetic device used to transfer an alternating current from one coil of wire to another through a magnetic field. (12)

transistor. A layered, three-terminal semiconductor device that is used to either switch or amplify an electrical signal. (14)

triac. A solid-state device with three terminals that conducts current in both directions. Current must be applied to its gate circuit in order to trigger conduction. It will only stop conducting when current drops below its preset holding current threshold. (14)

trial for ignition (TFI). The limited amount of time that an ignition control module gives an igniter to ignite a gas burner flame. TFI is usually measured in seconds. (41)

trigeneration. In a combined heat and power (CHP) plant that generates electricity, using some of the steam for heating and some of the steam to power an absorption chiller. Also called *polygeneration*. (34)

triple evacuation. A method of evacuating a refrigeration system in which a technician uses a vacuum pump to pull a vacuum of 28 in. Hg three times. After the first and second time the vacuum is pulled, the system is charged back to atmospheric pressure using nitrogen. (11)

tripped circuit breaker. A circuit breaker (electrical overload protection device) that has opened due to high current and must be manually reset. (16)

troposphere. The layer of the atmosphere that extends from sea level at the equator to an altitude of 56,000′ (10.6 mi). This layer contains 75% of the earth's air. (27)

trouble code. A form of visual communication used by a unit to indicate a malfunction. Trouble codes are typically communicated using a flashing LED on the unit. (3)

troubleshooting. A systematic analysis of a problem to determine the proper corrective action. (3)

troubleshooting chart. A chart that lists common troubles, symptoms, their causes, and remedies. The chart can be used as a general guide for identifying system problems. (25)

true power. The actual power used by a circuit, measured in watts. (13)

tube-within-a-tube condenser. A water-cooled condenser consisting of an inner tube through which water flows in one direction and a surrounding outer tube through which refrigerant flows in the opposite direction. (21)

tubular cased wire. An electrical heating element surrounded by magnesium oxide powder and enclosed in a heat- and corrosion-resistant steel tube. The tubular casing protects against electrical shock while still allowing the element to reach high temperatures. (43)

twist drill bit. A type of drill bit with a straight shank and fluted shaft, commonly used for drilling holes in metal, wood, and plastic. (7)

two-pipe fuel delivery system. A fuel delivery system that has a supply line from the fuel oil tank to the oil burner and a separate return line running from the oil burner back to the fuel oil tank. (42)

two-pipe hydronic system. A hydronic system in which one pipe supplies hot water from the boiler to the terminal

Copyright Goodheart-Willcox Co., Inc. 2017

units and another pipe carries return water from the terminal units back to the boiler. (39)

two-stage furnace. A furnace designed to produce two different levels of heating operation, allowing it to adjust heat output to meet demand. (38)

ultimate carbon dioxide content. In reference to furnaces and boilers, the specific amount of carbon dioxide by volume that is present in flue gas when the exact amount of air is supplied to achieve complete combustion. (41)

ultimate vacuum. A specification of a vacuum pump indicating the highest vacuum that a vacuum pump can pull, typically measured in microns. Also called *blank off pressure*. (10)

ultrasonic. A sound frequency above the range of human hearing. (25)

ultrasonic leak detector. An instrument that detects sound waves that are beyond the range of human hearing, such as the sound of vapor escaping from a pressurized system. (10)

ultraviolet lamp. A lamp that produces ultraviolet light, which is commonly used to help control bacteria and mold growth in HVACR applications. (47)

under-duct humidifier. A central humidifier that is designed to be installed through the bottom of a return or supply ductwork. (35)

ungrounded conductor. A hot wire connected to the phase lines of a transformer. (13)

unintentional voltage drop. A condition in which the applied voltage from a power source is unintentionally reduced in a circuit. This may be down to a level that is too low for safe use on electrical loads in the circuit. (13)

unit heater. A ductless, forced-air heating unit designed to heat a large area or to be used in a specific heating application. (38)

unitary central air-conditioning system. A system with all the components needed to heat, cool, dehumidify, filter, and move air included in one unit. (32)

unloader. A mechanism that reduces the load on a compressor to aid startup or to modulate a compressor's capacity. An unloader may be operated mechanically, electrically, or hydraulically. (18)

unvented attic. An attic that is closed off and essentially made into part of the conditioned space, often by heavily insulating the underside of the roof to prevent heat loss and heat gain. (29)

upflow furnace. A furnace in which return air is taken in from the bottom and forced upward around the heat exchanger and into the supply plenum. It is commonly installed in basements where ductwork runs above the level of the furnace. (38)

upright freezers. Freezer units that have the door on the side of the unit, like a refrigerator. (23)

U-value. See *thermal transmittance*. (37)

UVG. An acronym for *ultraviolet germicidal*. This refers to the use of the C band of ultraviolet light (UVC) in ductwork to kill microorganisms, such as viruses, bacteria, and fungi. (28)

vacuum gauge. An instrument for measuring pressures below atmospheric pressure. (10)

vacuum pump. A device used to evacuate a refrigeration system of moisture and contaminants by creating a very low pressure inside the system. (10)

valve adapter. A device used for connecting gauges and charging cylinders to a hermetic system. One part of the adapter has a removable valve stem that operates a small needle valve mounted in the other part of the adapter, which is installed on the compressor. (25)

valve core. The functional, internal part of a valve. Schrader valves often serve as valve cores for access valves and service ports on service valves. The removal of valve cores allows increased vapor flow for certain service procedures, such as pulling a vacuum. (10)

valve core remover. A tool used to remove a valve core. One type can be used when the system is empty (no refrigerant charge), and another specialized tool with a long stem is used to remove valve core when the system is charged or sealed off. (10)

valve plate. In a reciprocating compressor, the metal plate between the cylinder head and the cylinder block on which the valves are installed. (18)

vane anemometer. An instrument that measures air velocity using a small propeller. The propeller is placed in the airstream and revolves as air flows past the blades. (27)

vaporizing humidifier. A humidifier that uses its own heat source (electric heating coils) to create steam. The steam is added to the air to increase its humidity. (35)

vapor recovery method. An active refrigerant recovery method that uses a recovery machine to draw out vapor refrigerant from both sides of a system. (11)

variable frequency drive (VFD). A controller that changes the speed of a motor by varying the frequency of the electrical signal supplied to the motor. (15)

variable refrigerant flow (VRF) system. A refrigeration system that uses system controls and a variable-speed compressor to regulate the flow and volume of refrigerant pumped to match system capacity to the demand cooling load. Also called a *variable refrigerant volume (VRV) system*. (31)

vented attic. An attic that has vents or air openings between its inside and the outside. In the summer, hot air can escape. In winter, moisture and heat leakage from the conditioned space can escape to prevent ice dams from forming. (29)

ventilation. The exchange of air between an enclosed space and an outside source. (27)

venturi effect. The reduction in pressure that occurs when a fluid flows through a constricted section of pipe. The fluid speeds up as it passes through the constricted section, resulting in a decrease in pressure. (41)

very hard water. Well water that is untreated and has a mineral content that exceeds 15 grains per gallon of water. (35)

vibration absorber. A flexible type of refrigerant line that reduces or dampens any vibration or physical motion

Copyright Goodheart-Willcox Co., Inc. 2017

transmitted to it in order to prevent the formation of leaks and damage to parts of the system. (19)

viscosity. A fluid's resistance to flowing. A high-viscosity fluid flows very slowly and a low-viscosity fluid flows freely. The term can also refer to a rating of a fluid's ability to flow at different temperatures. (9)

vise. A clamping apparatus used to hold parts for drilling, filing, or assembly. (7)

volatile fluid. A fluid that vaporizes at a low temperature. Volatile fluids are used in sensing bulbs due to their ability to change pressure in response to changes in temperature. (16)

volt. A unit of electromotive force. One volt is the amount of electromotive force required to send one ampere of current through a resistance of one ohm. (12)

voltage. The electrical force or electrical pressure created by a potential difference in atomic charges between two points. Also called *electromotive force*. (12)

voltage drop. The voltage applied across an electrical load that is causing current to flow through it. Intentional voltage drops are good, while unintentional voltage drops can cause circuit problems. (12)

volt-ampere (VA). A unit of electrical power, equivalent to the watt. Apparent power and transformer ratings are commonly expressed in volt-amperes. (13)

voltmeter. An instrument used to measure the potential difference, or voltage, between two points in an electrical circuit. (17)

volumetric efficiency. In reference to compressors, the actual volume of vapor pumped divided by the theoretical volume of the compressor cylinder. (51)

volute. Spiral shaped, with a gradually decreasing cross-sectional area along the perimeter. Used to describe the shape of the stator of a centrifugal compressor. (18)

vortex tube. A simple device that provides cold air by separating it from hot air. (48)

walk-in cabinet. A large, heavily insulated refrigerated space used for storing various products in commercial applications. Also called a *butcher box*. (47)

water capacity (WC). The weight of the volume of water needed to fill an entire recovery cylinder of a given size. The maximum amount of refrigerant that can be charged into a cylinder is 80% of the water capacity by weight. (11)

water coil. In ground source heat pumps, a heat exchanger in which heat is transferred between refrigerant from the indoor coil and water from the ground loop or water loop. In general usage, any heat exchange coil through which water flows in one passage and refrigerant through an adjacent but isolated passage. (40)

water-cooled condenser. A condenser that uses water as the medium into which system heat is expelled in order to desuperheat, condense, and subcool the high-pressure refrigerant coming from the compressor. (21)

water cooler. A refrigeration system designed to cool and dispense drinking water. Also called a *drinking fountain*. (47)

water defrost. A method of defrost that runs tap water over the evaporator when the refrigeration system is off. (21)

water hammer. A single, distinct thump (rap) produced in some water pipes just as a valve closes. (54)

water level/conductivity probe. A device used to sense the level of the water in an ice machine's sump or water reservoir. (53)

water loop. In ground-source heat pump systems, a loop of polyethylene tubing running to and from a water coil. The loop of tubing is submerged in a body of water. Water inside the loop is pumped from the water coil to the body of water, where it absorbs or rejects heat, before returning to the water coil. (40)

water-source heat pump (WSHP). A type of ground-source heat pump that uses water as a heat-transfer medium by circulating it through a secondary circuit placed underground or underwater. A water coil functions as the heat exchanger between the water in the secondary circuit and the refrigerant in the heat pump. (40)

water valve. A valve that stops, allows, and regulates the flow of water through water-cooled condensers and cooling towers in commercial HVACR systems. (33)

watt (W). An SI unit of power equal to the force of one newton moving through a distance of one meter in one second. Also, a unit of electrical power. One watt is the electrical power produced when one ampere (1 A) of current flows through an electrical component due to a potential difference of one volt (1 V). (4)

Watt's law. A mathematical relationship among power, voltage, and current in an electrical circuit ($P = I \times E$). (13)

wattmeter. An instrument used to measure the true power, or wattage, used by a circuit or an electrical load. A wattmeter is connected in series with the circuit or load being measured. (13)

wax separation. The precipitation of wax out of refrigeration lubricant at low temperatures, which can cause clogs in a refrigeration system. (9)

weak solution. In absorption refrigeration systems, a solution in which the absorbant is not fully saturated with the refrigerant and could absorb more. To contrast, see *strong solution*. (34)

wear gauge. A gauge used to determine the wear on a product, such as a belt, sheave, or other mechanical part. (54)

weather. Conditions in the atmosphere, including temperature, wind velocity and direction, clouds, moisture, and atmospheric pressure. (27)

weight. In physics, the gravitational force exerted by the earth on an object. In general usage, weight refers to the relative mass of an object. (4)

weight valve. A simple valve consisting of a weighted needle, adjustment spring, valve seat, and an inlet and outlet ports. Used in systems with a high-side float valve, a weight valve is used to limit the flow of refrigerant

Copyright Goodheart-Willcox Co., Inc. 2017

and create a pressure drop between the liquid line and evaporator. (20)

wet-base boiler. A boiler in which the water surrounds the combustion area. (39)

wet-bulb temperature. A temperature measurement that takes into account the cooling effect of evaporation. Wet-bulb temperature increases as relative humidity increases. (27)

wet decks. Structures, within cooling towers, that are composed of fill and designed to increase contact between air and water. (33)

wet roof cooling. A method of cooling indoor temperature using the evaporation of water on a building's roof. (34)

wet-rotor centrifugal pump. In a hydronic system, a circulating pump with bearings that are lubricated by the circulating water rather than a petroleum-based lubricant. (39)

wet underfloor radiant heating system. A radiant heating system that consists of tubing embedded in concrete. (39)

Wheatstone bridge. An electronic circuit used to detect changes in a thermistor's resistance. A temperature change causes the resistances in the bridge to become unbalanced, which alters the bridge's output voltage and sends a signal to the controller. (16)

whole house fan. A high-volume fan that is placed between the conditioned space and a vented attic. It can provide whole house ventilation by drawing in outside air through open windows and blowing through a vented attic. It may also be referred to as an *attic fan*. (29)

wick lubricating system. A bearing lubrication system in which a fabric draws up oil from a well or reservoir in the end bell to lubricate the bearing and motor shaft. (17)

Wi-Fi enabled thermostat. A thermostat that can be controlled wirelessly from anywhere in the home or the world. (36)

windchill index. A measure of the combined effect of temperature and wind speed. Also called *chill factor*. (27)

with respect to. See *WRT*. (30)

work. In physics, a force multiplied by the distance through which it travels, expressed in foot-pounds or newton-meters. (4)

work hardened. The hardening of soft copper tubing that occurs due to repeated bending or hammering. Work-hardened tubing is susceptible to cracking at stress points when flared. (8)

workstation. A building control interface device used to monitor, control, and coordinate system functions. (45)

wrench. A hand tool that is used to grip and turn an object, such as a nut or bolt. (7)

WRT. Initials that stand for the phrase *with respect to*. This is used to indicate the reference to which a pressure reading is being compared. See text covering *blower door testing* and *duct testing*. (30)

Yoder loop. In domestic refrigerators and freezers, a liquid line loop that is routed around doors and openings to prevent condensation. Also called a *post-condenser loop*. (24)

Y tube. A Y-shaped tubing that allows an inlet to split into two outlets. This is widely used in ductless split systems to distribute refrigerant to indoor units that are connected in parallel. (32)

zeotrope. A refrigerant blend that has a range of boiling and condensing points because each refrigerant in the blend acts independent of the others. Also called *zeotropic blends* and *zeotropic refrigerants*. See *bubble point*, *dew point*, and *temperature glide*. (9)

zerk fitting. A grease fitting installed in a mechanical part, like a bearing collar. An ordinary grease gun can be connected to the zerk fitting to apply grease to the part. (17)

zone valve. In a hydronic system, a valve that regulates the flow of heated water through a zone based on the signal it receives from a room thermostat. Also called *zone control valve*. (39)

zoned system. An HVAC system designed to heat or cool different areas of a building to different comfort, humidity, and ventilation standards. (36)
